**Background** Intra-abdominal adhesions develop after nearly every abdominal surgery, commonly causing female infertility, chronic pelvic pain, and small bowel obstruction. Pentoxifylline (PTX) is a methylxanthine compound with immunomodulatory and antifibrotic properties. The aim of this study was to investigate whether PTX can reduce post-operative intra-abdominal adhesion formation via collagen deposition, tissue plasminogen activator (tPA) level, inflammation, angiogenesis, and fibrosis.

**Methods** Seventy male BALB/c mice were randomized into one of three groups: (1) sham group without peritoneal adhesion model; (2) peritoneal adhesion model (PA group); (3) peritoneal adhesion model with PTX (100 mg/kg/day i.p.) administration was started on preoperative day 2 and continued daily (PA+PTX group). On postoperative day 3 and day 7, adhesions were assessed using the Lauder scoring system. Parietal peritoneum was obtained for histological evaluation with hematoxylin and eosin (HE) and picrosirius red staining. Fibrinolysis was analyzed by tPA protein levels in the peritoneum by ELISA. Immunohistological analysis was also conducted using markers for angiogenesis (ki67<sup>+</sup>/CD31<sup>+</sup>), inflammation (F4/80<sup>+</sup>) and fibrosis (FSP-1<sup>+</sup> and  $\alpha$ -SMA<sup>+</sup>). All the comparisons were made by comparing the PA group with the PTX treated PA group, and  $p < 0.05$  was considered statistically significant.

**Results** Intra-abdominal adhesions were markedly reduced by PTX treatment. Compared with the PA group, PTX treatment had lower adhesion scores than the PA group on both day 3 and day 7 ( $p < 0.05$ ). Histological evaluations found that PTX treatment reduced collagen deposition and adhesion thickening. ELISA analysis showed that PTX treatment significantly increased the level of tPA in the peritoneum. In addition, in the immunohistological analysis, PTX treatment was found to significantly decreased the number of ki67<sup>+</sup>/CD31<sup>+</sup> cells at the site of adhesion. Finally, we also observed that in the PTX treated group, there was a reduction in the expression of F4/80<sup>+</sup>, FSP-1<sup>+</sup>, and  $\alpha$ -SMA<sup>+</sup> cells at the site of adhesion.

**Conclusion** PTX may decrease intra-abdominal adhesion formation via increasing peritoneal fibrinolytic activity, suppressing angiogenesis, decreasing collagen synthesis, and reducing peritoneal fibrosis. Our findings suggest that PTX can be used to decrease post-operative intra-abdominal adhesion formation.

# Abstract

## Background

Intra-abdominal adhesions develop after nearly every abdominal surgery, commonly causing female infertility, chronic pelvic pain, and small bowel obstruction. Pentoxifylline (PTX) is a methylxanthine compound with immunomodulatory and antifibrotic properties. The aim of this study was to investigate whether PTX can reduce post-operative intra-abdominal adhesion formation via collagen deposition, tissue plasminogen activator (tPA) level, inflammation, angiogenesis, and fibrosis.

## Methods

Seventy male BALB/c mice were randomized into one of three groups: (1) sham group without peritoneal adhesion model; (2) peritoneal adhesion model (PA group); (3) peritoneal adhesion model with PTX (100 mg/kg/day i.p.) administration was started on preoperative day 2 and continued daily (PA+PTX group). On postoperative day 3 and day 7, adhesions were assessed using the Lauder scoring system. Parietal peritoneum was obtained for histological evaluation with hematoxylin and eosin (HE) and picrosirius red staining. Fibrinolysis was analyzed by tPA protein levels in the peritoneum by ELISA. Immunohistological analysis was also conducted using markers for angiogenesis (ki67<sup>+</sup>/CD31<sup>+</sup>), inflammation (F4/80<sup>+</sup>) and fibrosis (FSP-1<sup>+</sup> and  $\alpha$ -SMA<sup>+</sup>). All the comparisons were made by comparing the PA group with the PTX treated PA group, and  $p < 0.05$  was considered statistically significant.

## Results

Intra-abdominal adhesions were markedly reduced by PTX treatment. Compared with the PA group, PTX treatment had lower adhesion scores than the PA group on both day 3 and day 7 ( $p < 0.05$ ). Histological evaluations found that PTX treatment reduced collagen deposition and adhesion thickening. ELISA analysis showed that PTX treatment significantly increased the level of tPA in the peritoneum. In addition, in the immunohistological analysis, PTX treatment was found to significantly decreased the number of ki67<sup>+</sup>/CD31<sup>+</sup> cells at the site of adhesion. Finally, we also observed that in the PTX treated group, there was a reduction in the expression of F4/80<sup>+</sup>, FSP-1<sup>+</sup>, and  $\alpha$ -SMA<sup>+</sup> cells at the site of adhesion.

## Conclusion

PTX may decrease intra-abdominal adhesion formation via increasing peritoneal fibrinolytic activity, suppressing angiogenesis, decreasing collagen synthesis, and reducing peritoneal fibrosis. Our findings suggest that PTX can be used to decrease post-operative intra-abdominal adhesion formation.

# Introduction

Post-operative intra-abdominal adhesion after laparotomy is a source of considerable morbidity. It is estimated that more than 90% of patients develop primary intra-abdominal adhesion after laparotomy. Post-operative adhesions affect the quality of life in millions of people worldwide, causing many different types of complications, including chronic pelvic or abdominal pain, small bowel obstructions (SBO), and even infertility (Arung et al. 2011; Liakakos et al. 2001). SBO is the most common complication of adhesion and is observed in up to 70% of patients undergoing laparotomy (Ellis 1997; Menzies & Ellis 1990; ten Broek et al. 2013). Although less commonly observed, up to 20% of female infertility has been associated with post-operative adhesions (Luijendijk et al. 1996).

