

Effects of Deuterium Oxide on Cell Cycle and Vesicle Speed in RBL-2H3 Cells

For the first time we show the effects of deuterium oxide on the cell cycle and vesicle transport in rat basophilic leukemia (RBL-2H3) cells. RBL-2H3 cultured with 15 moles/L deuterium oxide were observed to halt near the G2-M-phase of the cell cycle. Experimental observations also showed an increase in vesicle speed. This increase in vesicle speed was not observed in cultures treated with a microtubule-destabilizing drug suggesting that deuterium oxide affects microtubule-dependent vesicle transport.

INTRODUCTION

Roughly 70% of Earth's surface and animal bodies are made out of water (H_2O). Very few, if any, biological systems or reactions will function without water and one may conclude that the properties of H_2O are essential for life on Earth. In recent years research has indicated that water plays an active role in how biomolecules recognize and bind to each other (Ball, 2011). For example, in a biological system when a protein binds its ligand, associates with another protein, or folds into its functional form, the surrounding solvent must get out of the way. How water may act as a versatile intermediary and facilitator during these processes is still under investigation (Ball, 2011).

To study the effect of water (H_2O), one must find ways to change the properties of H_2O . This can be accomplished by substituting hydrogen (H) by its heavier deuterium (D) isotope resulting in deuterium oxide (D_2O), also known as heavy water or heavy-hydrogen water. All naturally-occurring water contains approximately 150 parts per million D and therefore, D_2O may be essential for some life forms (Lewis, 1934). Deuterium contains one proton and one neutron and bonds to oxygen (O) much stronger than H (one proton and no neutron) in H_2O . This results in small differences in the length of the covalent H-O-bonds and the angles between them, thus making D_2O roughly 11% denser and 25% more viscous than H_2O at 20°C (Hardy and Cottington, 1949). Due to the natural occurrence of D_2O and differences in chemical structure and physical properties compared to H_2O , researchers have used D_2O to study the effects of water on biomolecules and cells. Studies include effects of D_2O on tobacco seed growth (Lewis, 1934), IgE-Mediated histamine release from human leukocytes (Gillespie and Lichtenstein, 1972), actin filament velocities (Chaen et al., 2001), protein flexibility (Cioni and Strambini, 2002), human pancreatic tumor cells (Hartmann et al., 2005), phospholipid membranes (Beranova et al., 2012), kinesin-1 gliding assay (Maloney et al., 2014), and stabilization of tubulin as observed previously in microtubule gliding assays (Panda et al., 2000) and in biochemical experiments on isolated tubulin proteins from beef brain (Houston et al., 1974) and goat brain (Das et al., 2008). Microtubules are polarized polymers of α/β tubulin heterodimers and undergo alternating phases of growth and shrinkage with sudden transitions between the two (Bartolini et al., 2005). Microtubules are responsible for a wide variety of vital

cellular functions such as the formation of a bipolar spindle at mitosis. (Mitosis is the process, in the cell cycle, by which a cell duplicates into two genetically identical daughter cells.) However, it is still unknown how stabilization of tubulin, i.e. the stability of microtubules, due to D₂O affect microtubule-dependent vesicle transport in cell cultures.

In this paper we use the RBL-2H3 cell line, a typical mast cell model system (Thomas et al., 1992; Posner et al., 1995; Carroll-Portillo et al., 2010; Spendier et al., 2010), to start investigating this question. Mast cells are immune cells that originate from the bone marrow and circulate in an immature form in the body until they settle in tissue and mucosal surfaces, where they mature. When mast cells are activated by allergens, they cause allergic responses and protect the body from parasitic infection. A key player in this activation process is the IgE-receptor complex (IgE-FcεRI). Allergens or multivalent ligands, crosslink IgE-receptor complexes on the cell surface, leading to receptor phosphorylation (Metzger, 1992; Galli et al., 2008). A subsequent signaling cascade results in degranulation, i.e., fusion of secretory granules with the plasma membrane (exocytosis) to release a number of inflammatory mediators including histamine and serotonin (Galli et al., 2008). One of the paper's focus is to investigate the effect of D₂O on the transport speed of these secretory granules (secretory vesicles) that are known to be transported in a direct and microtubule-dependent manner towards the cell plasma membrane for exocytosis (Smith et al., 2003).

