Estimating the growth of fishes is critical to understanding their life history and conducting fisheries assessments. It is imperative to sufficiently sample each size and age class of fishes to construct models that accurately reflect biological growth patterns, but this may be a challenging endeavor for highly-exploited species in which older fish are rare. Here, we use the Gulf Corvina (*Cynoscion othonopterus*), a vulnerable marine fish that has been persistently overfished for two decades, as a model species to compare the performance of several growth models. We fit the von Bertalanffy, Gompertz, logistic, Schnute, and Schnute-Richards growth models to length-at-age data by nonlinear least squares regression and used simple indicators to reveal biased data and ensure our results were biologically feasible. We then explored the consequences of selecting a biased growth model with a per-recruit model that estimated female spawning-stock-biomass-per-recruit and yield-per-recruit. Based on statistics alone, we found that the Schnute-Richards model described our data best. However, it was evident that our data were biased by a bimodal distribution of samples and underrepresentation of large, old individuals, so we found the Schnute-Richards model output to be biologically implausible. By simulating an equal distribution of samples across all age classes, we found that sample distribution distinctly influenced model output for all growth models tested. Consequently, we determined that the growth pattern of the Gulf Corvina was best described by the von Bertalanffy growth model, which was the most robust to biased data, comparable across studies, and statistically comparable to the Schnute-Richards model. Growth model selection had important consequences for assessment, as the per-recruit model employing the Schnute-Richards model fit to raw data predicted the stock to be in a much healthier state than

per-recruit models employing other growth models. Our results serve as a reminder of the importance of complete sampling of all size and age classes when possible, and transparent identification of biased data when complete sampling is not possible.

**17 Abstract**

18 Estimating the growth of fishes is critical to understanding their life history and conducting  
19 fisheries assessments. It is imperative to sufficiently sample each size and age class of fishes to  
20 construct models that accurately reflect biological growth patterns, but this may be a challenging  
21 endeavor for highly-exploited species in which older fish are rare. Here, we use the Gulf Corvina  
22 (*Cynoscion othonopterus*), a vulnerable marine fish that has been persistently overfished for two  
23 decades, as a model species to compare the performance of several growth models. We fit the  
24 von Bertalanffy, Gompertz, logistic, Schnute, and Schnute-Richards growth models to length-at-  
25 age data by nonlinear least squares regression and used simple indicators to reveal biased data  
26 and ensure our results were biologically feasible. We then explored the consequences of  
27 selecting a biased growth model with a per-recruit model that estimated female spawning-stock-  
28 biomass-per-recruit and yield-per-recruit. Based on statistics alone, we found that the Schnute-  
29 Richards model described our data best. However, it was evident that our data were biased by a  
30 bimodal distribution of samples and underrepresentation of large, old individuals, so we found  
31 the Schnute-Richards model output to be biologically implausible. By simulating an equal  
32 distribution of samples across all age classes, we found that sample distribution distinctly  
33 influenced model output for all growth models tested. Consequently, we determined that the  
34 growth pattern of the Gulf Corvina was best described by the von Bertalanffy growth model,  
35 which was the most robust to biased data, comparable across studies, and statistically  
36 comparable to the Schnute-Richards model. Growth model selection had important consequences  
37 for assessment, as the per-recruit model employing the Schnute-Richards model fit to raw data  
38 predicted the stock to be in a much healthier state than per-recruit models employing other  
39 growth models. Our results serve as a reminder of the importance of complete sampling of all

40 size and age classes when possible, and transparent identification of biased data when complete  
41 sampling is not possible.

## 42 **Introduction**

43 Age and size data inform estimates of life history parameters that are crucial to fisheries  
44 stock assessments. In early assessments such as Beverton and Holt's yield-per-recruit model  
45 (1957), size at age was critical for estimating reproductive output and thus the sustainability of  
46 fisheries. In today's age-structured stock assessments, size at age is used to convert from biomass  
47 to number of fish, determine selectivity, and calculate expected length compositions (Francis,  
48 2016). Similarly, size (i.e., length or weight) at age is used in size-structured stock assessment  
49 models to inform transitions between size bins and determine length composition (Punt et al.,  
50 2016). Accurately representing the relationship between size and age is particularly important for  
51 vulnerable fish and in data-poor fisheries, in which life-history parameters and population  
52 structure often drive stock assessments and management decisions (Dulvy et al., 2004; Froese,  
53 2004; Honey et al., 2010; Hordyk et al., 2016). Specifically, these types of assessments rely  
54 heavily on age-length data to confer insights on vulnerability and overfishing (Erisman et al.,  
55 2014).

56 When modelling the relationship between age and size for the purposes of assessment, and  
57 for any purpose, each age and size class must be sufficiently represented to generate growth  
58 parameters that reflect biological growth (Cailliet et al., 1986; Cailliet and Tanaka, 1990; Francis  
59 and Francis, 1992; Cailliet and Goldman, 2004). It is important to make the distinction between  
60 this type of sampling and sampling to reflect population structure, which should not be the goal  
61 of age and growth studies as this reflects bias due to the relative scarcity of large and old

62 individuals. Sufficiently representing each size and age class may be especially difficult in  
63 highly-exploited species, as exploitation alters the population structure of fishes by preferentially  
64 selecting for large and old fish individuals (Mason, 1998; Berkeley et al., 2004). The  
65 ramifications for failing to acknowledge selection are clear, as length-selective fishing mortality  
66 distorts growth curves (Walker et al., 1998). Further, the lack of representation of large and old  
67 individuals could result in underestimation of lifespan and longevity, which makes fishery  
68 management measures less effective (Campana, 2001; Cailliet and Andrews, 2008; Goldman et  
69 al., 2012). Large and old fish drive estimates of the maximum average length parameter  $L_{\infty}$ , and  
70 without them,  $L_{\infty}$  is underestimated and the growth rate (typically denoted by  $K$ ) is  
71 overestimated. The underestimation of  $L_{\infty}$  and the overestimation of  $K$  lead to the assumptions of  
72 a shorter generation time and less mortality, and thus more resiliency to high levels of fishing  
73 pressure (Campana, 2001; Goldman et al., 2012; Harry, 2017). The  $L_{\infty}$  term is particularly  
74 important when growth models are incorporated into stock assessment (Wells et al., 2013). This  
75 problem may also occur in growth modelling for vulnerable fish or in data-poor fisheries, where  
76 lack of representation of each age and size class due to sampling constraints or the scarcity of  
77 individuals may similarly affect parameter estimates. Fishery dependent data are often the only  
78 data available for growth modelling, which may be acceptable only as long as the inherent biases  
79 and limitations are acknowledged.

80         Several models have been developed to quantify the relationship between age and size,  
81 with body length being the most common metric of size. Typically, asymptotic growth models  
82 are used to quantify this relationship. These models describe fast growth rate in the earliest years  
83 of life and slower growth in later years. Despite some criticism (Roff, 1980; Czarnolewski and  
84 Kozłowski, 1998), the most widely used is the von Bertalanffy growth model (Chen et al., 1992;

85 Kimura, 2008). Rooted in bioenergetics, this model is intended to give a biologically relevant  
86 representation of how catabolic and anabolic processes work within a fish to change growth over  
87 the lifespan of fishes (von Bertalanffy, 1938; Pauly, 2010). Over the years, there have been many  
88 re-parameterizations of von Bertalanffy with incorporation of growth-influencing factors and  
89 applications to a variety of situations (Gallucci II and Quinn, 1979; Ratkowsky, 1986; Helser and  
90 Lai, 2004; Kimura, 2008; Brunel and Dickey-Collas, 2010; van Poorten and Walters, 2016), but  
91 the original parametrization is still the most commonly used (Lorenzen, 2016). Other asymptotic  
92 growth models are commonly used in fisheries, such as the Gompertz growth model (Gompertz,  
93 1825) and the logistic growth model (Ricker, 1975).