The pathogenesis of post-operative intra-abdominal adhesion is a complex process that involves inflammation, collagen related clot formation, angiogenesis, fibrinolysis, and tissue repairs which include epithelial-mesenchymal transition (EMT)/endothelial-mesenchymal transition (EndMT) or mesothelial -mesenchymal transition (MMT) (diZerega 1997; Hellebrekers & Kooistra 2011; Homdahl & Ivarsson 1999). The key area in adhesion formation is the surface lining of the peritoneum. Injury of the peritoneum leads to activation of coagulation cascade and an inflammatory response consisting of hyperemia, fluid exudation, recruitment of floating mesothelial cells, and release of white blood cells and platelets into the peritoneal cavity(diZerega 1997; diZeregal & Campeau 2001). Normal fibrinolytic activity usually prevents fibrinous attachments for 3-4 day, and mesothelial repair occurs in 5-6 day after surgery (diZeregal & Campeau 2001). Therefore, previous studies focused on the cellular events 3-6 day after the peritoneal injury.

Pentoxifylline (PTX), a non-specific phosphodiesterase inhibitors, has been used to improve the walking ability in patients with intermittent claudication (Ernst 1994; Hood et al. 1996; Rossner & Muller 1987). Previous animal studies have also demonstrated that PTX can reduce post-operative adhesion, but the biological mechanisms that were responsible have not been fully clarified (Durmus et al. 2011; Hung et al. 2008; Jafari-Sabet et al. 2015; Tarhan et al. 2006). Five separate mechanisms on how PTX can alter the essential components in adhesion formation have been proposed: (1) reduction of inflammation (Durmus et al. 2011; Pollice et al. 2001); (2) reduction of collagen synthesis (Chen et al. 1999); (3) reduction of angiogenesis (Amirkhosravi et al. 1998) (4) increased fibrinolysis by up-regulation of tissue plasminogen activator (tPA) expression (Tarhan et al. 2006); (5) reduced fibrosis (Durmus et al. 2011; Wen et al. 2017). However, it is unclear if PTX can decrease post-operative intra-abdominal adhesion formation by simultaneously altering all of the five proposed mechanisms. Therefore, we aimed to

investigate the effects of PTX on peritoneum collagen expression, peritoneal tPA expression, peritoneum angiogenesis, inflammation, and peritoneal fibrosis.

# Methods

## Animals

Male BALB/c mice weighing 25-30 g (Charles River Laboratories, BioLasco, Taiwan) were maintained in a temperature and light-controlled room (12-hour light/dark cycle) and allowed free access to water and food. The experimental protocols were approved by the Institutional Animal Care and Use Committee (IACUCs) of the National Taiwan University Hospital (approval ID: 20120285). All the protocols are in adherence to the guidelines established in the Guide for the Care and Use of Laboratory Animals of the National Health Research Institutes.

## Experimental design

70 BALB/c mice were randomly divided into three different groups: (1) sham group without peritoneal adhesion model (sham group, n = 8); (2) peritoneal adhesion model (PA group, n = 31); (3) peritoneal adhesion model with PTX (Trental ) (100 mg/kg/day i.p., once daily) administration was started on preoperative day 2 and continued daily (PA+PTX group, n = 31). We used a slightly modified standard adhesion model (Oncel et al. 2001). The details for peritoneal adhesion model had been reported before (Lee et al. 2016).

Briefly, mice were anesthetized using 2% isoflurane in oxygen. The abdomen was then shaved and disinfected with povidone iodine. A 4 cm median laparotomy was performed to gain access to the abdominal cavity. In peritoneal adhesion model (PA and PA+PTX group), were pooled and randomly underwent surgery. The cecum was gently removed and abraded with 20 vertically reciprocal movements of dry gauze. After, the right abdominal sidewall be more aggressive with the abraded than cecum and until punctate bleeding was seen. The injury sites were cleaned with physiological salt solution and covered the gauze, making sure that was no active bleeding. The cecum was then placed back into the abdominal cavity and surgical wound was sutured. For the sham group, only open laparotomy and closure was conducted and there is no abrading of cecum and abdominal wall.

The PTX group received 100 mg/kg of PTX from left abdominal cavity, whereas the other two group (group sham and PA) received 0.125 ml of physiological saline solution. For preventing postoperative pain, buprenorphine (0.05 mg/kg s.c., twice daily) was administered during the two postoperative days. Mice were placed under a warming lamp and observed until they recovered

fully from anesthesia. Mice were monitored daily for signs of wound infection and general health condition periodically until 3 or 7 day after surgery.

# **Adhesion score**

Mice were euthanized on postoperative day 3 and day 7. The abdominal cavity was opened via a U-shaped incision. The adhesion score was evaluated was performed by an observer blinded treatment, using the Lauder scoring system (Lauder et al. 2011). The adhesion were graded in a blinded fashion using the classification system described (Table 1).

# **Histology staining**

Tissue samples from the parietal peritoneum, liver, and mesentery were collected after euthanasia. For histological staining, tissue were fixed in 10% neutral-buffered formalin (NBF), paraffin embedded, thinly sectioned. Tissue sections of 4-5µm thickness were prepared for staining. After deparaffinization and rehydration, sections were counterstained in Gill's hematoxylin (Sigma, St Louis, MO) and for 5 min, cleared in 0.1% acid alcohol for 30 sec, and rinsed in tap water, then stained in eosin (Sigma) for 2 min, cleared in 95% alcohol , and rinsed 70% alcohol to remove the staining solution, dehydrated, and mounted, for histologic assessment.

# **Picrosirius red staining**

Picrosirius red staining was used to compare collagen and fibrosis in tissue between different groups. Peritoneal sections (4-5 µm) were deparaffinized, rehydrated and then subsection to counterstaining in Gill's hematoxylin (Sigma) for 5 min, cleared in 0.1% acid alcohol 30 sec, and rinsed in running tap water. Then stained in picrosirius red stain kit (polysciences, Warrington, PA). Subsequently, sections were dehydrated and mounted for assessment.

