Fine scale sexual segregation outside of the mating season is common in sexually dimorphic and polygamous species, particularly in ungulates. A number of hypotheses predict sexual segregation but these are often contradictory with no agreement as to a common cause, perhaps because they are species specific. We explicitly tested three of these hypotheses which are commonly linked by a dependence on sexual dimorphism for animals which exhibit fine-scale sexual segregation; the Predation Risk Hypothesis, the Forage Selection Hypothesis, and the Activity Budget Hypothesis, in a single system the pheasant, *Phasianus colchicus*; a large, sedentary bird that is predominantly terrestrial and therefore analogous to ungulates rather than many avian species which sexually segregate. Over four years we reared 2400 individually tagged pheasants from one day old and after a period of 8-10 weeks we released them into the wild. We then followed the birds for 7 months, during the period that they sexually segregate, determined their fate and collected behavioural and morphological measures pertinent to the hypotheses. Pheasants are sexually dimorphic during the entire period that they sexually segregate in the wild; males are larger than females in both body size and gut measurements. However, this did not influence predation risk and predation rates (as predicted by the Predation Risk Hypothesis), diet choice (as predicted by the Forage Selection Hypothesis), or the amount of time spent foraging, resting or walking (as predicted by the Activity Budget Hypothesis). We conclude that adult sexual size dimorphism is not responsible for sexual segregation in the pheasant in the wild. Instead, we consider that segregation may be mediated by other, perhaps social, factors. We highlight the importance of studies on a wide range of taxa to help further the knowledge of sexual segregation.

24 **Abstract**

25 Fine scale sexual segregation outside of the mating season is common in sexually
26 dimorphic and polygamous species, particularly in ungulates. A number of hypotheses predict
27 sexual segregation but these are often contradictory with no agreement as to a common cause,
28 perhaps because they are species specific.

29

30 We explicitly tested three of these hypotheses which are commonly linked by a
31 dependence on sexual dimorphism for animals which exhibit fine-scale sexual segregation; the
32 Predation Risk Hypothesis, the Forage Selection Hypothesis, and the Activity Budget
33 Hypothesis, in a single system the pheasant, *Phasianus colchicus*; a large, sedentary bird that is
34 predominantly terrestrial and therefore analogous to ungulates rather than many avian species
35 which sexually segregate.

36

37 Over four years we reared 2400 individually tagged pheasants from one day old and after
38 a period of 8-10 weeks we released them into the wild. We then followed the birds for 7 months,
39 during the period that they sexually segregate, determined their fate and collected behavioural
40 and morphological measures pertinent to the hypotheses.

41

42 Pheasants are sexually dimorphic during the entire period that they sexually segregate in
43 the wild; males are larger than females in both body size and gut measurements. However, this
44 did not influence predation risk and predation rates (as predicted by the Predation Risk
45 Hypothesis), diet choice (as predicted by the Forage Selection Hypothesis), or the amount of
46 time spent foraging, resting or walking (as predicted by the Activity Budget Hypothesis).

47

48 We conclude that adult sexual size dimorphism is not responsible for sexual segregation
49 in the pheasant in the wild. Instead, we consider that segregation may be mediated by other,
50 perhaps social, factors. We highlight the importance of studies on a wide range of taxa to help
51 further the knowledge of sexual segregation.

52

53 Introduction

54 Sexual segregation, in which females and males are separated in time and/or space outside of the
55 mating season, is common in a variety of birds, mammals, fish and reptiles (Bleich et al. 1997;
56 Ruckstuhl & Neuhaus 2005; Ruckstuhl & Neuhaus 2000). Fine scale sexual segregation, in
57 which segregation occurs within a small area, is particularly prevalent in species with strong
58 sexual dimorphism (Ruckstuhl & Neuhaus 2002) and those with polygynous mating systems
59 (Clutton-Brock 1989). However, there is little consensus about the underlying factors driving
60 sexual segregation (Alves et al. 2013; Bonenfant et al. 2007).

61

62 There are four main, but non-exclusive, hypotheses proposed to explain why sexual
63 segregation occurs in polygynous populations that are commonly linked by a dependence on
64 sexual (size) dimorphism (Bon & Campan 1996; Bowyer 2004; Ruckstuhl & Neuhaus 2005).
65 The first, the Predation Risk Hypothesis (PRH), or Reproductive Strategy Hypothesis, postulates
66 that sexual segregation results from each sex investing differentially in strategies to maximise
67 their own reproductive success (Main & Coblentz 1996). Females, perhaps accompanied by
68 dependent and vulnerable young, avoid higher predation risks and forage in places or at times
69 that offer lower nutrient intake (Corti & Shackleton 2002; Main & Coblentz 1996). In contrast,
70 males may opt to maximize their competitive advantage by investing in growth and therefore
71 exploit nutrient rich habitats despite the increased risk of predation (Clutton-Brock et al. 1982;
72 Prins 1989). The second, the Forage Selection Hypothesis (FSH), or Sexual Dimorphism Body-
73 size Hypothesis (Main 1996), predicts that allometric differences in body size, bite size, energy
74 requirements and/or fibre digestion between the sexes can lead to differences in diet selection
75 and habitat choice (Barboza & Bowyer 2000; Demment 1982; Main & Coblentz 1996).
76 Individuals with a smaller gut system are less able to digest lower quality food items and are
77 predicted to feed on higher quality diets than larger conspecifics (Barboza & Bowyer 2001;
78 Demment & Van Soest 1985). The third, the Activity Budget Hypothesis states that body size
79 dimorphism promotes differences in activity budgets and synchrony of these behaviours results
80 in aggregation of the sexes (Conradt 1998; Ruckstuhl & Neuhaus 2002; Ruckstuhl & Neuhaus
81 2000). Here, energetic requirements and digestive abilities predict that the smaller sex will spend
82 more time foraging and less time resting and digesting than the larger sex (Ruckstuhl 1999;
83 Ruckstuhl 1998), such that females will congregate to engage in foraging together while males