94 In recent years, fish growth models have moved from a foundation in bioenergetics to  
95 being more statistically driven (van Poorten and Walters, 2016). These models are inherently  
96 more flexible, allowing them to capture subtleties in growth patterns that may not be captured by  
97 the more inflexible growth models. The Schnute model (Schnute, 1981), for example, has four  
98 curve families that the model may assume based on which types of data the model is fit to and  
99 what other functions are incorporated into the framework. Another flexible growth model, the  
100 Schnute-Richards model (Schnute and Richards, 1990), can describe biphasic growth among  
101 several other forms. By design, the Schnute-Richards model may be equivalent to the other  
102 growth models discussed above when the proper values are specified for its dimensionless  
103 parameters. Fish growth is inherently plastic and fish do not all grow the same way (Weatherley,  
104 1990; Lorenzen, 2016), so a flexible growth model may be advantageous in certain situations.  
105 However, these flexible models may also be more sensitive to sampling biases in data,  
106 potentially producing growth patterns that reflect the size-frequency distribution of fish collected  
107 rather than the biological growth pattern of the species.

108           The Gulf Corvina (*Cynoscion othonopterus*) is an ideal species to examine the  
109 performance of multiple growth models in a vulnerable marine fish. Endemic to the northern  
110 Gulf of California, Mexico (Robertson and Allen, 2008), it is currently listed as vulnerable under  
111 the International Union for the Conservation of Nature (IUCN) Redlist (Chao et al., 2016). Gulf  
112 Corvina have experienced persistent overfishing on their spawning aggregations for the past two  
113 decades, which have resulted in growing concern for the fishery's stability and longevity  
114 (Erisman et al., 2012; Ruelas-Peña et al., 2013; Erisman et al., 2014; Ortiz et al., 2016). The life  
115 history of this species has been well documented and provides an ideal foundation for future  
116 analysis of individual and population growth (Román-Rodríguez, 2000; Gherard et al., 2013.  
117 With a documented maximum size of 1013 mm total length (TL) and a documented maximum  
118 age of 9 years, Gulf Corvina is a fast growing, short lived species which reaches sexual maturity  
119 at 2 years of age (Gherard et al., 2013). However, the combination of highly efficient, size-  
120 selective gear and persistent overfishing have severely truncated the age structure of the  
121 population (Erisman et al., 2014; Ortiz et al., 2016). The mean age of capture of Gulf Corvina is  
122 5 years (*ca.* 700 mm TL), and few individuals older than age 7 or younger than age 4 have been  
123 observed in the fishery (Gherard et al., 2013; Erisman et al., 2014; Ortiz et al., 2016).

124           Past studies of Gulf Corvina growth, which have relied solely on fishery-dependent data  
125 with incomplete sampling of all size and age classes, have produced different results due to  
126 differences in model selection approach. Based on the congruence of the model with the growth  
127 pattern of many species of the genus *Cynoscion* and other sciaenid fishes (Rutherford et al.,  
128 1982; Lowerre-Barbieri et al., 1995; Rodriguez and Hammann, 1997), Gherard et al. (2013) took  
129 a conservative, single model approach and fit the von Bertalanffy growth model to Gulf Corvina  
130 age-length data. Conversely, Aragón-Noriega (2014) chose a statistically-driven approach and fit

131 several models to multiple datasets, concluding that Gulf Corvina grew in a biphasic pattern with  
132 slow growth in the beginning of life, rapid growth after age two, and slow growth after age four.  
133 Notably, Aragón-Noriega's (2014) estimates for the  $L_{\infty}$  parameter varied greatly, from 735.0 to  
134 1126.6 mm, depending on which dataset was used. Given this variability, absence of biphasic  
135 growth patterns in similar sciaenids, and the distance from the maximum observed length of Gulf  
136 Corvina (1013 mm; Gherard et al., 2013), Aragón-Noriega's (2014) estimates may be  
137 biologically unrealistic. Mendivil-Mendoza et al. (2017) took a similar approach and found a  
138 similarly wide range of  $L_{\infty}$  values (666.7 – 1306.0 mm). However, despite fitting models to  
139 similar data and selecting the same model as Aragón-Noriega (2014), Mendivil-Mendoza et al.  
140 (2017) did not describe the biphasic growth pattern recorded by Aragón-Noriega (2014). The  
141 existence of discrepancies between the previous Gulf Corvina growth studies and the importance  
142 of the age-length relationship to the stock assessment of the fishery merit further investigation on  
143 the growth pattern of the species.

144         Here, we model the growth of Gulf Corvina and draw conclusions about data needs and  
145 fisheries assessments. Our specific objectives were to: (1) assess how representation of size and  
146 age classes affected growth parameter estimates and (2) compare the performance of multiple  
147 growth models for describing age-at-length data for Gulf Corvina. Through generating a more  
148 complete dataset than previous studies and testing for biases in our data with simple indicators,  
149 we addressed these objectives. Moreover, using the results of simulations with a per-recruit  
150 model, we discussed the implications of misrepresenting growth in highly-exploited, vulnerable  
151 marine fishes.

## 152 **Materials and Methods**

### 153 *Data collection*

154           Seven hundred and forty-nine Gulf Corvina were sampled from 2009 through 2013 at the  
155 three locations in the upper Gulf of California: El Golfo de Santa Clara (Sonora), San Felipe  
156 (Baja California), and El Zanjón (Baja California). Information on total length (TL) was  
157 recorded to the nearest mm for each fish collected, and the sagittal otoliths were removed, dried  
158 whole and stored until further use. Five hundred and thirty of these samples were collected from  
159 the commercial Gulf Corvina fishery and from bycatch from the shrimp fishery. These data were  
160 used by Gherard et al. (2013). In order to increase representation of size and age classes that  
161 were scarce in the dataset used by Gherard (2013), we collected 219 additional samples in 2012-  
162 2013 from the bycatch of other fisheries (e.g., shrimp), fishery-independent sampling of small  
163 individuals (<30 cm TL), and the commercial Gulf Corvina fishery. All fish were deceased at the  
164 time of collection from fishers. The research protocol was approved under UCSD IACUC ID no.  
165 S13240 and data were collected under CONANP permit no. CNANP-00-007.

166           Otolith preparation and ageing protocols were followed according to the methods  
167 developed by Gherard et al. (2013) for Gulf Corvina. Whole sagittal otoliths were first mounted  
168 on wood blocks with a cyanoacrylate adhesive and a 0.5 mm dorsal-ventral cross-section was cut  
169 through the otolith focus using a double-bladed Buehler Isomet 1000 precision saw (Allen et al.,  
170 1995). Sub-sections were then mounted on a glass slide using thermoplastic glue and submerged  
171 in a glass petri dish with water and a black background. Transmitted light under a Zeiss Stemi  
172 2000-C microscope with a Zeiss AxioCam 105 color camera at 6.25x total magnification was  
173 used to count the alternating opaque and translucent growth zones that define an annulus (Figure  
174 1). For the purposes of this study, an annulus was defined as one full opaque and translucent  
175 zone of growth (Cailliet et al., 1996), which was validated for Gulf Corvina by previous studies  
176 (Rowell et al., 2005; Román-Rodríguez, 2000; Gherard et al., 2013) Each otolith was aged by

177 two independent readers from digital images of cross-sections, as direct observation through the  
 178 scope did not distort band pattern and did not affect age estimates. Samples were excluded from  
 179 analysis when discrepancies between readers occurred.

180 *Model fitting and assessment of fit*

181 *Growth modelling*

182 A suite of growth models was fit to age data determined from otoliths as described, and  
 183 length data obtained in the field. Model parameters were estimated using non-linear least squares  
 184 regression with the Levenberg-Marquardt algorithm, and confidence limits were placed around  
 185 parameter estimates in R studio (using the R packages FSA, minpack.lm, and nlstools).

186 The specialized von Bertalanffy growth model (von Bertalanffy, 1938) is given by:

187 Eq. 1: 
$$L(t) = L_{\infty}[1 - e^{-K(t-t_0)}]$$

188 where  $L(t)$  is size (in mm TL) at age  $t$ ,  $L_{\infty}$  is the maximum average length (in mm TL),  $K$  is the  
 189 growth rate coefficient (in year<sup>-1</sup>), and  $t_0$  is the theoretical age at which length is zero (in years).

190 The Gompertz growth model (Gompertz, 1825) is given by:

191 Eq. 2: 
$$L(t) = L_{\infty}e^{(-\frac{1}{K})e^{-K(t-t_0)}}$$

192 where the parameters are the same as described for Eq. 1.