# **Tissue plasminogen activator**

Peritoneal tissue were prepared by grinding on ice in radioimmunoprecipitation assay buffer (RIPA buffer) with protease inhibitor cocktail (Sigma). After the samples were centrifuged at 12,000g for 15 min at 4°C, supernatants were aspirated and placed in new tubes. Samples were analyzed for total antigen concentration of tPA, using commercially available ELISA kits from Molecular Innovations (Molecular Innovations, Novi, MI). Total protein content was determined by Bradford assay (Sigma).

# **Immunohistochemistry**

Formalin-fixed and paraffin-embedded peritoneal tissue was sectioned at 4-5  $\mu\text{m}$  and then subjected to double immunostaining. Briefly, sections were deparaffinized, rehydrated and endogenous peroxidase activity was quenched by 3% hydrogen peroxide ( $\text{H}_2\text{O}_2$ ) for 10 min. Sections were subjected to antigen retrieval was performed in pH 6.0 citrate buffer using a microwave oven for 15 min. Blocking of non-specific binding was done by incubation with 2.5% horse serum at room temperature for 30 min. Sections were incubated with primary antibodies, rabbit anti-ki67 (1:200, Abcam, Cambridge, MA), rat anti-F4/80 (1:200, Abcam) or rabbit anti-FSP-1 (1:200, Abcam) overnight at 4°C. After washing with Tris-buffered saline (TBS, pH7.4), sections were incubated using the ImmPRESS AP anti-rabbit polymer reagent (Vector Laboratories, Burlingame, CA) for 30 min at room temperature. Positive signal resulted in blue nuclear staining with the VECTOR Blue kit (Vector Laboratories). After washing and blocking again, the sections were incubated with goat anti-CD31 (1:500, R&D System, Minneapolis, MN) for 1 hour at room temperature. After washing, ImmPRESS HRP anti-goat polymer reagent (Vector Laboratories) was used for 30 min at room temperature. Positive reactions for endothelial cells resulted in brown red staining with the NovaRed substrate kit (Vector Laboratories). Sections were examined by light microscopy (Nikon Instruments, Nikon Corporation, Tokyo, Japan).

# **Immunofluorescence staining**

Peritoneal tissue sections (4-5  $\mu\text{m}$ ) were performed for double immunofluorescence staining. Briefly, sections were deparaffinized, rehydrated and were treated with 0.3%  $\text{H}_2\text{O}_2$  for 10 min to block endogenous peroxide activity and boiled in pH 6.0 citrate buffer using a microwave oven for 15 min. Sections were subsequently incubated with 5% Donkey serum for 20 min at room temperature. Sections were incubated with rabbit anti-cytokeratin 18 (CK18) (1:200, Enogene, New York, NY) overnight at 4°C, washed in phosphate-buffered saline (PBS, pH7.4) and incubated using donkey anti-rabbit DyLight 488 antibody (Thermo Scientific, Rockford, IL) and Cy3-conjugated mouse anti- $\alpha$ -smooth muscle actin ( $\alpha$ -SMA) (Sigma) and then mounted and subjected to fluorescence microscopy (Leica DMRA, Leica Microsystems, Wetzlar, Germany). Images were recorded at x100, x200 and x400 magnification of light microscopy, which were then digitalized and analyzed using Image-Pro Plus 6.0 software (Media Cybernetics, Rockville, MD).

# **Statistical Analysis**

Normal distributed continuous data were expressed as mean  $\pm$  standard error (SE). For non-parametric data, results were expressed as median  $\pm$  interquartile range (IQR). The difference between continuous variables were evaluated using one-way ANOVA when data distribution

was normal and a Mann-Whitney test was used for non-normal distributed continuous data. A  $p$  value of less than 0.05 was considered statistically significant. The statistical analyses were performed with GraphPad Prism (version 6.0, GraphPad Software, Inc., La Jolla).

## Results

### Deaths of animal

Surgical procedures were successfully completed on 69 animals, except for one mice in the sham group, which died due to anesthesia-related complication before the commencement of surgery. One mice in the PA+PTX group died during recovery from anesthesia. Four mice died within 48 hour of surgery and were excluded from the study (PA and PA+PTX group,  $n = 2/\text{group}$ ). Two mice in the PA group were excluded due to severe distress, according to three criteria in Health Evaluation of Experimental Laboratory Mice: very rough hair coat, hunched, and not eating or drinking. No mice in the PA+PTX treated group incurred any life-threatening side effects or deaths at 48 hours after surgery, which lead to exclusion from the study. Therefore, a total of 8 animals were excluded from the study.

Mice were euthanatized for the planned experiments on postoperative day 3 (PA group,  $n = 14$ ; PA+PTX group,  $n = 13$ ) and day 7 (sham group,  $n = 7$ ; PA group,  $n = 13$ ; PA+PTX group,  $n = 15$ ).

### Pentoxifylline Treatment Reduces Adhesion score

Total adhesion scores data was examined and plotted for post-operative day 3, and 7 (Figure 1). We observed that the sham group, which had not undergone the adhesion model, had significantly lower adhesion score than the animals that had undergone adhesion model, as expected. PA+PTX group (median, 1.00; IQR, 0.50-2.00) had significantly lower adhesion score than the PA group (median, 2.00; IQR, 2.00-3.00) on day 3 ( $p < 0.05$ ). On day 7, mice treated with PTX (median, 3.00; IQR, 0.00-3.00) still had lower adhesion score than the PA group (median, 3.00; IQR, 3.00-4.50) ( $p < 0.05$ ).