84 rest in areas with low risk of predation. A fourth, and much less studied hypothesis is the
85 Weather Sensitivity Hypothesis which suggests that animals could differ in their weather
86 sensitivity (e.g. Young & Isbell 1991), where larger individuals, often males, suffer higher
87 absolute heat loss and therefore opt for warmer habitats often at the expense of foraging
88 availability (Conradt et al. 2001)

89

90 There is little consensus as to what are the driving mechanisms underpinning sexual
91 segregation (Conradt & Roper 2000; Ruckstuhl et al. 2006). Typically, studies are unable to
92 tease apart which hypothesis best predicts why species segregate, often suggesting that multiple
93 hypothesis could be the cause (Alves et al. 2013; Bonenfant et al. 2007; Loe et al. 2006). One
94 reason for this could be that much of the research concentrates on ungulates (Alves et al. 2013;
95 Bon & Campan 1996; Bowyer & Kie 2004), in particular ruminants (Bowyer & Kie 2004) in
96 systems that are notoriously difficult to study in the wild (Michelena et al. 2004). It is not always
97 feasible in such free-ranging mammalian systems to collect the physiological and behavioural
98 data necessary to explicitly separate and test these competing hypotheses. Furthermore, in some
99 study locations, their natural predators have disappeared, rendering it difficult to explore the
100 effects of predation risk. Finally, many species that have been studied are dietary specialists,
101 meaning that variations in diet quality may chiefly depend on differences between particular
102 plants, even those of the same species, and thus dietary intake is difficult to determine accurately
103 without measuring the nutrient quality of each mouthful (Dove & Mayes 1996).

104

105 The pheasant, *Phasianus colchicus*, provides a novel, alternative system to ungulates to
106 try to tease apart hypotheses of segregation based on sexual size dimorphism. Many avian
107 species sexually segregate (e.g. northern giant petrels (*Macronectes halli*) (González-Solís et al.
108 2000) and Great bustards (*Otis tarda*) (Palacín et al. 2009)), however it is often attributed to
109 differential settlement of the sexes in discrete habitats, often over large distances, and is
110 primarily restricted to difference in migration behaviours or broad differences in habitat use
111 (Catry et al. 2006). Pheasants, however, exhibit a pattern of fine scale sexual segregation similar
112 to the regularly studied ungulate, in that they segregate, outside of the mating season, within the
113 same area as each other (Hill & Ridley 1987). Specifically, during the late autumn and winter,
114 females aggregate in same sex groups whereas males avoid both males and females (Whiteside et

115 al. 2018). Such segregation persists until early March (Hill & Ridley 1987; Hill & Robertson
116 1988) when harems of females visit and eventually join territory-holding males, which likely
117 reduces their harassment by other males (Ridley and Hill 1987) and allows females to decrease
118 their vigilance levels and so increase time spent foraging (Whiteside et al. 2016a), until they
119 independently start to nest and incubate their eggs (Taber 1949). Pheasants become sexually
120 dimorphic by three weeks of age (Whiteside et al. 2017), and chicks in captivity (<8 weeks old)
121 exhibit preference for their own sex (Whiteside et al. 2017). As adults, males have highly
122 conspicuous plumage and are 40% larger than the cryptic females (Witzell 1991). Between
123 October and February, before the breeding season, released first year pheasants show increasing
124 levels of segregation (Whiteside et al. 2018). Therefore, pheasants present a system that is
125 analogous to the currently studied ungulates, yet being distantly related this may offer more
126 general insights as to how size-dimorphism may influence sexual segregation for species with
127 fine scale sexual segregation.

128

129 Mechanisms that drive sexual segregation of pheasants are poorly understood. In the
130 wild, sexual segregation of adults was observed at both a spatial and temporal scale that could
131 not be explained by crude measures of habitat structure, although the homogenous nature of the
132 study and reliance on data from supplementary feeding sites meant that fine scale differences in
133 habitat structure may have not been captured (Whiteside et al. 2018). During early life when the
134 sexes differ little in their size, juvenile pheasants reared in captivity in an environment that
135 controlled for habitat selection and diet, albeit under unnaturally high numbers but in a sex ratio
136 analogous to that observed in the wild, exhibited strong preferences for same-sex individuals in
137 binary choices which may drive segregation (Whiteside et al. 2017). It was suggested that at this
138 stage, females aggregate with other females in response to male aggression. When adults, body-
139 size dimorphism is more pronounced and the habitat is more heterogeneous and consequently we
140 may find other factors may influence sexual segregation. We excluded the possibility that
141 segregation in wild-living pheasants arises because of the Weather Sensitivity Hypothesis.
142 Pheasants typically spend the majority of their time in hedgerows (Hill & Robertson 1988), a
143 place that offers protection from the weather but also a site with a high abundance of natural
144 forage (e.g. insects, leaves, berries, wild fruit and nuts Lachlan & Bray 1973). This violates a
145 major assumption of the Weather Sensitivity Hypothesis in that a habitat should offer either

146 shelter or good foraging opportunity, not both. Often game-keepers will provide a designated
147 cover crop that is designed to provide both (Hill & Robertson 1988). Therefore, in this study we
148 tested the remaining three main hypotheses for sexual segregation that relate to sexual (size)
149 dimorphism in free-living adult pheasants.