193 The logistic model (Ricker, 1975) is given by:

194 Eq. 3: 
$$L(t) = L_{\infty}[1 + e^{-K(t-t_0)}]^{-1}$$

195 where the parameters are the same as described for Eqs. 1 and 2.

196 The Schnute model where  $a$  and  $b$  are not equal to zero (Schnute, 1981) is given by:

197 Eq. 4: 
$$L(t) = \left[ L_1^b + (L_2^b - L_1^b) \frac{1 - e^{-a(t-T_1)}}{1 - e^{-a(T_2-T_1)}} \right]^{1/b}$$

198 where  $T_1$  is the first specified age,  $T_2$  is the second specified age,  $L_1$  is size at age  $T_1$ ,  $L_2$  is size at  
199 age  $T_2$ ,  $a$  is the constant relative rate of relative growth (in year<sup>-1</sup>), and  $b$  is the incremental  
200 relative rate of relative growth (dimensionless),

201 Finally, the Schnute-Richards model (Schnute and Richards, 1990) is given by:

202 Eq. 5: 
$$L(t) = L_\infty \left( 1 + \alpha e^{-at^c} \right)^{1/b}$$

203 where  $\alpha$ ,  $b$ , and  $c$  are dimensionless parameters, and  $a$  has the unit of year<sup>-b</sup>.

#### 204 *Statistical measures of fit*

205 Model fit was assessed with the bias-corrected Akaike Information Criterion (AICc)  
206 (Shono, 2000; Burnham and Anderson, 2004), and Bayesian Information Criterion (Schwarz,  
207 1978) in R Studio (using the R package AICcmodavg).

208 The formula for AICc is given by:

209 Eq. 6: 
$$AIC_c = AIC + \frac{2k(k+1)}{n-k-1}$$

210 where:

211 Eq. 7: 
$$AIC = -2 \log(L) + 2k$$

212 and  $n$  is the number of observations,  $k$  is the number of model parameters, and  $L$  is the likelihood.

213 The formula for BIC is given by:

214 Eq. 8: 
$$BIC = 2\ln(L) + k \log(n)$$

215 where parameter definitions are the same as described for Eq. 7.

216 The smallest AICc and BIC values indicate the best model. The difference between the  
217 two criteria is that AICc is designed to select the model that describes reality the best while  
218 treating no models as true, which is consistent with an information theory approach, whereas  
219 BIC is designed to select the true model. Practically, BIC penalizes for the number of parameters  
220 more heavily than AICc. AICc was used instead of AIC as it is bias-corrected at small  $n$  values  
221 or high  $k:n$  ratios; AICc converges to AIC at large  $n$  values (Burnham and Anderson, 2004).  
222 AICc and BIC values were calculated to show the absolute difference between model fits. Next,  
223 AICc weights were calculated for model averaging of parameter estimates; the AIC weighting  
224 formula is given by:

225 Eq. 9: 
$$w_i = \frac{e(-0.5\Delta_i)}{\sum_{k=1}^5 e(-0.5\Delta_k)}$$

226 where parameter definitions are the same as described for Eqs. 7 and 8.

227 *Simple indicators of biased data*

228 *Simulation of an ideal sampling outcome*

229 To test for the influence of sampled population structure on growth model output, different  
230 amounts of simulated data were added to raw data so that each age observed (1-8) had 200 total  
231 observations. Data were simulated from a normal distribution with the same mean and standard  
232 deviation as the raw data at each age class. This simulation was not intended to generate the true  
233 population structure of Gulf Corvina in the Gulf of California, but rather to generate an equal  
234 number of samples in each age and size class. This simulation did not explicitly account for

235 selectivity or limits in sampling effort, but filled in gaps left by these factors and others that  
236 prevented more equal representation of each size and age class in the raw data. Models were fit  
237 to the new dataset and goodness of fit was assessed in the same manner as was described above.

### 238 *Froese and Binohlan's empirical relationship*

239 Froese and Binohlan's (2000) empirical relationship between the longest fish in the data  
240 set ( $L_{max}$ ) and  $L_{\infty}$  was used to specifically test for the influence of the lack of large and old fish in  
241 the raw dataset, which is likely due to heavy exploitation. If large and old fish are insufficiently  
242 represented in the dataset, it stands to reason that the  $L_{\infty}$  predicted by this relationship will be  
243 greater than the modelled  $L_{\infty}$ . This relationship is given by:

244 Eq. 10: 
$$\log L_{\infty} = 0.044 + 0.9841 * \log (L_{max})$$

245

### 246 *Literature review*

247 A brief literature review of sciaenid growth modelling was conducted to assess how the  
248 results of this study compared with other studies on fishes closely related to the Gulf Corvina  
249 (e.g., other species in the genus *Cynoscion*). In conjunction with Froese and Binohlan's empirical  
250 relationship and the simple simulation of an ideal sampling scenario, this brief literature review  
251 was intended to check if the samples used in this study produced a biologically plausible growth  
252 pattern when growth was modelled.

### 253 *Simulations with a per-recruit model*

254 To be able to discuss the implications of misrepresenting growth in Gulf Corvina, we ran  
255 simulations with a per-recruit model detailed in Appendix S1. In brief, this per-recruit model

256 estimates the female spawning-stock-biomass-per-recruit (SSBR; a proxy of reproductive  
257 capacity) and yield-per-recruit (YPR; exploitable biomass) of Gulf Corvina in relation to the  
258 annual exploitation rates of the old adults ( $\geq 5$  year-old individuals) of the species ( $E_{OA}$ ). In this  
259 per-recruit model, Gulf Corvina is assumed to grow according to one of five alternative growth  
260 models: (1) the von Bertalanffy model developed in Gherard et al. (2013), referred to as the  
261 “Gherard model”; (2) the von Bertalanffy model fit to raw data in the present study; (3) the von  
262 Bertalanffy model fit to raw data bolstered by simulation values in this study; (4) the Schnute-  
263 Richards model fit to raw data in the present study; and (5) the Schnute-Richards model fit to  
264 raw data bolstered by simulation values in this study. The current  $E_{OA}$  was estimated to be 0.825  
265 year<sup>-1</sup> (Appendix S1). We first ran simulations with the per-recruit model to determine the  
266 maximum value of the YPR of Gulf Corvina ( $YPR_{max}$ ) and the natural SSBR of Gulf Corvina  
267 (NSSBR), i.e., its SSBR in the absence of fishing (Appendix S1). Then, we estimated the current  
268 fraction of NSSBR (current FNSSBR, i.e., the ratio of current SSBR to NSSBR) and the current  
269 YPR over  $YPR_{max}$  of Gulf Corvina, when each of the five abovementioned growth models is  
270 used to represent the growth in length of Gulf Corvina.

## 271 **Results**

### 272 *Length and age structure*

273 A bimodal distribution was observed in the length and age structure of the fish used in  
274 this study (Figures 2 and 3). The first mode of the distribution represents Gulf Corvina caught as  
275 bycatch, whereas the second represents Gulf Corvina caught in the targeted fishery. Lengths  
276 ranged from 141-1013 mm TL, and ages ranged from 1-8 years.

### 277 *Model fitting and assessment of fit for models fit to raw data*

278 *Growth patterns and parameter estimates for models fit to raw data*

279 The Gompertz, logistic, and von Bertalanffy models yielded asymptotic growth patterns,  
280 while the Schnute-Richards model described biphasic growth and the Schnute model described  
281 near-linear growth after 1.5 years of life (Figure 4). Modelled length at age was most similar  
282 among models at intermediate ages, where samples were most abundant (Figure 4). Conversely,  
283 modelled length at age was most variable at young and old ages, where samples were most  
284 scarce (Figure 4). Estimates of  $L_{\infty}$  ranged from 730.91 mm (Schnute-Richards model) to 916.05  
285 mm (von Bertalanffy model). All parameter estimates are summarized in Table 1, while  
286 confidence intervals around parameter estimates are reported in Appendix S2.

287 *Measures of statistical fit for models fit to raw data*

288 AICc and BIC values indicated that the Schnute-Richards model described the raw data  
289 best, followed by the logistic, Gompertz, von Bertalanffy, and Schnute models (Table 2). The  
290 AIC weighting formula gave full support to the Schnute-Richards model, so no model averaging  
291 of parameters was necessary.