To our knowledge, the presented investigations have not been performed previously on RBL-2H3 cells. In this paper, we study the effects of D₂O on RBL-2H3 cell growth and vesicle transport. For this first investigation, one specific concentration of 15 moles/L D₂O was chosen. This concentration was previously reported to significantly increase histamine release in human leukocytes (Gillespie and Lichtenstein, 1972). Experiments outlined below indicate that this concentration of D₂O slows RBL-2H3 cell growth by halting the cell cycle near the G₂-M-phase and causes an increase in vesicle speed. Specifically, the data suggests an increase in vesicle speed for microtubule-dependent transport.

METHODS

Cells

The RBL-2H3 cell line was purchased from ATCC. RBL-2H3 cells were maintained in minimal essential medium (MEM) supplemented with 10% fetal bovine serum (FBS), 1% Penicillin Streptomycin (Pen-Strep), and 1% L-glutamine (L-glut). For the experiment cells were grown under 5% CO₂ atmosphere in 6-well dishes for up to five days with media made from MEM powder containing 0 moles/L or 15 moles/L D₂O. Anti-DNP IgE was purchased from Sigma-Aldrich. Before microscopy, cells were IgE primed by incubation with 0.5 mg/mL of IgE overnight. After the addition of cells to the microscope imaging chamber, cells were stimulated with DNP-conjugated BSA (DNP₂₅-BSA) at 2 μg/mL for up to 30 minutes. For colchicine drug treatment cells were treated with 100 μM colchicine for 45 min (Smith et al., 2003). Trypan blue stained cells were used to count viable (alive) and dead cells on a hemacytometer. The presented studies on this cell line have been approved by the University of Colorado at Colorado Springs Institutional Review Board, approval number IBC 13-001.

Supported lipid bilayers

Prior to use, microscope glass cover slips were cleaned of organic residues with a mixture of sulfuric acid and hydrogen peroxide (*piranha* solution). Supported lipid bilayers (Carroll-Portillo et al., 2010; Spendier et al., 2010) were made by spontaneous liposome fusion (Werner et al., 2009). Lipids, obtained from Avanti, were dissolved in chloroform, dried under air flow, and then placed under a vacuum for 1 h to remove traces of oxygen. The lipid film was then suspended in PBS to 1.3 mM and sonicated for 5 min using a probe sonicator in an ice bath. Laterally mobile bilayers were formed from 1-palmitoyl-2-oleoyl-sn-glycero-3-phosphocholine (POPC) and 5 mol% N-dinitrophenyl-aminocaproyl phosphatidylethanolamine (DNP-Cap PE) on *piranha*-cleaned cover glass for 15 min on a slide warmer at 37°C. Each bilayer coated coverslip was kept water immersed during transfer to the imaging chamber. Prior to adding cells to the bilayer, the chamber was flushed with Hanks's buffered saline solution.

DiI labeling

For fluorescent imaging of lipid membrane vesicles, approximately 3×10^5 cells were suspended in 1 mL of Hanks's buffered saline solution and incubated with $2 \mu\text{L}$ Vibrant DiI (Life Technologies, Grand Island, NY) at 2 mM concentration for 2 minutes. After incubation, the cells were washed at least three times in Hanks's buffered saline solution.

Flow Cytometry measurements

RBL-2H3 cell cycle was analyzed by quantization of DNA content with a Beckman Coulter Cytomics FC 500 MPL Flow Cytometer using forward scatter (FS), side scatter (SS), and fluorescence 3 (FL3, 620nm Band Pass Filter) channels. The brightness of the propidium iodide (PI) fluorescent dye was used to evaluate DNA content. A 488 nm laser beam was focused onto the flowing stream at a fixed point illuminating the cells as they pass through. To prepare cell samples, cells were first trypsinated and then washed with MEM of the appropriate D_2O concentration. Cells were fixed and PI-stained by re-suspending cell pellets in $250 \mu\text{L}$ of MEM, $250 \mu\text{L}$ of ethanol and $100 \mu\text{L}$ of PI at 0.1 g/L. PI-stained cell samples were refrigerated overnight and analyzed the following day. Samples were run 100 s or until the count exceeded 10,000 cells. For analysis, the single cell population was first gated using FS vs. SS to remove obvious cell debris and non-cellular elements. This gate was then applied to FS vs. FL3 to reduce doublets, i.e. two cells stuck together that may register as a single cell. These two gates were then combined and applied to give the final PI histogram plots.