### Pentoxifylline Treatment Inhibits Collagen Deposition

We used the HE staining to compare changes in peritoneal structure (Figure 2A). In general, there were increased thickness of submesothelial layer on day 3, and the adhesion score also increased. We observed that the sham group, had the thin submesothelial layer as demonstrated

in (Figure 2A). The severe adhesion and thick submesothelial layer was observed, as well as increased cellularity in the PA group. In contrast, PA+PTX group had less peritoneal submesothelial thickness and adhesion severity as compared with the PA group.

We further used picrosirius red staining to assess the quality of collagen fiber in peritoneal adhesion (Figure 2B). Compared with PA group, PA+PTX group had less collagen deposition and the thickness of the abdominal adhesions. Our data suggested that PTX could decrease collagen deposition during adhesion formation.

### **Pentoxifylline Treatment Increased tPA level**

The tPA protein levels in the peritoneum of mice were perceived to be measured and plotted on post-operative day 3 and 7 (Figure 3). We observed that the sham group of mice had the lowest tPA protein level throughout the study period ( $p < 0.001$ ). Those mice were treated with PTX had higher tPA protein level than those untreated mice (sham and PA group). There was significant difference between PA+PTX group and PA group on day 7 ( $0.365 \pm 0.024$  vs.  $0.193 \pm 0.03$ ,  $p < 0.001$ ).

### **Pentoxifylline Treatment Reduced Angiogenesis**

We performed immunohistochemical staining assay to analyze the status of angiogenesis during peritoneal repair. Proliferating endothelial cells were identified as those cells with cytoplasmic CD31 staining and nuclear Ki67 staining (Figure 4A, arrows). Cells that staining positive for CD31 but without nuclear staining for Ki67 were scored as nonproliferating endothelial cells. We examined the effect of endothelial cell proliferation in peritoneum was quantified by measuring the number of  $ki67^+$   $CD31^+$  cell at the site of adhesion (Figure 4B). Our results showed that PA group had significantly higher proliferating endothelial cells compared to both sham and PA+PTX group on day 3 and day 7 (all  $p < 0.001$ ). We also observed that number of  $ki67^+$   $CD31^+$  proliferating endothelial cell count decrease substantially over time ( $p < 0.001$ ) in the PA group. Otherwise, we examined the angiogenic effect in peritoneum by measuring the area of  $CD31^+$  microvessel at the site of adhesion (Figure 4C). We also observed that the PA group, which had vessel coverage (percentage of area covered by  $CD31^+$  per field) of 1.63% at day 3, and 3.63% at day 7, respectively. On post-operative day 7, PA group demonstrated an increase in CD31 expression compared to the day 3 and indicated that blood vessel formation was significantly more prominent in the PA group compared to PA+PTX groups ( $p < 0.001$ ). Thus, PTX can significantly suppress angiogenesis during peritoneal repair.

## 243 **Pentoxifylline Treatment Reduced Inflammation**

244 Inflammation, an important component both in normal and pathological healing, is a protective  
 245 response of the tissue injury, designed for removal of the causative agent and restoration of tissue  
 246 structure and function. We performed immunohistochemical staining assay to analyze the  
 247 infiltration of macrophage during peritoneal repair. F4/80 is a macrophage-specific marker in the  
 248 mice. As shown in figure 5A, a large number of F4/80<sup>+</sup>-expressed cells were observed in the PA  
 249 group. Quantification analysis of IHC image revealed significantly increased expression of  
 250 F4/80<sup>+</sup> cells on day 3 ( $0.80\% \pm 0.10\%$ ), and highest expression on day 7 ( $2.56\% \pm 0.22\%$ ) in the  
 251 PA group as compared to the sham group ( $p < 0.01$  for both day 3 and day7) or PA+PTX group  
 252 ( $1.37\% \pm 0.28\%$ ,  $p < 0.01$  on day 7, Figure 5B). PA+PTX group had significantly lower  
 253 expression of F4/80<sup>+</sup> as compared with PA group.

## 254 **Pentoxifylline Treatment Reduced the Expression of Fibrosis Marker FSP-1**

255 FSP-1, also known as fibroblast-specific protein 1 (FSP1), belongs to the S100 superfamily of  
 256 cytoplasmic calcium-binding proteins and can be expressed by cell of mesenchymal origin or  
 257 fibroblastic phenotype. This protein is reported to be specific for fibroblasts and to play a causal  
 258 role in EMT. As shown in figure 6A and 6B, a large number of FSP-1<sup>+</sup>-expressed cells were  
 259 observed in the PA group. Quantification analysis of IHC image revealed significantly increased  
 260 expression of FSP-1<sup>+</sup> on day 3 ( $5.37\% \pm 1.03\%$ ), and highest expression on day 7 ( $11.26\% \pm$   
 261  $1.66\%$ ) in the PA group compared to the PA+PTX group ( $p < 0.05$  for both day 3 and day7,  
 262 Figure 6C). Consistently, we found the mice were treated with PTX had significantly reduced  
 263 expression of FSP<sup>+</sup> as compared with PA group.

## 264 **Pentoxifylline Treatment Reduced the Expression of Fibrosis Marker $\alpha$ -SMA**

265 As a response to injury, mesothelium is undergoing change to mesothelial-to-mesenchymal  
 266 transition (MMT). Thus, we further performed double immunofluorescence staining for CK18  
 267 and  $\alpha$ -SMA for peritoneal injury (Figure 6, A and B). Many studies have demonstrated that  
 268 mesenchymal cell markers, including  $\alpha$ -SMA, is proposed as indicator of EMT (Margetts et al.  
 269 2005). Cytokeratin (CK) are structural marker proteins specific for epithelial cell, and CK18 is  
 270 highly expressed in mesothelial cells.  $\alpha$ -SMA has become the most reliable marker of  
 271 myofibroblasts. Figure 7A are consistent with previous studies, in the PA group observed a few  
 272 CK18<sup>+</sup> $\alpha$ -SMA<sup>+</sup> double-positive cells appear first in the mesothelial monolayer and later in the  
 273 reorganized submesothelial matrix. We examined the extent of accumulation of myofibroblasts  
 274 in peritoneum was quantified by assessing the percentage  $\alpha$ -SMA<sup>+</sup> cells (Figure 7C). Our result  
 275 showed that PA group had significantly increased  $\alpha$ -SMA<sup>+</sup> expression at day 3 ( $3.48\% \pm 1.28\%$ ),  
 276 and highest expression at day 7 ( $13.71\% \pm 1.40\%$ ) compared with the PA+PTX group ( $p < 0.05$   
 277 for day 3 and  $p < 0.01$  for day 7, respectively). PTX significantly attenuated thickening of fibrotic