292 *Simple indicators of biased data*

293 *Growth patterns and parameter estimates for models fit to raw data bolstered by*  
294 *simulated values*

295 The Schnute-Richards, Gompertz, logistic and von Bertalanffy growth models yielded  
296 asymptotic growth patterns, while the Schnute model described near-linear growth after 1.5 years  
297 of age (Figure 5). Modelled length at age was similar at intermediate ages among all growth  
298 models except for the Schnute one, but differed slightly at young and old ages (Figure 5).

299 Estimates of  $L_{\infty}$  ranged from 834.34 mm (logistic model) to 951.30 mm (von Bertalanffy model)  
300 (Table 3). All parameter estimates for each growth model are summarized in Table 3.

301 *Measures of statistical fit for models fit to raw data bolstered by simulated values*

302 The von Bertalanffy growth model described the raw data bolstered by simulated values  
303 best according to AICc and BIC values (Table 4). However, it was only marginally better than  
304 the Schnute-Richards and Gompertz models based on AICc. Thus, the von Bertalanffy growth  
305 model received 53% of AICc weighting to the Schnute-Richards' 33%, and Gompertz' 15%. The  
306 logistic model fit the data better than the Schnute model, but neither models received any support  
307 from AICc weighting. Model averaging  $L_{\infty}$  based on AICc weights resulted in an estimated  $L_{\infty}$  of  
308 945 mm, an estimate 6 mm shorter than the that predicted by the von Bertalanffy model. In  
309 contrast to AICc values, BIC values indicated that the Gompertz model fit the data better than  
310 the Schnute-Richards model. Both Gompertz and Schnute-Richards models fit the data better  
311 than the logistic and Schnute models according to BIC values, as was indicated by AICc values.

312 *Froese and Binohlan's empirical relationship*

313 Froese and Binohlan's empirical relationship between  $L_{max}$  and  $L_{\infty}$  predicted a  $L_{\infty}$  of 1006  
314 mm from a maximum observed length of 1013 mm. This estimate is larger than all estimates of  
315  $L_{\infty}$  derived from growth models fit to raw data (Table 1) and raw data bolstered by simulated  
316 values (Table 3).

317 *Literature review*

318 Results from our review of 24 sciaenid growth studies and citations are summarized in Table  
319 5. Age and body length relationships in sciaenids were represented by the von Bertalanffy  
320 growth model in 20 of 24 (83%) of the studies we reviewed, as reported in Atlantic Croaker

321 (*Micropogonias undulatus*), Black Drum (*Pogonias chromis*), Red Drum (*Scianops ocellatus*),  
322 Southern Kingfish (*Menticirrhus americanus*), Spotted Seatrout (*Cynoscion nebulosus*),  
323 Weakfish (*Cynoscion regalis*), and Whitemouth Croaker (*Micropogonias furnieri*). Notably,  
324 growth of the Totoaba (*Totoaba macdonaldi*), a sciaenid closely related to Gulf Corvina and also  
325 found in the Gulf of California, was modelled by the von Bertalanffy growth model. Growth of  
326 the Gulf Corvina was modelled using the von Bertalanffy growth model in two previous studies.

327 Other growth models have been used to describe age and body length relationships in  
328 sciaenids in 5 of 24 (21%) the studies we reviewed. The Gompertz model was used to model  
329 growth in female Spotted Seatrout. A linear model was used to model growth in male Spotted  
330 Seatrout, although it was noted that the linear growth pattern may have been due to lack of  
331 sampling of large and old individuals. Multi-model approaches similar to this study were  
332 employed three times (13%). One study on the Gulf Corvina selected the von Bertalanffy growth  
333 model for two datasets, and the Schnute-Richards model for two other datasets. As such, this  
334 study was counted in as one of the 20 studies that used the von Bertalanffy growth model to  
335 model sciaenid growth, and as one of the five studies that employed other growth models. The  
336 most recent age and growth study on Gulf Corvina selected the Schnute-Richards model, but did  
337 not describe a biphasic growth pattern. The other study that employed multiple models fit them  
338 to Spotted Seatrout age-length data and found the most statistical support for the three-parameter  
339 logistic model.

#### 340 *Model selection*

341 Synthesis of the above considerations and assessments led to the selection of the von  
342 Bertalanffy growth model as the best model to represent Gulf Corvina growth. Of models fit in  
343 this study, the von Bertalanffy growth model had the 4<sup>th</sup> best statistical fit to raw data (AICc =

344 8813.66,  $\Delta$  AICc = 53.84, AICc weight = 0; BIC = 8832.08,  $\Delta$  BIC = 44.66; Table 2) and the  
345 best statistical fit to raw data bolstered by simulated values (AICc = 18678.72,  $\Delta$  AICc = 0. AICc  
346 weight = 0.53; BIC = 18700.20,  $\Delta$  BIC = 0; Table 4). Of models fit in this study, the von  
347 Bertalanffy growth model produced an  $L_{\infty}$  closest to the  $L_{\infty}$  predicted by Froese and Binohlan's  
348 empirical relationship of 1006 mm (raw data: 916.05 mm; raw data bolstered by simulated  
349 values: 951.30 mm; Tables 1 and 3). Further, the von Bertalanffy growth model was used to  
350 represent sciaenid growth in 83% of studies reviewed.

### 351 *Simulations with a per-recruit model*

352 The current value of the exploitation rate of old adults of Gulf Corvina  $E_{OA}$  that we  
353 estimated is *ca.* twice larger than the value of  $E_{OA}$  at which the YPR of Gulf Corvina reaches a  
354 maximum, regardless of the growth model employed for simulations with the per-recruit model  
355 (Appendix S1). However, the current FNSSBR of Gulf Corvina predicted when using the  
356 Schnute-Richards growth model fit to raw data only (0.60) is noticeably greater than the current  
357 FNSSBR of Gulf Corvina predicted when using all the other growth models (0.42-0.53) (Figure  
358 6A). The value of fraction of natural SSBR that causes population collapse typically is in the  
359 range of 0.1-0.6 and lower for short-lived fish species such as Gulf Corvina (Myers et al., 1999;  
360 Grüss et al., 2014). Thus, the per-recruit model employing Schnute-Richards growth model  
361 predicts the Gulf Corvina stock to be in a much healthier state than the per-recruit models  
362 employing other growth models. The current YPR over  $YPR_{max}$  of Gulf Corvina predicted when  
363 using the Schnute-Richards growth model fit to raw data only (0.80) is also greater than the  
364 current YPR over  $YPR_{max}$  of Gulf Corvina predicted when using all the other growth models  
365 (0.70-0.74) (Figure 6B).

## 366 **Discussion**

367           This study illustrates the pitfalls of using statistical considerations alone when selecting a  
368 growth model for a vulnerable and highly-exploited species, due to the high likelihood of a  
369 biased distribution of samples. The combination of highly efficient, size-selective gear and high  
370 fishing effort have altered the age structure of the Gulf Corvina population (Ortiz et al., 2016),  
371 making sufficient representation of each size and age class difficult (Erisman et al., 2014). The  
372 influence of the lack of large and old fish in the dataset used for this study is clear, as Froese and  
373 Binohlan's (2000) empirical relationship predicted an  $L_{\infty}$  that was 89.95 – 275.09 mm greater  
374 than the  $L_{\infty}$  predicted by growth modeled fit to raw data. This predicted  $L_{\infty}$  from Froese and  
375 Binohlan's (2000) empirical relationship of 1006 mm was identical to the  $L_{\infty}$  estimated by  
376 Gherard et al. (2013) with the von Bertalanffy growth model. Growth patterns (Figures 4 and 5)  
377 and parameter estimates (Tables 1 and 3) were far less variable for models fit to data where  
378 sample size was equal at age, compared to models fit to raw data alone.