150

151 Firstly, pheasants are at risk from terrestrial predators, such as the fox, *Vulpes vulpes*
152 (Hessler et al. 1970; Krauss et al. 1987), and aerial predators, such as goshawks, *Accipiter*
153 *gentilis*, sparrow hawks, *Accipiter nicus*, and buzzards, *Buteo buteo*, (Kenward et al. 2001;
154 Kenward et al. 1981) producing high mortality rates of up to 80% in the first month after release
155 into the wild (Hessler et al. 1970). Sexual segregation occurs prior to the first breeding season
156 (Hill & Ridley 1987; Whiteside et al. 2018), and this therefore removes the possibility that
157 females caring for young are avoiding particularly risky sites or times. However, males may still
158 opt for a riskier foraging and movement strategy if there is a benefit for their growth. Therefore,
159 if the Predation Risk Hypothesis influences segregation then we expect that predation risk (in
160 terms of willingness to approach an area where predators have recently visited) and consequently
161 predation rates will differ between sexes.

162

163 Secondly, adult pheasants are dietary generalists (Hoodless et al. 2001) and dietary
164 choices can be assayed post-mortem from food that is well preserved and identifiable in the crop
165 of birds that have been shot during recreational hunting (Whiteside et al. 2015). Post-mortem
166 analyses of these shot birds also allows for the measurements of gut morphometrics. Both these
167 factors permit explicit testing of the Forage Selection Hypothesis. While gut size is likely to co-
168 vary with body size, with larger males possessing larger guts, allometric differences are
169 meaningful from a nutritional point of view as larger guts are more effective digesters and
170 absorbers of low quality diet (Barboza & Bowyer 2000). In addition, body size dimorphisms may
171 correspond to differences in food processing efficiency via bite size (Illius & Gordon 1987) or
172 grinding capacity in the gizzard (Putala & Hissa 1995). If the Forage Selection Hypothesis
173 influences segregation then we expect that the larger sex (males in the case of pheasants) will
174 have larger guts and heavier gizzards, and this will be matched by a difference in diet
175 corresponding to spatial or temporal segregation.

176

177 Thirdly, adult pheasants are large, sedentary, diurnal and sexually distinct. Consequently,
178 their behaviours in the wild can be easily observed and their activity recorded. Differences in
179 behaviour between the sexes have been observed during the breeding season (Whiteside,
180 Langley et al 2016), however little is known about behavioural differences outside the breeding
181 season during the period when pheasants sexually segregate. If the Activity Budget Hypothesis
182 operates then we expect that during the periods of sexual segregation male and female pheasants
183 will differ in their behaviour, specifically state behaviours known to influence sexual segregation
184 in ungulates (e.g. foraging, locomotion or resting time (Ruckstuhl 1998)). Male pheasant chicks
185 in captivity were more aggressive than females and was a potential mechanisms driving
186 segregation (Whiteside et al. 2017). However, pheasants in the wild exhibit little aggression
187 during the periods that they sexually segregate, with male-male aggression rising from the start
188 of the breeding season and peaking mid-breeding season (Ridley 1983).

189

190 To tease apart these hypotheses we draw on two populations of individually identifiable
191 pheasants that were reared in captivity, had their morphometrics taken and then released into the
192 wild (see Table 1 for a description of each population and what was measured). The first
193 population was released into an environment that did not have predator control or recreational
194 shooting. Although initial release density was unnaturally high (~200 birds in a 0.5 Ha release
195 pen), after one month birds had dispersed across the study site. At this point the population density was
196 ~40 birds/km² which matched those of wild populations, falling within the density (16-54 birds/km²) for
197 wild pheasants living in managed farmland in Austria and the density (0.6-64 birds/km²) for pheasants in
198 their native range in China (Li 1996 in Johnsgard 1999). Crucially, within one month of release this
199 population showed clear sexual segregation which became pronounced as the year progressed
200 (see Whiteside et al. 2018). Releasing on sites without either predator control or recreational
201 hunting allowed us to measure natural predation rates. By using a system of motion sensitive
202 camera traps at feeding sites we were able to determine: 1) if pheasants avoid areas where foxes
203 had been present: and 2) if sexes differ in their willingness to enter an area where a fox had
204 previously been seen (essential for the PRH). The second population were birds that were reared
205 in captivity and released into the wild in large numbers (~ 350 birds in a 0.5 Ha release pen) as
206 part of a restocking programme. However, these birds were released on a much larger site and
207 within a few weeks of birds dispersing resulted in much lower density over the entire estate. On

208 this site there was managed predator control and the birds were subject to hunting. Birds released
209 using this method still show patterns of sexual segregation (Hill & Ridley 1987) similar to that
210 observed in pheasants released at lower density. Releasing onto a site that has recreational
211 hunting allows for us to conduct post mortem analysis that: 1) allows us to determine the extent
212 of sexual dimorphism in body size (essential for PRH, FSH and ABH) and in gut morphology
213 (essential for FSH); and 2) acts as a dietary snapshot, whereby crop sample analyses allows us to
214 determine diet (essential for FSH). Observing behaviour of pheasants during this period allows
215 us to determine activity budgets (essential for ABH).