278 peritoneum, and accumulation of  $\alpha$  SMA<sup>+</sup> myofibroblasts in peritoneum after injury.

# Discussion

In this study, we demonstrated that PTX treatment could effectively reduce post-operative intra-abdominal adhesion formation. PTX could prevent peritoneum adhesion formation via 5 related biological processes: increasing fibrinolysis; reducing inflammation; reducing angiogenesis; reducing collagen deposition; and reducing fibrosis.

Post-operative intra-abdominal adhesion formation is considered to be an inevitable result of peritoneum injury after abdominal surgery. Peritoneum injury initiates an inflammatory response, which increase in vascular permeability leading to fibrin release and adhesion formation (diZeregal & Campeau 2001). Under normal conditions, the majority of fibrin is degraded within a few days by locally released proteases of the fibrinolytic system (Harris et al. 1995; Sulaiman et al. 2002). In a pathological state, fibrinolysis does not occur within 5-7 days of the peritoneal injury, the provisional fibrin matrix persists and more gradually becomes organized as the collagen-secreting myofibroblasts and other repairing cell infiltrate the matrix (Homdahl & Ivarsson 1999). This process leads to peritoneal adhesion and new blood vessel formation (angiogenesis) (Saltzman et al. 1996).

We hypothesized that there are at least four mechanisms that PTX treatment might result in reduce post-operative adhesion. First, PTX has been reported to alter rheological properties of blood such as: decreasing blood viscosity by stimulating fibrinolysis to reduce plasma fibrinogen concentrations, increasing erythrocyte flexibility and platelet deaggregation, and inhibiting neutrophil activity to reduce the tissue damage (McCarty et al. 2016). The alteration in the rheological properties of blood may be the reason why we observed that the tPA level was significantly higher in the PTX treated group than those without PTX treatment group. In fact, we have previously found that mice treated with therapeutic hypothermia, have increased tPA levels and reduced post-operative adhesion (Lee et al. 2016).

Second, the anti-inflammation property of PTX has been well established by several previous studies, and has been found to attenuate the cardiopulmonary bypass (CPB)-induced systemic inflammatory response syndrome and postoperative mortality (Barkhordari et al. 2011; Heinze et al. 2007; Otani et al. 2008). PTX has been found to affect inflammation by reducing the plasma levels of pro-inflammatory cytokines such as TNF- $\alpha$ , IL-1 and IL-6 (Otani et al. 2008; Pollice et

al. 2001). The reduction of cytokines at the site of injury may explain why we observed a reduction in the infiltration of macrophage in the PTX treated group.

Third, PTX also has been reported by previous studies to inhibit endothelial cell proliferation and angiogenesis (Gude et al. 2001; Hasebe et al. 2000). Vlahos *et al.* reported that PTX might cause suppression of endometriotic lesions by suppressing angiogenesis through VEGF-C and flk-1 expression (Vlahos et al. 2010). Recent evidence also found that PTX inhibits PKC-dependent activation of NF $\kappa$ B and prevent hypoxia-induced expression of VEGF (Amirkhosravi et al. 1998). Our results on reduction in angiogenesis in PTX treated groups correspond with the above findings.

Fourth, PTX was reported by previous studies to down regulate the intracellular signaling of TGF- $\beta$ ; which can affect collagen synthesis and fibrosis through the cAMP-PKA pathway (Fang et al. 2000; Kucich et al. 2000). Through PKA, PTX has been found to reduce TGF- $\beta$ -induced collagen synthesis in vascular smooth muscle cells and human peritoneal mesothelial cells (Chen et al. 1999; Hung et al. 2003). This might explain why we observed lower amount of collagen deposition in PTX treated mice. Moreover, TGF- $\beta$ 1 has been reported to be the key initiating factor of fibrosis, and is also known to strongly induce EMT or EndMT (Lamouille et al. 2014; Piera-Velazquez et al. 2011). EMT is defined as a cellular and molecular changes that are usually characterized by loss of cell-cell adhesion, the down-regulation of E-cadherin and other epithelial genes, accompanied by the acquisition of mesenchymal cell morphology, increased contractility and actin stress fibers. This might explain why we observed reduction in markers of fibrosis with PTX treatment.

In this study, we found that PTX treatment decreased intra-abdominal adhesion formation by reducing fibrosis, but it is not in our initial objective to confirm whether the reduction in fibrosis might affect general wound healing. The main reason is because several studies have already found that PTX can instead improve general wound healing. Parra-Membrives et al. (2007) showed that PTX improved healing of experimental ischemic colorectal anastomoses by reducing wound and intra-abdominal infections, adhesion formation, and leaks. Comert et al. (2000) showed PTX has positive effect of the obstructive jaundice on healing of intestinal anastomosis healing by suppressing endotoxin-induced TNF- $\alpha$  release from macrophages and monocyte and stabilizing effect on the neutrophils. Therefore, future studies may need to clarify

the time-frame on how PTX treatment can reduce fibrosis and yet improve wound healing, before clinical trial of PTX can be recommend on post-operative patients. In addition, future studies can also clarify the mechanism on how streptokinase interact synergistically with PTX to reduce post-operative adhesion (Jafari-Sabet et al. 2015).