379           Unfortunately, heavy exploitation of Gulf Corvina makes the use of biased data in age  
380 and growth studies an unavoidable reality. Length data collected from the continuous monitoring  
381 of the fishery (Erisman et al., 2015; Ortiz et al., 2016) indicate that Gulf Corvina may be able to  
382 grow longer than their maximum reported length of 1013 mm and live longer than their  
383 maximum reported age of 9 years, but heavy exploitation (exploitation rate of 0.825 year<sup>-1</sup> for  
384 Gulf Corvina five years-old and older; Erisman et al. 2014) prevents them from doing so. Thus,  
385 despite our best efforts, we were unable to sufficiently represent large and old fish in our dataset.  
386 Further, while we made a concerted effort to sample small individuals, our data set would have  
387 been improved if we were able to collect more. This led to our decision to employ our simulation  
388 exercise to understand how the biases in our data affected our results. Similarly biased data have  
389 been the only data available for age and growth studies with Gulf Corvina, and previous studies

390 have taken markedly different approaches to dealing with its limitations. Gherard et al. (2013)  
391 chose to use the inflexible and widely comparable von Bertalanffy growth model while  
392 acknowledging the data's limitations and caveating results accordingly. Alternatively, Aragón-  
393 Noriega (2014) and Mendivil-Mendoza (2017) employed a multi-model approach that leaned  
394 exclusively on statistics. Their statistical procedures led to the selection of the flexible Schnute-  
395 Richards model to describe Gulf Corvina growth. Despite reporting different growth patterns  
396 depending on which dataset was used, Aragón-Noriega (2014) did not acknowledge the  
397 limitations of fishery-dependent data and concluded that Gulf Corvina grew in a biphasic pattern.

398         The same suite of models employed by Aragón-Noriega (2014) and Mendivil-Mendoza  
399 et al. (2017) were fit to our data, and statistical measures of fit similarly supported the Schnute-  
400 Richards model as the best model for Gulf Corvina. Further, a biphasic growth pattern was  
401 described by the model, as it did in Aragón-Noriega's (2014) study. However, our review of 24  
402 sciaenid growth studies indicated that only two (8%) studies used the Schnute-Richards model to  
403 describe sciaenid growth (Aragón-Noriega, 2014; Mendivil-Mendoza et al., 2017), of which only  
404 one described biphasic growth (Aragón-Noriega, 2014). The biological implausibility of this  
405 growth pattern was further supported by the distance between Froese and Binohlan's predicted  
406  $L_{\infty}$  and the  $L_{\infty}$  estimated by the Schnute-Richards model (1006 vs. 730.91 mm, i.e., a 275.09 mm  
407 difference). Finally, simulating an ideal sampling scenario where each age class was equally  
408 represented revealed that this biphasic growth pattern was due to bimodal distribution of samples  
409 and a lack of large, old fish. Both the parameter estimates and growth pattern changed  
410 substantially when simulated data was added to raw data so that sample size was equal for each  
411 age (Figure 5 and Table 3). The Schnute-Richards model is flexible by design, and is, therefore,  
412 not suited for use with datasets that do not sufficiently represent each size and age class. Thus,

413 by integrating the results of our statistical measures of fit, literature review, and simple indicators  
414 of biased data, we selected the von Bertalanffy growth model as the best model to represent Gulf  
415 Corvina growth.

416         The results of our study reinforce the well-established, but often forgotten, principle that  
417 each size and age class must be sufficiently represented for growth modelling to produce  
418 biologically reasonable results (Cailliet et al., 1986; Cailliet and Tanaka, 1990; Francis and  
419 Francis, 1992; Cailliet and Goldman, 2004). Ensuring sufficient representation may be difficult  
420 for highly-exploited fishes, as exploitation alters the population structure of fishes by  
421 preferentially selecting for large and old fish individuals (Berkeley et al., 2004; Mason, 1998).  
422 Similar challenges are faced when studying growth for vulnerable fishes or in data-poor  
423 fisheries, where there may not be resources available for extensive fishery-independent sampling  
424 or fish are scarce in general. Despite difficulty, ensuring sufficient representation of each size  
425 and age class should be a priority. The distinction between sampling to sufficiently represent  
426 each size and age class and sampling to represent population structure is an important one to  
427 make, as sampling to represent population structure should not be a goal of age and growth  
428 studies due to the bias created by the natural scarcity of large and old fish. As such, the simple  
429 simulation of an ideal sampling scenario with an equal number of samples at each age was not  
430 intended to represent the population structure of Gulf Corvina or to reflect the relative  
431 probability of obtaining samples of particular size and age classes in the real world.

432         Life-history parameters such as those estimated in growth models are influential in  
433 assessments for vulnerable and data-poor species (Fournier et al., 1990; Dulvy et al., 2004;  
434 Froese, 2004; Honey et al., 2010; Hordyk et al., 2016). These types of assessments rely on age-  
435 length data to determine vulnerability and overfishing, and problems emerge when all size and

436 age classes are not sufficiently represented. The average maximum length ( $L_{\infty}$ ) is underestimated  
437 and the growth rate ( $K$ ) is overestimated when large and old fish are absent. Accordingly, a short  
438 generation time and lower levels of mortality are estimated, conferring more resilience to  
439 exploitation that the population possesses (Campana, 2001; Goldman et al., 2012; Harry, 2017).  
440 This idea was demonstrated with simulations with a per-recruit model, where the per recruit  
441 model using the Schnute-Richards growth model fit to raw data (which had the lowest  $L_{\infty}$  in the  
442 present study) predicted Gulf Corvina reproductive capacity to be in a much healthier state than  
443 the per recruit models using other growth models (Fig. 6A). This false resiliency makes fishery  
444 management measures less effective (Campana, 2001; Cailliet and Andrews, 2008; Goldman et  
445 al., 2012), and may be present in Gulf Corvina assessments, as length and age truncation in the  
446 catch has increased progressively since biological monitoring of the fishery began in 1997  
447 (Erisman et al., 2014). Given this length and age truncation, published growth models reported  
448 for this species may not be representing biology but rather the influence of exploitation.

449         Our results have implications for estimating growth within a stock assessment. Piner  
450 (2016) documented an increase in precision in parameter estimates, ability to account for  
451 selectivity, and ability to incorporate multiple data sources when growth was estimated within a  
452 stock assessment. However, the influence of sample distribution on model output should be  
453 carefully examined if this approach is to be taken. So-called haphazard sampling strategies that  
454 ensure that all age and size classes are represented (e.g. Wells et al., 2013) make growth  
455 estimation within a stock assessment model more difficult, though are necessary if the density of  
456 samples at a particular age is driving model fit or preventing accurate estimation of  $L_{\infty}$ . Precision  
457 may be improved, but care must be taken to ensure that precision is being improved around  
458 biological reality.

459 We found that Gulf Corvina exhibit a high degree of variation in length-at-age, a pattern  
460 that is common among coastal fishes in the Gulf of California and other regions of the eastern  
461 Pacific characterized by significant annual variations in precipitation, ocean temperatures, and  
462 productivity in response to climate forcing that are known to influence growth rates in marine  
463 fishes (e.g., El Niño Southern Oscillation, ENSO; (Wells et al., 2006; Williams et al., 2007;  
464 Black, 2009). Specifically, growth rate is higher in Gulf Corvina during El Niño years, mainly in  
465 association with increased sea surface temperatures in the region (Reed, 2017). ENSO has been  
466 shown to affect fish growth in other areas, such as the waters of New Caledonia (Lehodey and  
467 Grandperrin, 1996), New Zealand (Gillanders et al., 2012), and north-western Australia (Ong et  
468 al., 2016, 2015). As the present study was conducted over multiple years, it is reasonable to  
469 assume that variations in ENSO over the study period (i.e., a succession of El Niño/La Niña  
470 events) could have affected the fish harvested for this study, explaining the observed variation in  
471 length-at-age. These effects may affect estimates of growth derived with growth models, but in  
472 order to identify these effects with confidence, complete sampling must be conducted with this  
473 purpose in mind. Another explanation for length-at-age variation could be measurement error  
474 (Neilson, 1992; Campana, 2001). Most of the fish in this study were harvested during their  
475 spawning season, which is around the time when they form new annuli. Therefore, it would be  
476 reasonable to conservatively assume that the precision of this study is more or less one year of  
477 age. However, we have high confidence in our reading of these otoliths, as annuli are clearly  
478 seen with minimal preparation (Figure 1) and we excluded any samples for which there was a  
479 disagreement between readers.