Fluorescent imaging

DiI stained RBL-2H3 cells were imaged using a total internal reflection fluorescence (TIRF) microscope. Cell samples were maintained at 37°C using an objective heater. In TIRF microscopy, cells were allowed to settle onto a fluid lipid POPC bilayer with 5 mol% DNP lipid or on piranha-cleaned glass under gravity. Objective-based TIRF microscopy was performed with a S-TIRF module (Spectral Applied Research, Canada) attached to a Leica DMI3000 B inverted microscope with a $100\times$ and 1.47 N.A. oil immersion objective using a 561 nm laser (Coherent Inc.) excitation. A $1.5\times$ lens was also added to the excitation beam path resulting in a final magnification of $150\times$. The penetration

depth of the evanescent wave for 561 nm excitation was calculated to be 200 nm. A 600/50 nm single-band bandpass filter (Chroma) was used to collect fluorescence. TIRF images were collected with an EMCCD camera (Evolve Delta; Photometrics) operated by Micro-Manager (Stuurman et al., 2007).

Single-vesicle tracking

Image processing was conducted in MATLAB (MathWorks, Inc., Natick, MA), in conjunction with the DIPImage image processing toolbox (Delft University of Technology). Image backgrounds were averaged and subtracted to reduce noise. Fluorescent particles of size within the microscope resolution limit were identified as vesicles. Vesicle coordinates were identified in each frame by a direct Gaussian fit algorithm and a cost function was employed to link coordinates together into trajectories (Andrews et al., 2008). Trajectories were histogrammed by average hop speed for each vesicle trajectory. Hop speed was calculated as a function of distance/frame, where each frame represents a 20 ms time interval. Any distinct fluorescent clusters of low speed defined as less than $10^{-2} \mu\text{m}/\text{s}$ were removed to separate vesicles from stationary cellular structures.

RESULTS AND DISCUSSION

The effect of deuterium oxide on RBL-2H3 cell growth and viability

It is known that D₂O can reduce cell growth in human pancreatic tumor cells (Hartmann et al., 2005). To confirm that a similar trend is observed in RBL-2H3 cells, cell growth and cell viability was monitored over a period of 5 days. RBL-2H3 cells were cultured in 6 well plates in cell media containing 0 moles/L D₂O or 15 moles/L D₂O. The plates were seeded at the same time to ensure similar initial cell seeding concentration for each well. Cells were allowed to divide for 24 hours before the first measurement. Figure 1 shows that when cells were cultured in 15 moles/L D₂O (open circles) a 7-fold decrease in RBL-2H3 cell growth was observed after five days compared to cells cultured in 0 moles/L D₂O (closed circles). Cell viability also dropped by 20% for cells cultured in D₂O (open circles) as shown in Fig. 1B. These results are qualitatively consistent with studies on human pancreatic tumor cells (Hartmann et al., 2005).

The observed reduction in cell growth and viability may be caused by differences in pH between the two growing conditions (Lardner, 2001). For cell media containing 0 moles/L D₂O and 15 moles/L D₂O, the average pH was 7.58 ± 0.29 and 7.48 ± 0.12 , respectively during a 5 day period. The error is represented by the standard deviation. No statistical significant difference was observed and therefore we conclude that changes in pH did not cause the observed decrease in cell growth.

Effect of D₂O on the RBL-2H3 cell cycle

The cell cycle has four distinct phases that can be recognized in a proliferating cell population: the G₁- (growth phase), S- (DNA synthesis phase), G₂- (growth phase and preparation for mitosis) and M-phase (mitosis). It is known that high-levels of deuterium slow down the rate of mitosis (Lamprecht et al., 1989, 1990), but the exact mechanism is still under investigation. A possible mechanism of the antimitotic action of D₂O is that centrosomally controlled transformation of the microtubular cytoskeleton into the mitotic spindle is impaired by D₂O (Lamprecht et al., 1990). For example, one study showed that D₂O arrests the cell cycle of PtK2 cells during interphase (Schroeter et al., 1992) and another study showed that human pancreatic tumor cells arrest in the G₂-M-phase of the cell cycle (Hartmann et al., 2005). A very detailed and recent study by Mosin and Ignatov (2014) demonstrated that the effects observed at the cellular growth on D₂O possess a complex multifactor character connected to changes of cytological, morphological and physiological parameters including, cellular size, non-uniform distribution of DNA, magnitude of the lag-period, time of cellular generation, a ratio of amino acids, protein, carbohydrates and fatty acids synthesized in D₂O.