## Conclusion

In conclusion, our study showed that PTX may decrease intra-abdominal adhesion formation via increasing peritoneal fibrinolytic activity, reducing inflammation, suppressing angiogenesis, decreasing collagen synthesis, fibroblast producing and peritoneal fibrosis. We believe that future studies should take into the account that PTX can reduce intra-abdominal adhesion formation through multiple pathways.

**Table 1**(on next page)

Scoring system for intra-abdominal adhesion.

1	<b>Score</b>	<b>Adhesion grading scale</b>
2	0	No adhesion
	1	Thin filmy adhesion
	2	More than one thin adhesion
	3	Thick adhesion with focal point
	4	Thick adhesion with planar attachment
	5	Very thick vascular adhesion or more than one planar adhesion

# Figure 1

Intra-abdominal adhesion score.

The PA+PTX group had lower adhesion score. Data are expressed as the median  $\pm$  IQR. \* $P < 0.05$ , \*\* $P < 0.01$ , \*\*\* $P < 0.001$ , respectively.

# Figure 2

## Pentoxifylline Treatment Inhibits Collagen *Deposition*

(A) Representative images of HE staining. No adhesion was observed in the sham group. Severe Liver or bowel adhesion and was observed in the PA group, whereas PTX treated group decreased adhesion severity. (B) Representative images of picrosirius red staining. The thickness of the collagen deposition was increased in PA group, whereas PTX treated group has less collagen deposition. (Original magnification, x200, bar = 100  $\mu$ m).

# Figure 3

The levels of tPA protein in peritoneum .