480 Assessing the biological feasibility of growth model output, here accomplished with the  
481 use of simple indicators of biased data and literature review, is crucial for age and growth

482 studies. Statistical measures of fit alone may not lead to the selection of a model that represents  
483 biological reality (Wang et al., 1995; Cailliet et al., 2006; Araya and Cubillos, 2006). By  
484 integrating measures of statistical fit with results from the simple indicators and literature review,  
485 we concluded that the von Bertalanffy growth model best described the growth of Gulf Corvina  
486 and was most appropriate for the quality of available data. Though the Schnute-Richards model  
487 had the best statistical fit, it was not biologically reasonable, comparable between studies, or  
488 robust to biased data. Simple indicators such as those described in this paper should be used to  
489 reveal biases in data, and the use of flexible growth models such as the Schnute-Richards model  
490 to represent the growth of Gulf Corvina and similarly exploited fishes should be halted if biases  
491 are not accounted for.

## 492 **Conclusions**

493 Sample distribution influences growth model output, especially for flexible, statistically-driven  
494 models. Data used in growth modelling studies should be thoroughly examined for bias, as  
495 statistical measures of fit are insufficient for selecting a model that reflects biological reality.  
496 Reflecting biological reality in growth models is critical for vulnerable fish and in data-poor  
497 fisheries, where age-length data are integral to assessing vulnerability and overfishing. In this  
498 case, the von Bertalanffy growth model represented biological reality best among the models  
499 tested. We warn against the production and use of growth models without recognizing biases in  
500 data given the serious implications for stock assessments and the management of vulnerable fish  
501 populations and data-poor fisheries.

## 502 **Acknowledgements**

503 We acknowledge the Gulf of California Marine Program at Scripps Institution of Oceanography,  
504 project participants from El Centro para la Biodiversidad Marina y la Conservación and the  
505 fishers of the upper Gulf of California, Mexico for their contributions to data collection efforts.  
506 We thank Gregor Cailliet for his pre-submission comments on the manuscript, Chip Cotton,  
507 Brian Moe, and Grant Scholten for their feedback during data analysis, and Tyler Loughran for  
508 her help with formatting figures.

## Figure 1

Transverse section of a sagittal otolith from a five-year old Gulf Corvina

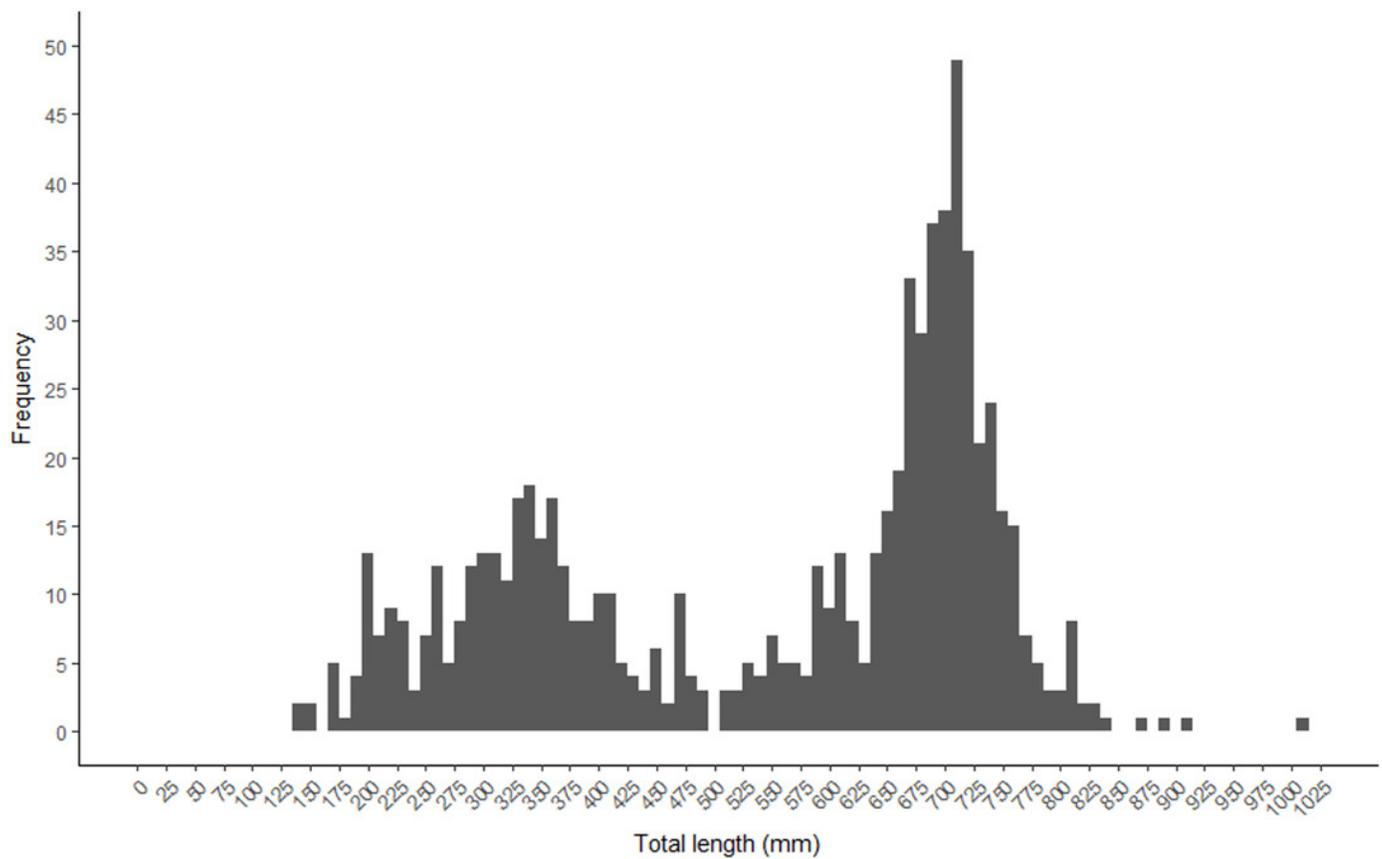

Annuli are numbered and marked by white rectangles. Transmitted light under a Zeiss Stemi 2000-C microscope with a Zeiss Axiocam 105 color camera at 6.25x total magnification was used to count the alternating opaque and translucent growth zones that define an annulus.