To test whether D₂O also arrests RBL-2H3 cell cycle and in which phase this arrest occurs, Flow Cytometry measurements were performed to monitor RBL-2H3 cell cycle by measuring DNA content (Darzynkiewicz et al., 1994). Here, PI was used as a DNA probe to investigate the cell cycle in particular the G₀-G₁-, S- and G₂-M-phases. Each of these phases can be identified by DNA content. G₀-G₁ is diploid and has a normal complement of DNA. In S-phase, DNA synthesis occurs and in the G₂-M-phase, twice the amount of DNA is found in the cells than in the G₀-G₁ phase. Therefore, a typical DNA content frequency histogram of proliferating (multiplying) cells shows two clearly separated peaks, a

G0-G1-peak and a lower G2-M-peak separated by the cell subpopulation in the S-phase.

Figure 2 depicts DNA content frequency histograms for RBL-2H3 cells in untreated cultures (Fig. 2A) and in cultures treated with D₂O (Fig. 2B). For untreated cells, the second and lower G2-M-peak is recognizable and indicated by the arrow. This peak does not significantly change four days after seeding (red line in Fig. 2A) compared to one day after seeding (black line in Fig. 2A). In one-day old D₂O treated cultures, the G2-M-peak can also be identified (black line in Fig. 2B) but disappears in a four-day old culture (red line in Fig. 2B) indicating that RBL-2H3 cell proliferation halts near the G2-M-phase and is consistent with previous reports in literature as mentioned above.

Dil-stained RBL-2H3 cells for vesicle tracking

A possible mechanism for the observed cell cycle arrest in RBL-2H3 cells cultured in D₂O is microtubule stabilization. In this case, vesicles that are transported in a microtubule-dependent manner should experience different transport speeds in untreated and D₂O treated cultures. As shown by Smith et al. (2003) during mast cell activation via IgE-FcεRI crosslinking, secretory granules are transported in a direct and microtubule-dependent manner towards the cell plasma membrane for exocytosis. To mark these secretory vesicles for studies presented here, diI was used as fluorescent lipophilic membrane stain (Anantharam et al., 2010). DiI is weakly fluorescent until incorporated into lipid membranes. It labels all cell membrane barriers, including the cell plasma membrane and membrane-bound organelles such as the nucleus, endoplasmic reticulum, golgi apparatus, lysosomes, endosomes, and mitochondria (see supplemental Fig. S1).

TIRF microscopy was employed to reduce background fluorescence from the cell plasma membrane and fluorescence from membrane-bound organelles. In TIRF microscopy, the excitation laser beam is totally internally reflected at the glass-water interface and only an evanescent wave traveling parallel to the interface penetrates into the sample. The evanescent wave decays rapidly with a perpendicular distance from the interface, and selectively excites the sample within a distance of about 200 nm from the surface. Besides reduction of background fluorescence, the advantage of using TIRF microscopy is selective excitation of vesicles that are within the evanescent field. In mast cells, membrane-bound granules

are approximately 300-400 nm in diameter (Martynova et al., 2005). Therefore in the experiments outlined below, vesicles were identified as fluorescent particles of size within the microscope resolution limit. Since secretory granules are transported in a direct manner towards the cell plasma membrane for exocytosis, TIRF microscopy makes it possible to track these vesicles.

To test the ability of diI to label secretory vesicles, diI-stained, IgE-loaded RBL-2H3 cells cultured in 0 moles/L D₂O were allowed to settle onto glass over a 5 min period, and then stimulated with multivalent DNP₂₅-BSA for 30 min. Cells were imaged before the addition of DNP₂₅-BSA and during the incubation period using TIRF microscopy at 20 frames/s. Supplemental movie S1 clearly shows sustained vesicle motion 26 min after DNP₂₅-BSA stimulation (right panel in top row of supplemental movie S1). Some vesicle motion, albeit slower, was also observed in unstimulated RBL-2H3 cells which is consistent with previous work by Smith et al. (2003). To shorten cell-settling time to less than 1 min and achieve good cell-substrate contact required for TIRF imaging, cells were allowed to settle onto a supported lipid bilayer with 5 mol % DNP-Cap PE for single-vesicle tracking experiments outlined below. One of the authors showed previously that RBL-2H3 cells in contact with liganded-bilayers composed of 5 mol % DNP-Cap PE exhibit degranulation levels similar to un-stimulated cells (Carroll-Portillo et al., 2010).