216

217 **Material and methods**

218

219 *Rearing*

220

221 In May 2012 and 2013 we reared 1800 pheasants (900 / year) from one day old as part of
222 a long-term study to determine how early rearing conditions can influence development and post
223 release mortality. Chicks were placed in houses of 30 individuals with an equal sex ratio and
224 each house was randomly allocated a rearing treatment. While not relevant to this study, the
225 treatments included differences in supplemented diet in 2012 (see Table 1 and Whiteside et al.
226 2015) and access to perches in 2013 (see Table 1 and Whiteside et al. 2016b) as well as controls.
227 In 2014 and 2015 we reared a further 400 pheasants (200 / year) from one day old and housed
228 them in groups of 50 under identical conditions (see Table 1). Each year the birds were housed
229 for two weeks in heated sheds (2012/13: 1.3 m x 1.3 m; 2014/15: 2 m x 2 m) and were then
230 given access to an additional open grass run (2012/13 = 1.3 m x 6.8 m; 2014/15: 4 m x 12 m)
231 until release. All chicks were provided with age specific commercial chick crumbs (Sportsman
232 Game Feeds) *ad lib* and in excess. Water was provided *ad lib*. In all four years, birds were
233 marked with patagial wing tags (Roxan Ltd, Selkirk, UK) for identification with additional white
234 PVC wing tags (25mm x75 mm) with individually unique identifying numbers which could be
235 viewed from several tens of meters away.

236

237 *Release into the wild*

238

239 Following rearing, birds were randomly mixed from across different housing groups and
240 placed into open topped pens. Release pens typically consisted of wire mesh fences ~2 m high
241 enclosing an extensive area of woodland (GWCT 1991). In these pens birds were provided with
242 food and water *ad lib*. Birds could disperse from these pens and were free to roam and mix with
243 other released, as well as resident, pheasants. In 2012 and 2013 when birds were approximately
244 seven weeks old we released them onto the Middleton Estate, Hampshire, UK (51°18'N, 1°4'W).
245 The estate, predominantly arable, hosts a game shoot and employs two game keepers to manage
246 the released pheasants through habitat management, providing supplementary food, and
247 controlling predator numbers. Between October and February birds were shot as part of a
248 recreational shoot. In 2014 and 2015 when birds were ten weeks old they were released at North
249 Wyke Farm, Devon (50°77'N, 3°9'W). This site is grazed by cattle and sheep and no game
250 shooting or predator control occurred there. Forty feeders, filled with wheat, were placed within
251 the pen (n = 4) and in the surrounding countryside (n = 36) at a density of 0.16 per hectare. In
252 2014, each feeder was continuously monitored with Bushnell® Trophy motion activated
253 cameras. All animals that visited a feeder and its surrounding area were photographed and the
254 images were then viewed manually to record the time that pheasants and foxes visited the feeder
255 site. Individual pheasants could be identified from their wing tag numbers.

256

257 *Body size dimorphism*

258

259 We recorded the mass (Slater Super Samson spring balance – precision 5 g) and tarsus
260 length (precision 1 mm) of all birds upon release into the wild and for birds released in 2012 and
261 2013 we scored the same measures within four hours of them being shot.

262

263 For the released populations we used a General Linear Mixed Model (GLMM) to identify
264 whether males differed from females in their mass and tarsus length with rearing treatment and
265 sex as fixed factors and the rearing house as a random factor, with all two way interactions
266 included (Table 2). In 2014 and 2015 all birds were reared under identical conditions and
267 therefore rearing treatment was not included in the model. For birds shot in 2012 and 2013 a
268 General Linear Model (GLM) was used to ask if sexes differed in mass and tarsus length as

269 adults. The bird's age when shot, its rearing treatment and all two way interactions were included
270 in the GLM (Table 2).

271

272

273 *A test for the Predation Risk Hypothesis: First appearance at a feeder after the presence of a fox*

274

275 We recorded every sighting of a fox and pheasant at each of our feeder sites during
276 December 2014 and January 2015 using the motion camera traps. In order to test whether the
277 presence of foxes at feeders was an indicator of a risky environment that pheasants attended to,
278 we asked whether birds took longer to return to feeders after a fox had been there compared to
279 the time it took them to appear at a feeder after a time-matched control point the previous day.
280 We excluded instances where there were low visitation rates at a feeder, indicated by long
281 periods (>420 mins) between the time-matched control point and the first pheasant appearing.
282 This cut-off point was meaningful and discrete (Figure 1). This left a subset of the previous data
283 including 110 cases. We used a t-test to ask if pheasants took longer to approach a feeder if it had
284 been visited by a fox compared a time matched control point the previous day. We then looked at
285 each appearance of a fox and recorded the sex of the next pheasant to enter the same feeder
286 within a subsequent 30 minutes. We used a binomial test to determine if sexes differed in their
287 likelihood of approaching a feeder following a fox visit.

288

289 *A test for the Predation Risk Hypothesis: Do predation rates differ with sex*

290

291 In 2012 and 2013 we conducted searches of areas surrounding the release site to retrieve
292 birds that had been killed by predators. Searches were conducted daily from August-October and
293 then again in February. During the hunting season (late October to February) the area was visited
294 less frequently but more methodically by beaters who were engaged in driving the game to the
295 waiting hunters. They were informed of the project and searched for carcasses and tags as they
296 walked through the site. In 2015 we collected birds that had been killed by a predator by
297 searching the release site and surrounding areas for carcasses, locating these either directly or
298 guided by radio tags placed on 50 birds. In 2014 we did not conduct detailed searches for

299 carcasses. A binomial test was used to test whether predation numbers differed between sexes
300 with the expected outcome based on the released sex ratio.

301

302

303 *A test for Forage Selection Hypothesis: Measuring gut morphology*

304

305 We collected linear gut measures (oesophagus, intestine, colon and ceca) and gut masses
306 (oesophagus, intestine, crop, gizzard and ceca; for methods see Leopold 1953) of 186 birds shot
307 in 2012. Ceca length and ceca mass were calculated as the average for both ceca. Gizzard
308 volume was measured as the height multiplied by width. We used a GLM to test whether gut
309 morphologies differed with sex. Since rearing treatment can influence gut morphology
310 (Whiteside et al. 2015) we included the rearing treatment and the age at which the bird was shot
311 as fixed factors (Table 2).