## Figure 2

Length frequency of Gulf Corvina from raw data represented in 10 mm bins

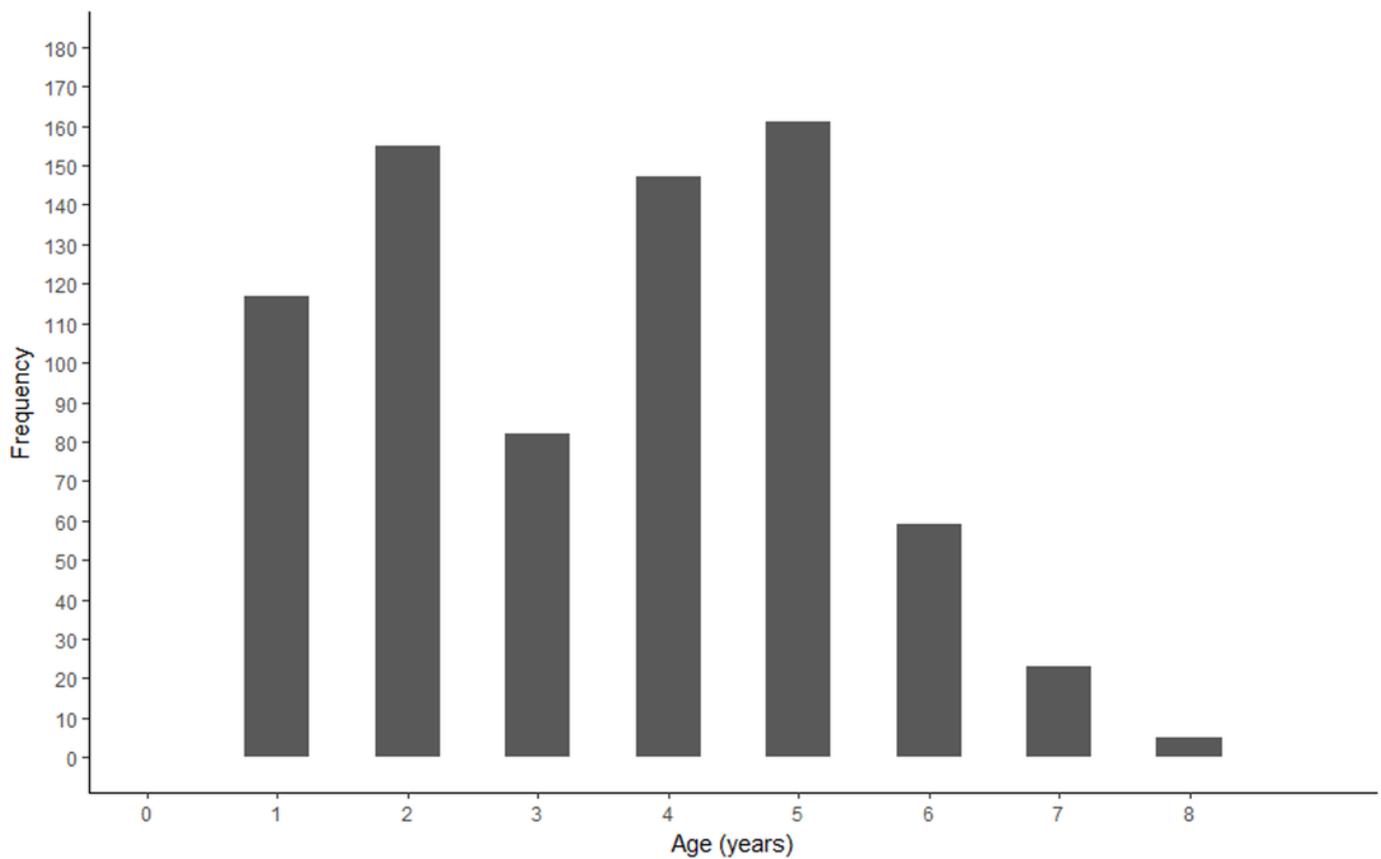

A bimodal distribution is observed, with the first consisting of Gulf Corvina caught as bycatch, and the second largely consisting of fish from the directed fishery. Few fish larger than 750 mm are present in this dataset.

## Figure 3

Age frequency of Gulf Corvina from raw data

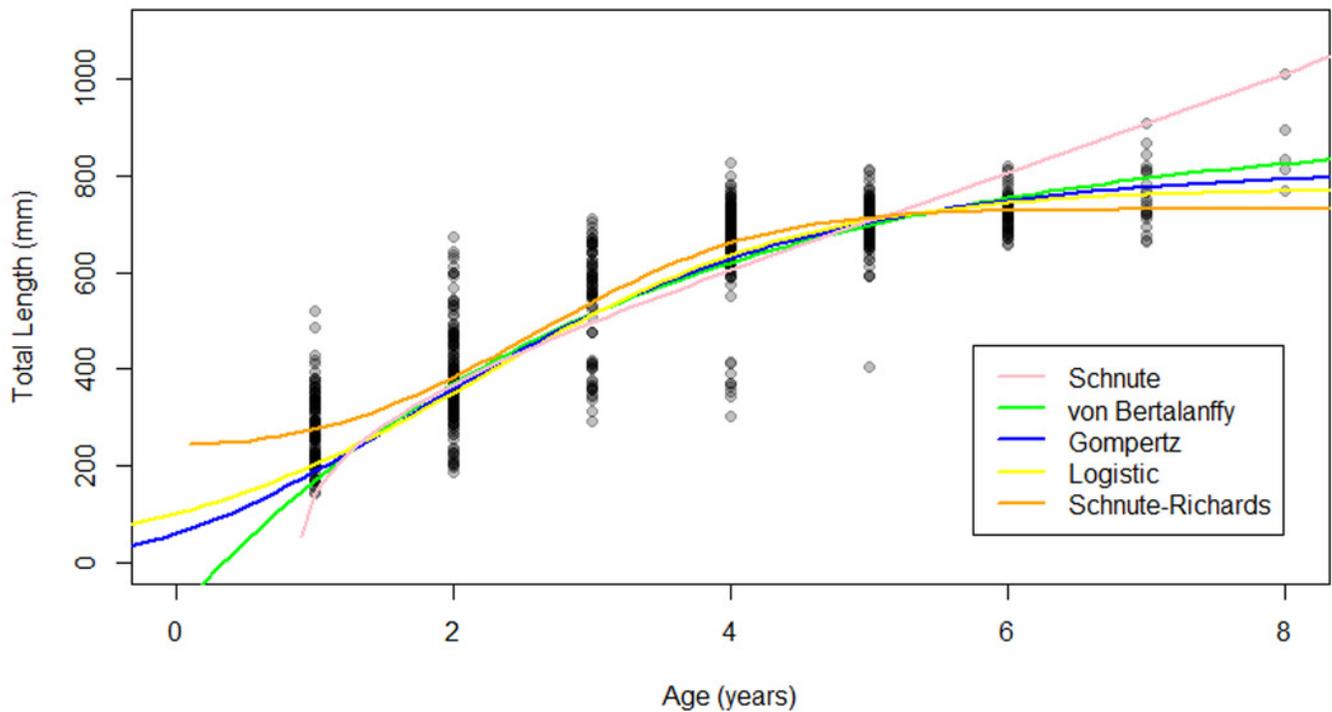

A bimodal distribution is observed, with the first consisting of Gulf Corvina caught as bycatch, and the second largely consisting of fish from the directed fishery. Few fish older than age 6 are present in this dataset.

## Figure 4

Growth models fit to raw age-length data for Gulf Corvina

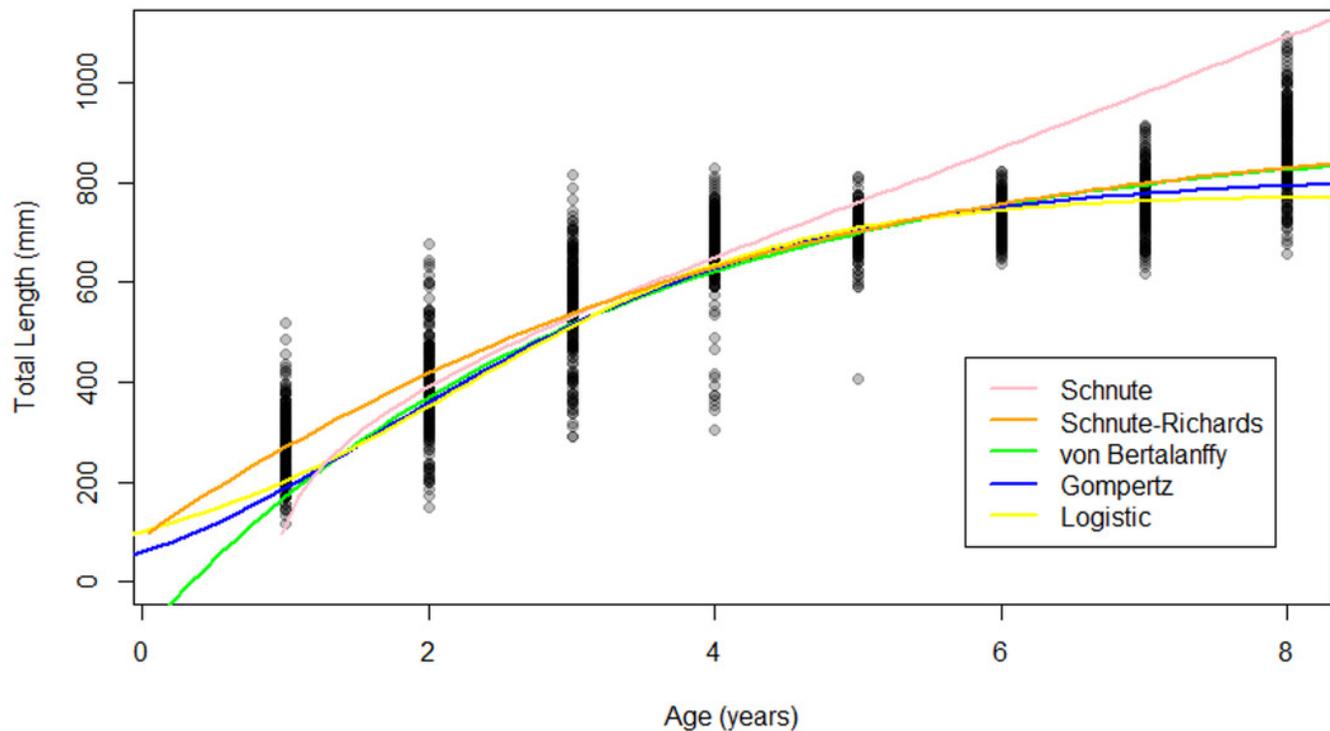

The Gompertz, Logistic, and von Bertalanffy models yield asymptotic growth patterns. However, the Schnute-Richards model describes bi-phasic growth, and the Schnute model describes near-linear growth after the first 1.5 years of life. Differences in modelled size at age are most pronounced at the beginning and end of life, where samples are most scarce.