Effect of D₂O on vesicle motion in RBL-2H3 cells

As pointed out above, diI labels all membrane barriers including vesicles that are not transported on microtubules. However, if a large number of vesicles in DNP₂₅-BSA activated cells are tracked within the cell-substrate contact area, a significant population of these vesicles is expected to be secretory, i.e. vesicles that are transported on microtubules for exocytosis. Therefore, over 1500 individual vesicle were tracked using TIRF microscopy. For each vesicle-trajectory, the mean hop speed was calculated. The average of these mean vesicle hop speeds for cells cultured in 0 moles/L D₂O was $3.61 \pm 0.13 \mu\text{m/s}$. This average speed was significantly slower than the average of $8.50 \pm 0.44 \mu\text{m/s}$ computed from the mean vesicle hop speeds for cells cultured in 15 moles/L D₂O. This difference was statistically significant as determined by the Student's t-test with a p-value of less than 0.05.

To test whether some of the diI-labeled vesicles tracked with TIRF microscopy are secretory, a known microtubule destabilizing drug called colchicine was used which is expected to slow down secretory vesicle transport (Smith et al., 2003). For cells cultured in 0 moles/L D₂O the average of mean vesicle hop speeds for colchicine treated cells did not significantly change and was measured to be $4.24 \pm 0.33 \mu\text{m/s}$. However, for cells cultured in 15 moles/L D₂O the average for colchicine treated cells decreased significantly to $2.44 \pm 0.28 \mu\text{m/s}$ as expected for microtubule-dependent vesicle transport.

Figure 3 shows four box plots of mean hop speeds obtained from analyzing over 1500 individual vesicle trackjectories. Going from left to right, the first and second plot represent mean vesicle hop speeds in cells cultured in 0 moles/L D₂O without colchicine (Fig. 3 H₂O) and with colchicine (Fig. 3 H₂O with Colchicine) treatment, respectively. The third and fourth plot represent mean vesicle hop speeds in cells cultured in 15 moles/L D₂O without colchicine (Fig. 3 D₂O) and with colchicine (Fig. 3 D₂O with Colchicine) treatment, respectively. In Fig. 3 the red crosses represent outliers and the red lines the medians for each distribution. It is likely that the tails of the distributions (indicated by red crosses) for colchicine untreated cultures represent secretory vesicle speeds since these tails disappear in colchicine treated cultures.

CONCLUSIONS

The primary goal of our investigations above was to study the unknown effects of D₂O on RBL-2H3 cell cycle and vesicle transport. A 7-fold decrease in cell growth was observed in five-day old cultures for cells grown in 15 moles/L D₂O compared to untreated cells. Using Flow Cytometry, the decrease in cell proliferation was observed to halt near the G₂-M-phase of the cell cycle. Using TIRF microscopy in conjunction with single-vesicle tracking in antigen-stimulated and diI-labeled RBL-2H3 cells, the average vesicle hop speed increased significantly in D₂O cultures. Average vesicle hop speed decreased after treating cells with colchicine, a microtubule-destabilizing drug, indicating that a population of tracked vesicles were transported along microtubules for vesicle exocytosis. This observation together with previous reports on D₂O's microtubule stabilization effect in microtubule gliding assays (Panda et al., 2000) and on isolated tubulin proteins (Houston et al., 1974; Das et al.,

2008), suggest that the observed increase in vesicle hop speed for D₂O treated RBL-2H3 cultures may be due to stabilization of tubulin. Since G₂-M-cell cycle arrest can be associated with problems in mitotic spindle structure (Holy, 2002), increased stability of microtubules may be the cause for the observed decrease in RBL-2H3 cell proliferation. However to fully investigate deuterium oxide's microtubule stabilization effect on secretory vesicle transport, future experiments that clearly identify secretory vesicles and microtubules are warranted. Such investigations were out of the scope in the presented study. Nevertheless, the reported results can be used as a spring board for future investigations.

ACKNOWLEDGMENTS

The authors would like to thank Dr. Yuriy Garbovskiy for cell culturing and William Townsend for useful discussions and help with flow cytometry measurements. This work was supported by the University of Colorado, Colorado Springs BioFrontiers Center.

Figure 2

The effect of deuterium oxide on RBL-2H3 cell cycle as shown by propidium iodide intensity (FL3) histogram plots. Cells grown (A) in media containing 0 moles/L D_2O and (B) in media containing 15 moles/L D_2O . The black lines represent one-day old cultures and the red lines represent four-day old cultures. The arrows indicates position of the G2-M-cell cycle phase.

Figure 3

Figure 3

Box plots of mean vesicle hop speeds for cells cultured in 0 moles/L D_2O without (H_2O) and with (H_2O with Colchicine) colchicine and cells cultured in 15 moles/L D_2O without (D_2O) and with (D_2O with Colchicine) colchicine. The red crosses represent outliers and the red lines the median for each distribution.