312

313 *A test for Forage Selection Hypothesis: Measuring crop contents in the wild*

314

315 In 2012, we removed the crops of 159 shot birds and measured the mass before and after
316 removal of its contents. Measures were transformed using the $\sqrt{(x)}$ transformation to meet
317 assumptions of normality and then a GLM was used to test if mass of crop content differed
318 between males and females. In 2013, we emptied the crops of 168 shot birds and quantified their
319 contents. We used a GLM to ask whether males differed from females in the number of different
320 food items discovered in their crops. Diet availability will change depending on when the bird is
321 shot and diet choice is influenced by rearing treatment (Whiteside et al. 2015) therefore in both
322 GLMs we included rearing treatment and the age of the bird when it was shot in the model
323 (Table 2). We separated all known items into common food categories (Wheat, Maize, Grass, Oil
324 Seed Rape, Insects, Seeds, Galls, Acorns) and used binomial tests to determine if sexes differed
325 in the likelihood of their crop containing food of each category.

326

327 *A test for Activity Budget Hypothesis: Measuring behaviour in the wild*

328

329 In 2012, we conducted continuous focal follows, for a maximum of 10 minutes,
330 observing 167 released pheasants between 18 September and 5 November. All observations were
331 conducted from inside a vehicle at a distance of > 10 m (e.g. Whiteside et al. 2016a) either
332 during the first 2 hours after first light or the final 2 hours before last light (Taber 1949). We
333 recorded the total time we observed the birds, the time spent foraging and the number of foraging
334 bouts they performed. A foraging bout began with the lowering of the head and neck towards the
335 ground and ended when the neck was raised. The proportion of time an animal spent foraging
336 was normalised using a logit transformation: $\log(y/1-y)$ (Warton & Hui 2010) and a GLM was
337 used to ask if the percentage of time spent foraging differed between the sexes.

338

339 In 2013, between 15 August and 16 September we conducted a series of 10 minute focal
340 follows with an instantaneous point sampling procedure at 30 second intervals on 214 pheasants.
341 This allowed us to collect state behaviours; in particular time spent performing resting, foraging
342 and locomotive behaviours and also aggressive interactions. All birds were identifiable from
343 their wing tags and were observed from a distance so as to not disturb their natural behaviours.
344 Vigilance was described as sitting or standing with neck extended and eyes open. Resting was
345 determined as either standing or lying with eyes closed. Aggressive interactions included threats,
346 run threats, lateral struts and fights (see Hill & Robertson 1988; Ridley 1983). We used a
347 Generalised Linear Model with a binomial distribution and a probit link function to ask if sexes
348 differed in their vigilance, walking and resting likelihoods. In all models early rearing
349 environment, time of day (AM or PM), and degree of aerial protection (open or closed) were
350 included as fixed factors, and all two-way interactions were assessed (Table 2).

351

352 *Statistical Analyses*

353 All GLM and GLMM analyses were conducted using SPSS v23. All models were
354 visually inspected for homogeneity of variance, normality of error and linearity.

355

356 *Ethical Statement*

357

358 All birds were reared using commercial procedures that adhere to the DEFRA Code of
359 Practice for the Welfare of Game Birds Reared for Sporting Purposes (DEFRA 2009). During

360 rearing, minimal handling was used for obtaining morphometrics and placing birds in testing
361 chambers. In 2012 and 2013, once birds dispersed from the release pen, gamekeepers supplied
362 supplementary feed and water, which was reduced after the shooting season (from 1st February).
363 The birds were shot as a part of a commercial shoot, and were not specifically shot for this study.
364 In 2014 and 2015 released birds were attended to by the authors and there was no shooting on the
365 study site. The work was approved by the University of Exeter Psychology Ethics Committee
366 and conducted under Home Office licences number PPL 30/3204 & PPL 30/2942

367

368 RESULTS

369

370 *Are birds sexually dimorphic during the period of the study?*

371

372 Males were significantly heavier (Table 3) and had longer tarsi (Table 4) compared to
373 females upon release into the wild and when they were shot as adults prior to their first breeding
374 season

375

376 *A test for the Predation Risk Hypothesis: Do sexes differ in their likelihood of being the first to*
377 *approach a feeder visited by a fox?*

378

379 Pheasants took significantly longer (approx. 2.5 times longer) to appear at a feeder after a
380 fox was present (193±35mins) than after a time-matched control point the previous day
381 (76±9mins) ($t_{109} = 3.37$, $P = 0.001$, Figure 2). There was no difference in the likelihood that a
382 male or female would be first to approach a feeding site in the following 30 minutes after the
383 sighting of a fox (female = 20; male = 30; Binomial test: $P = 0.20$).

384

385 *A test for Predation Risk Hypothesis: Do predation rates differ with sex?*

386

387 Predation did not differ with sex in the first 8 months after release in 2012 (Binomial
388 tests: 2012: female = 8; male = 5, $P = 0.58$); 2013 (Binomial test: female = 6; male = 12: $P =$
389 0.20); and 2015 (Binomial test: female = 15; male = 27: $P = 0.12$).

390

391 *A test for Forage Selection Hypothesis: Do sexes differ in their gut morphology?*

392

393 Males significantly differed from females in all aspects of measured gut morphologies
394 with larger and heavier gut regions, crops and gizzards (Table 5).