## Figure 5

Growth models fit to raw Gulf Corvina age-length data bolstered by simulated values

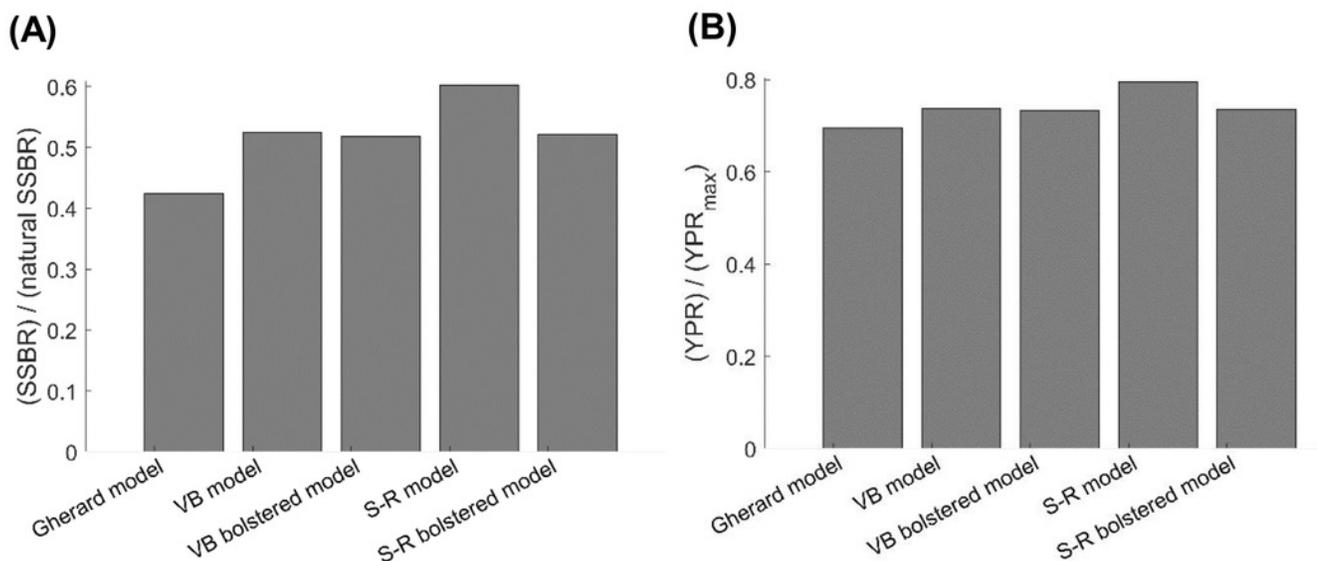

All models except for the Schnute describe asymptotic growth, and only show slight differences in modelled size at age. Differences in modelled size at age are most pronounced at the beginning and end of life.

## Figure 6

Consequences of using different growth models on (A) the current female SSBR over natural SSBR and (B) current YPR over  $YPR_{max}$  of Gulf Corvina (*Cynoscion othonopterus*)

SSBR = spawning-stock-biomass-per-recruit. YPR = yield-per-recruit. Gherard model = von Bertalanffy model developed in Gherard et al. (2013). VB model = von Bertalanffy model fit to raw data in the present study. VB bolstered model = von Bertalanffy model fit to raw data bolstered by simulation values in this study. S-R model = Schnute-Richards model fit to raw data in the present study. S-R bolstered model = Schnute-Richards model fit to raw data bolstered by simulation values in this study.

**Table 1** (on next page)

Parameter estimates for growth models fit to raw age-length data for Gulf Corvina

Estimates of  $L_{\infty}$  are variable, but not as variable as those reported in previous multi-model studies of Gulf Corvina growth (Aragón-Noriega, 2014; Mendivil-Mendoza, 2017). Confidence intervals around parameter estimates may be found in the supplemental information.

| Model name       | Model equation when fit to raw data   |
|------------------|---|
| von Bertalanffy  | $L(t) = 916.05[1 - e^{-0.28(t - (-0.17))}]$   |
| Gompertz         | $L(t) = 820.64e^{(-\frac{1}{0.51})e^{-0.51(t - 1.29)}}$   |
| Logistic         | $L(t) = 778.88[1 + e^{-0.76(t - 1.92)}]^{-1}$   |
| Schnute          | $L(t) = \left[ 141^{-0.33} + (1013^{-0.33} - 141^{-0.33}) \frac{1 - e^{-3.36(t-1)}}{1 - e^{-3.36(8-1)}} \right]^{1/0.33}$ |
| Schnute-Richards | $L(t) = 730.91 \left( 1 + (-0.003)e^{-(0.12)t^{2.18}} \right)^{1/0.003}$  |

**Table 2** (on next page)

Statistical measures of fit for growth models fit to raw age-length data for Gulf Corvina

The Schnute-Richards model fits the data best according to AICc and BIC values, but is only marginally better than the logistic, Gompertz, and von Bertalanffy models. Note: K indicates the number of parameters in each model.

\*3 parameters were estimated by nonlinear least squares, but 4 additional parameters were manually inputted (maximum and minimum ages and lengths) for the Schnute model.

**Table 3** (on next page)

Parameter estimates for growth models fit to raw Gulf Corvina age-length data bolstered by simulated values

Compared to parameter estimates for models fit to raw data alone, estimates of  $L_{\infty}$  are less variable and generally increase. These estimates are closer to the  $L_{\infty}$  of 1006 predicted by Froese and Binohlan's (2000) empirical relationship between  $L_{\infty}$  and the longest fish in a dataset

| Model            | Model fit to data bolstered by simulated values   |
|------------------|---|
| von Bertalanffy  | $L(t) = 951.30[1 - e^{-0.25(t - (-0.33))}]$   |
| Gompertz         | $L(t) = 870.48e^{(-\frac{1}{0.62})e^{-0.62(t - 1.34)}}$   |
| Logistic         | $L(t) = 834.34[1 + e^{-0.62(t - 2.10)}]^{-1}$   |
| Schnute          | $L(t) = \left[ 141^{-0.78} + (1013^{-0.78} - 141^{-0.78}) \frac{1 - e^{-6.06(t-1)}}{1 - e^{-6.06(8-1)}} \right]^{1/0.78}$ |
| Schnute-Richards | $L(t) = 938.80 \left( 1 + (-0.0046)e^{-(0.67)t^{0.72}} \right)^{1/0.0019}$  |

**Table 4**(on next page)

Statistical measures of fit for growth models fit to raw Gulf Corvina age-length data bolstered by simulated values

The von Bertalanffy growth model describes the data best according to AICc and BIC values. However, AICc weighting indicates that the Schnute- Richards and Gompertz models have nearly equivalent fits. Note: K indicates the number of parameters in each model.

\*3 parameters were estimated by nonlinear least squares, but 4 additional parameters were manually inputted (maximum and minimum ages and lengths) for the Schnute model.

**Table 5** (on next page)

Models used to describe growth in sciaenid fishes similar to and including the Gulf Corvina

A review of 24 sciaenid growth studies indicates that sciaenid growth is most commonly modelled by the von Bertalanffy growth model (20 studies; 83 % of studies reviewed).

| Growth model selected | Genus and species   | References  |