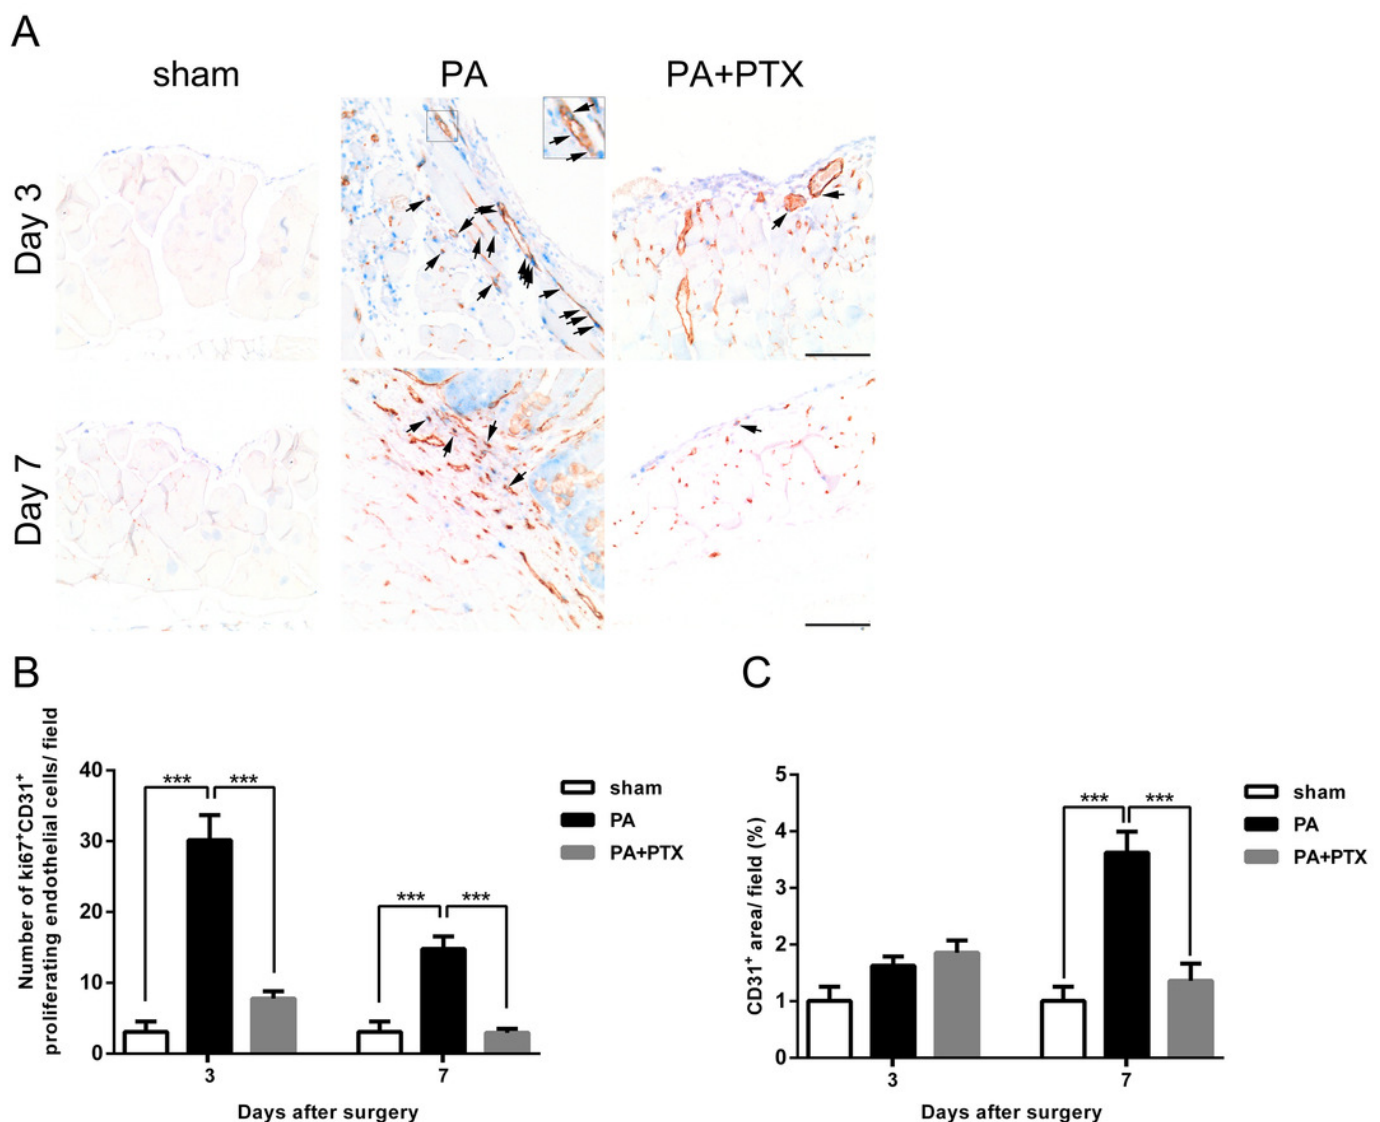

tPA protein level increased in both PA group and PA+PTX group on postoperative day 3 and day7. PTX-treated mice increased tPA protein level at 7 day postoperative compared with 3 day postoperative. Data are expressed as the mean  $\pm$  SE. \* $P < 0.05$ , \*\* $P < 0.01$ , \*\*\* $P < 0.001$ , respectively.

# Figure 4

## Pentoxifylline Treatment Reduced Angiogenesis.

(A) Representative examples of double immunohistochemistry staining of ki67 (blue) and CD31 (brown-red) (arrows) in peritoneum on day 3 and day 7. (Original magnification, x200, bar = 100  $\mu$ m). (B) The graph shows numbers of cells expressing Ki67<sup>+</sup> and CD31<sup>+</sup> (proliferating endothelial cells) on day 3 and day 7. (C) The graph shows the percentage of CD31<sup>+</sup> vessel area per field at x200 magnification on day 3 and day 7. Data are expressed as the mean  $\pm$  SE. \* $P$  < 0.05, \*\* $P$  < 0.01, \*\*\* $P$  < 0.001, respectively.