395

396 *A test for Forage Selection Hypothesis: Does diet composition differ between sexes?*

397

398 Males ($17.38\text{g} \pm 1.62$) shot in 2012 had significantly more forage in their crops compared
399 to females ($12.75\text{g} \pm 1.08$) ($F_{1,131} = 4.29$, $P = 0.040$, Figure 3). However, males (3.33 ± 0.16) did
400 not differ from females (3.52 ± 0.27) in the variety of food items found within their crop ($F_{1,147} =$
401 0.93 , $P = 0.34$). The sexes appeared to utilise a similar diet with both sexes carrying similar
402 proportions of eight common food types in their crops. Males did not differ from females in the
403 likelihood that their crop would contain wheat, maize, grass, oil seed rape, insects, seeds, galls or
404 acorns (Table 6).

405

406 *A test for Activity Budget Hypothesis: Do other behaviour differ between sexes?*

407

408 Sexes did not differ in their percentage of time spent foraging; the length of each foraging
409 bout (Table 7); their likelihood of being vigilant ($F_{1,186} = 0.20$, $P = 0.66$) or their likelihood of
410 walking ($F_{1,186} = 2.54$, $P = 0.13$). There was only one incidence of resting behaviour during the
411 focal watches which was demonstrated by a male and there were no aggressive interactions
412 performed hence sex differences in these behaviours could not be compared.

413

414 **DISCUSSION**

415

416 During the late autumn and winter, when pheasants show an increased tendency to
417 sexually segregate (Whiteside et al. 2018), pheasants exhibited strong sexual size dimorphism.
418 Adult males were significantly heavier than females and had larger gut dynamics and heavier
419 gizzards, however, we found little evidence that sexes differed in behavioural and dietary
420 measures that are predicted to explain sexual segregation according to the three existing

421 hypotheses purporting to explain segregation due to size dimorphism (Bleich et al. 1997;
422 Bonenfant et al. 2007; Conradt 1998; Ruckstuhl 1998).

423

424 Males pheasants were 1.3x heavier than females which is similar to levels of dimorphism
425 seen in Northern giant petrel (*Macronectes halli*) (1.25: González-Solís 2004) but less than the
426 great bustard (*Otis tarda*) (2.48: Alonso et al. 2009), two avian species that are known to
427 sexually segregate. The extent of pheasant size dimorphism also closely matched that observed
428 in mammals exhibiting sexual segregation (red deer, *Cervus elephus*, (1.33: Clutton-Brock et al.
429 1982; Weckerly 1998), merino sheep, *Ovis aries*, (1.50: Michelena et al. 2004), bighorn sheep,
430 *Ovis canadensis*, (1.43: Blood et al. 1970). Pheasants share similarities with such ungulates
431 being highly terrestrial and sedentary, in contrast to the wide ranging and migratory petrel and
432 bustard.

433

434 Pheasants may reduce their risk of predation by increasing the lag between feeder
435 visitations after a fox visit compared to a time-matched control point the previous day,
436 suggesting that time taken to visit a feeder after a fox has been there provided a good assay of
437 risk sensitivity. However, we found that sexes did not differ in their exposure to fox predation
438 risk, at least at feeders, indicated by their likelihood of being the first bird to visit a feeding site
439 after a fox had been present. Such patterns of risk sensitivity may differ at non-feeding sites.
440 Better integrating our understanding of predator and pheasant movement would also help clarify
441 how predator risk might influence segregation. This similarity between the sexes in their
442 willingness to enter an area previously visited by a fox, the most common predator of pheasants
443 in the UK, may explain why we also found no differences in predation rates between sexes
444 across all three years in which we monitored predation. This may appear somewhat surprising,
445 particularly if the size and colouration of males makes them more conspicuous and indeed we
446 tended to find more males predated than females, perhaps because we used visual searches
447 favouring detection of the larger and more visible males. However, other studies using radio
448 collared release populations, also revealed no differences in predation rates between sexes (Musil
449 & Connelly 2009; Turner 2007). In contrast to the breeding season when nesting females are
450 more exposed to foxes either while sitting on the nest or attending dependent young, pheasants of
451 both sexes faced similar predation risks and rates during autumn/winter prior to the breeding

452 season. Therefore during this period they may not discriminate against high predation risk
453 habitats because they do not have to protect their young. In contrast, immediately after the
454 breeding season, precocial pheasant chicks frequently stay with their mother for over 28 days
455 (Riley et al. 1998) and during this time (June-August) females with young may occupy low risk
456 habitats. However, our recording periods did not encompass this time and our females were all
457 birds hatched in the spring and therefore had not yet bred. The similarity between the sexes in
458 predation risk and consequent predation rates suggests that the Predation Risk Hypothesis may
459 not adequately account for sexual segregation in pheasants.

460

461 During the period that pheasants sexually segregate, females were smaller in both body
462 size and in all aspects of their gut morphology. The longer intestinal system in male pheasants
463 suggests a better ability to efficiently digest a lower quality diet (Moss 1983). Larger gizzards in
464 the males also suggest a more effective grinding mechanism, perhaps allowing the digestion of
465 harder food items (Putala & Hissa 1995). Such gastro-intestinal dimorphism is common in
466 sexually segregating ungulates, often with males having a larger rumen, small intestine and
467 colon, allowing for them to forage on much less digestible forage (Barboza & Bowyer 2000).
468 Such differences in morphologies could cause sexes to differ in their diet, perhaps with female
469 pheasants choosing higher quality foods which are easy to grind in the gizzard. However, we did
470 not observe differences in crop content when considering a suite of common food items.
471 Similarity in dietary preference was also observed in pheasants when tested as chicks in captivity
472 and presented with a choice of a variety of natural and man-made food items (Whiteside et al.
473 2017). Dietary difference between sexes often occurs, or become more pronounced, in periods
474 leading up to nesting and incubation (Lewis et al. 2002; Nisbet 1997). During the same period
475 that data from this study was collected, the degree of sexual segregation becomes stronger as the
476 pheasants get older (Whiteside et al. 2018), which may indicate that females begin to
477 differentiate their foraging behaviours more in the run up to the start of the breeding season in
478 March. Our sampling of crop contents finished at the start of February corresponding with the
479 end of the shooting season, so we may have missed this dietary switch at the advent of the
480 breeding season. Although dimorphic in gastro-intestinal morphology, our findings that sexes do
481 not differ in dietary breadth or composition suggest that the Forage Selection Hypothesis may
482 not adequately explain pheasant sexual segregation witnessed during the pre-breeding period.