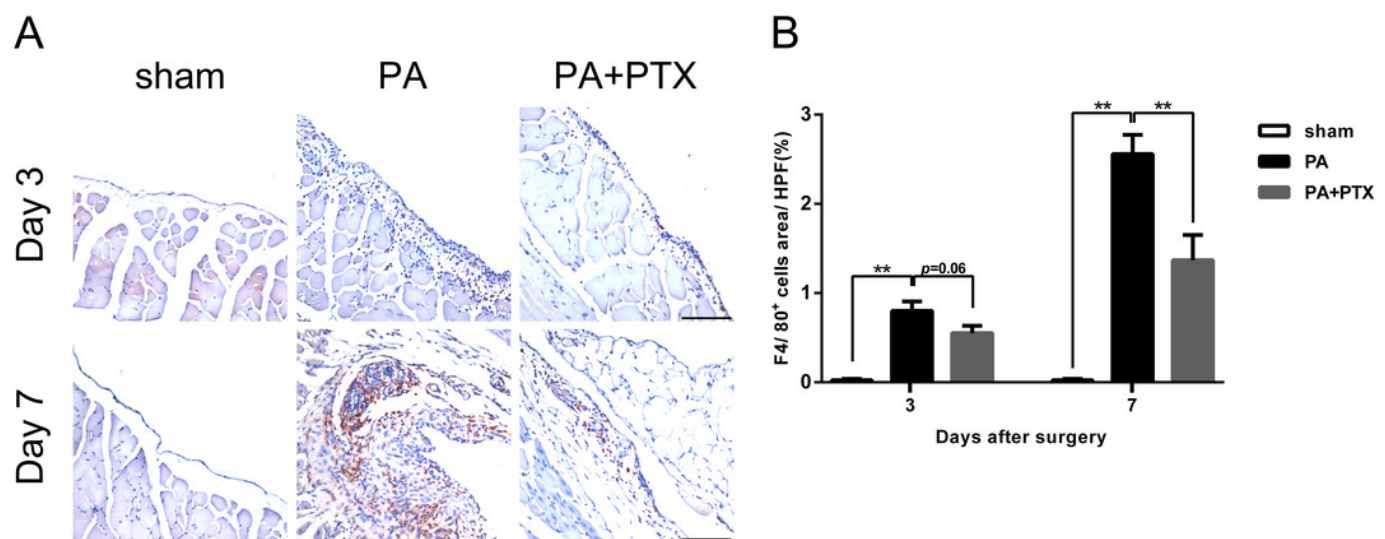

# Figure 5

## Pentoxifylline Treatment Reduced Inflammation

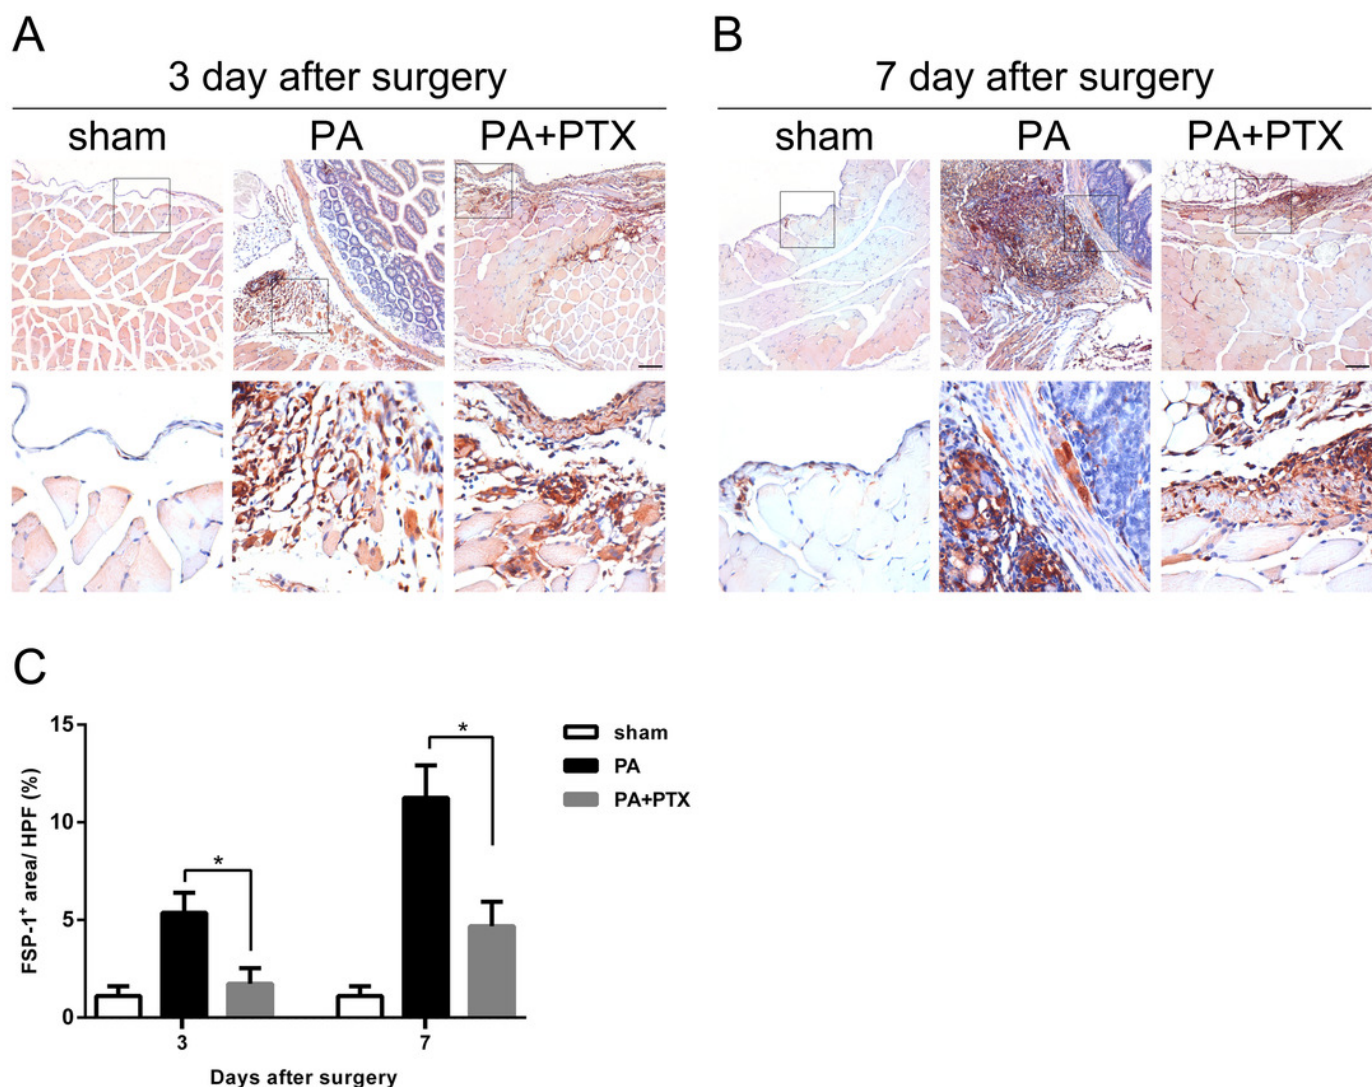

(A) Immunohistochemistry for F4/80 was performed on mice peritoneal tissue in the different groups at day 3 and day 7. The F4/80 expression was increased in PA group. Representative images of the sham group, PA group, and PA+PTX group are shown (Original magnification, x200, bar = 100  $\mu$ m). (B) Quantification of F4/80<sup>+</sup> cells (%) in high-powered field (HPF) at x400 magnification. Data are expressed as the mean  $\pm$  SE. \* $P$  < 0.05, \*\* $P$  < 0.01, \*\*\* $P$  < 0.001, respectively.

# Figure 6

## Pentoxifylline Treatment Reduced the Expression of Fibrosis Marker FSP1

(A-B) Immunohistochemistry for FSP-1 was performed on mice peritoneal tissue in the different groups at day 3 and day 7. The FSP-1 expression was increased in PA group. Representative images of the sham group, PA group, and PA+PTX group are shown. (Original magnification, x100, bar = 100  $\mu$ m). (C) Quantification of FSP-1<sup>+</sup> cells (%) in high-powered field (HPF) at x400 magnification. Data are expressed as the mean  $\pm$  SE. \* $P$  < 0.05, \*\* $P$  < 0.01, \*\*\* $P$  < 0.001, respectively.

# Figure 7

## Pentoxifylline Treatment Reduced the Expression of Fibrosis Marker $\alpha$ -SMA

(A-B) Double immunofluorescence was performed with CK18 and  $\alpha$ -SMA in mice peritoneum in the different groups at day 3 and day 7. Immunofluorescence shows the staining of mesothelial cells by CK18 was expressed in green color, and myofibroblast by  $\alpha$ -SMA was expressed in red color. In PA group, we observed a few CK18<sup>+</sup> cells was co-localization with  $\alpha$ -SMA in the mesothelial layer. (Original magnification, x400, bar = 100  $\mu$ m). (C)

Quantification of  $\alpha$ -SMA<sup>+</sup> cells (%) in high-powered field (HPF) at x400 magnification. Data are expressed as the mean  $\pm$  SE. \* $P$  < 0.05, \*\* $P$  < 0.01, \*\*\* $P$  < 0.001, respectively.