483

484 Nutrient intake requirements are proportional to body size for many species (Demment &
485 Van Soest 1985), yet we found the dietary breadth and composition was similar for both sexes of
486 pheasants (see above). Therefore, we predicted that males would forage more than females,
487 while exhibiting correspondingly lower levels of alternative behaviours such as walking or
488 vigilance, leading to segregation. However we found that males and female pheasants did not
489 differ in their proportion of time spent foraging. One explanation is that there is a sex difference
490 in foraging efficiency and that males can consume enough nutrients in a similar time period.
491 Such an explanation is supported by the observation that male pheasant chicks were twice as
492 quick as females when presented with a novel food handling challenge (Whiteside et al. 2017). A
493 lack of sex differences in foraging has also been observed in desert big horn sheep, *Ovis*
494 *canadensis mexicana*, (Mooring et al. 2003) and musk ox, *Ovibos moschatus* (Côté et al. 1997).
495 Where sex differences in time spent foraging are observed it is often attributed to their
496 investment in reproduction (Lewis et al. 2002) and differences in parental care roles (Gray &
497 Hamer 2001; Thaxter et al. 2009). Although female pheasants will forage more than males prior
498 to nesting (Ridley & Hill 1987; Whiteside et al. 2016a), this occurs in early spring after hens
499 have abandoned their segregated winter aggregations and joined harems.

500

501 Much of the post-ingestion processing of foods in pheasants is conducted in the gizzard
502 (Putaala & Hissa 1995), with coarse material being fermented in the ceca, both of which are
503 smaller in females. Given the consistency in diet between sexes (see above) we predict that
504 females spend longer processing food. However, unlike in some sexually dimorphic ruminants
505 (Ruckstuhl & Neuhaus 2002) we found that males did not differ from females in the likelihood
506 that they would be resting, hence suggesting that resting activity cannot explain patterns of
507 sexual segregation.

508

509 The Activity Budget Hypothesis is not restricted to behaviours related to food processing,
510 as synchrony of other behaviours can also result in aggregation of the same sex. For instance,
511 increased movement rates by females have been suggested as a reason for sexual segregation in
512 big horn sheep (Ruckstuhl 1998). However, we found that male pheasants did not differ from
513 females in their occurrence of walking. Similar movement patterns across the sexes were

514 observed in merino sheep (Michelena et al. 2004). All locomotor behaviours that we measured
515 were consistent across sexes, therefore we believe that the Activity Budget Hypothesis fails to
516 predict sexual segregation in pheasants.

517

518 Aggression in pheasants is rarely seen between the sexes and male-male aggression is
519 typically restricted to the breeding season, peaking at the end of March (Ridley 1983) and
520 therefore it is not surprising that we observed no aggressive interactions at any of our point
521 samples. Consequently, we can, tentatively, reject aggression as a potential behavioural
522 mechanism driving sexual segregation. This contrasts with what we observed in young pheasants
523 in captivity where high levels of aggression was observed in males (Whiteside et al. 2017), and
524 perhaps a memory of these effects can persist over the following months driving segregation
525 post-release. However, this does not explain why the level of segregation becomes stronger over
526 time. Our use of state behaviour recording in this study may have missed sporadic but important
527 aggressive interactions, so if we suspect that segregation is driven by one sex trying to avoid
528 aggression by the other a more detailed recording of aggression is required.

529

530 It is important to acknowledge the limitation of using captive-reared pheasants as a model
531 system to help understand sexual segregation. Firstly, they are reared in an unnatural
532 environment. Whilst an artificial rearing environment allows us to control for important factors
533 like experience (e.g. of diet, predators) it may also distort future social dynamics due to the lack
534 of adult role models and a relatively limited and barren physical environment. Secondly, the
535 pheasants are released at high densities, greater than that of natural populations, and this could
536 influence availability of habitat or forage. However, such populations still exhibit sexual
537 segregation post release (Hill & Ridley 1987; Ridley 1983; Whiteside et al. 2018), although we
538 cannot confirm that the drivers of segregation match those of truly wild birds. Confirmation
539 would require a similarly detailed study on a wild population study where predators could be
540 observed and gut morphology and contents recorded.

541

542 Sexual dimorphism is fundamental to a suite of hypotheses that predict why many
543 species, mainly ungulates, sexually segregate at a fine scale (Pérez-Barbería & Gordon 1999).
544 Sexual size (and plumage) dimorphism is also observed and pronounced in pheasants and we

545 expected that it may explain observed patterns of sexual segregation outside the breeding season.
546 However, we found that the sexes did not differ in their predation risk, diet or behaviour. We
547 therefore found no support that the Predation Risk, Forage Selection or Activity Budget
548 hypotheses adequately explain sexual segregation of pheasants. We can conceive of three
549 explanations for this. First, birds (including pheasants) exhibit highly plastic gastro-intestinal
550 systems in order to reduce excess mass which is costly to flight (Dudley & Vermeij 1992;
551 Gasaway 1976; Whiteside et al. 2015). This flexibility may mean that gut size, and hence the
552 efficiency of nutrient absorption which underpins the hypotheses we tested, is not as closely
553 linked to body size as in ungulates. Consequently, the differences we observe in body size in
554 pheasants do not match differences in dietary needs or foraging patterns and so do not lead to a
555 segregation of the sexes. Second, segregation may be driven by other, social, factors. Pheasants
556 younger than those tested in this paper prefer to associate with others of the same sex in binary
557 choice tests, perhaps because males are aggressive and so seek out same sex partners to spar
558 with, or because females actively avoid males that may injure them (Whiteside et al. 2017). Such
559 preferences developed early in life may persist into early adulthood, even though the adults look
560 markedly different from the appearance of the chicks that we tested. Female pheasants older than
561 those tested in this paper also prefer to associate other females in binary choice tests (Madden &
562 Whiteside 2013). For example, subtle initial differences in diet preferences may initially lead to
563 same sex aggregations (Forage Selection Hypothesis) in which the sexes learn improved foraging
564 techniques from one another (Social Attraction Hypothesis), which leads to synchronised
565 exploitation of specific food types (Activity Budget Hypothesis). Understanding why the sexes
566 segregate may require a more nuanced and integrative consideration of the current hypotheses.

Figure 1

Distributions of the times for pheasants to appear after a time-matched control period, showing a clear break after ~420mins.

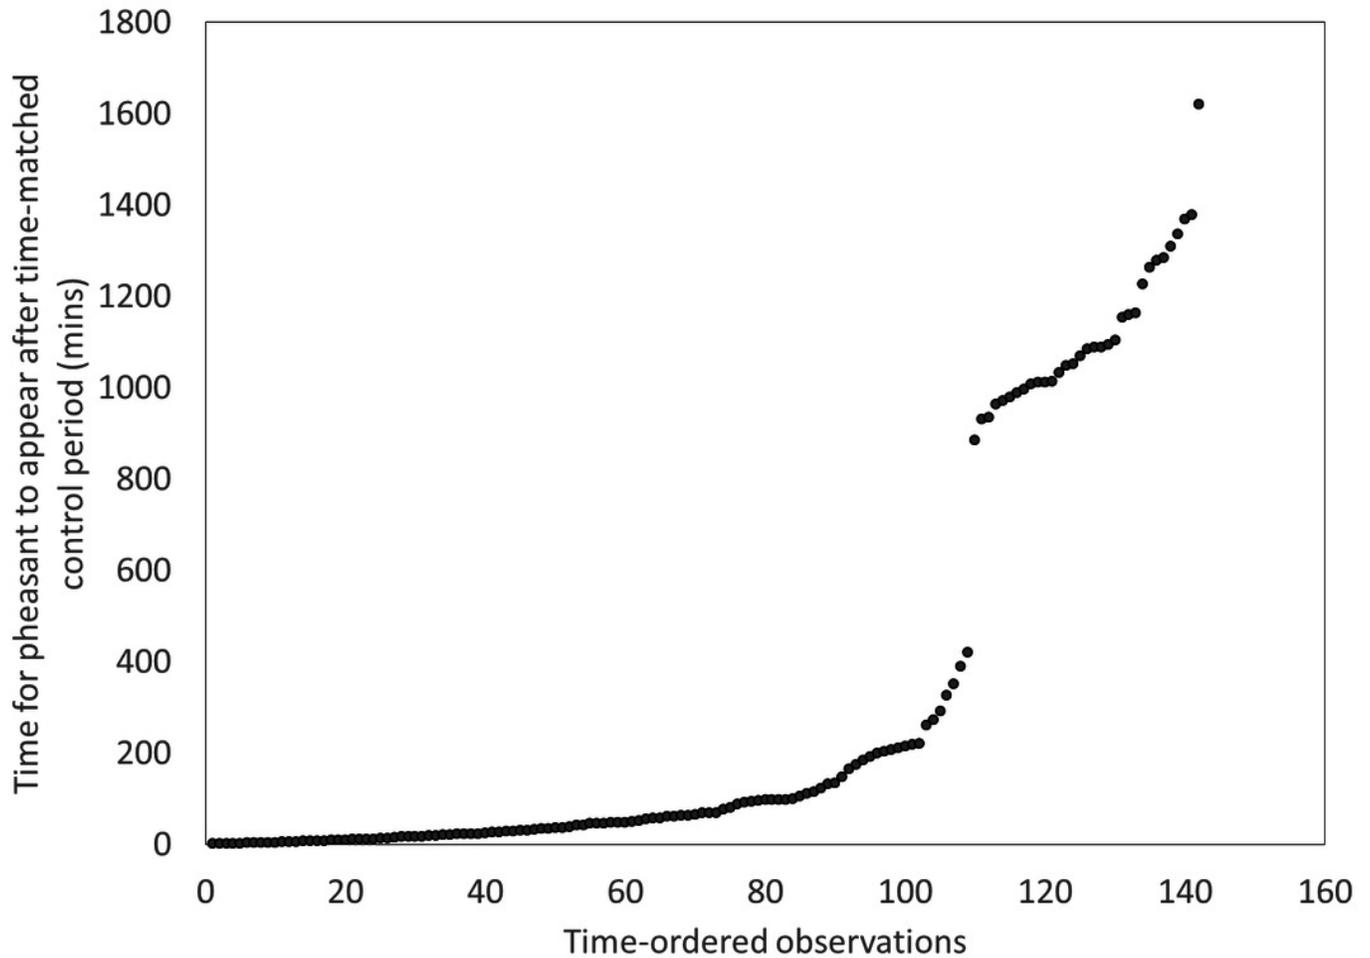

Figure 2

Time delay before a pheasant appears at a feeder after a fox has been present or a paired, time-matched control period 24hrs before the fox was sighted. Error bars = $\pm 1SE$.

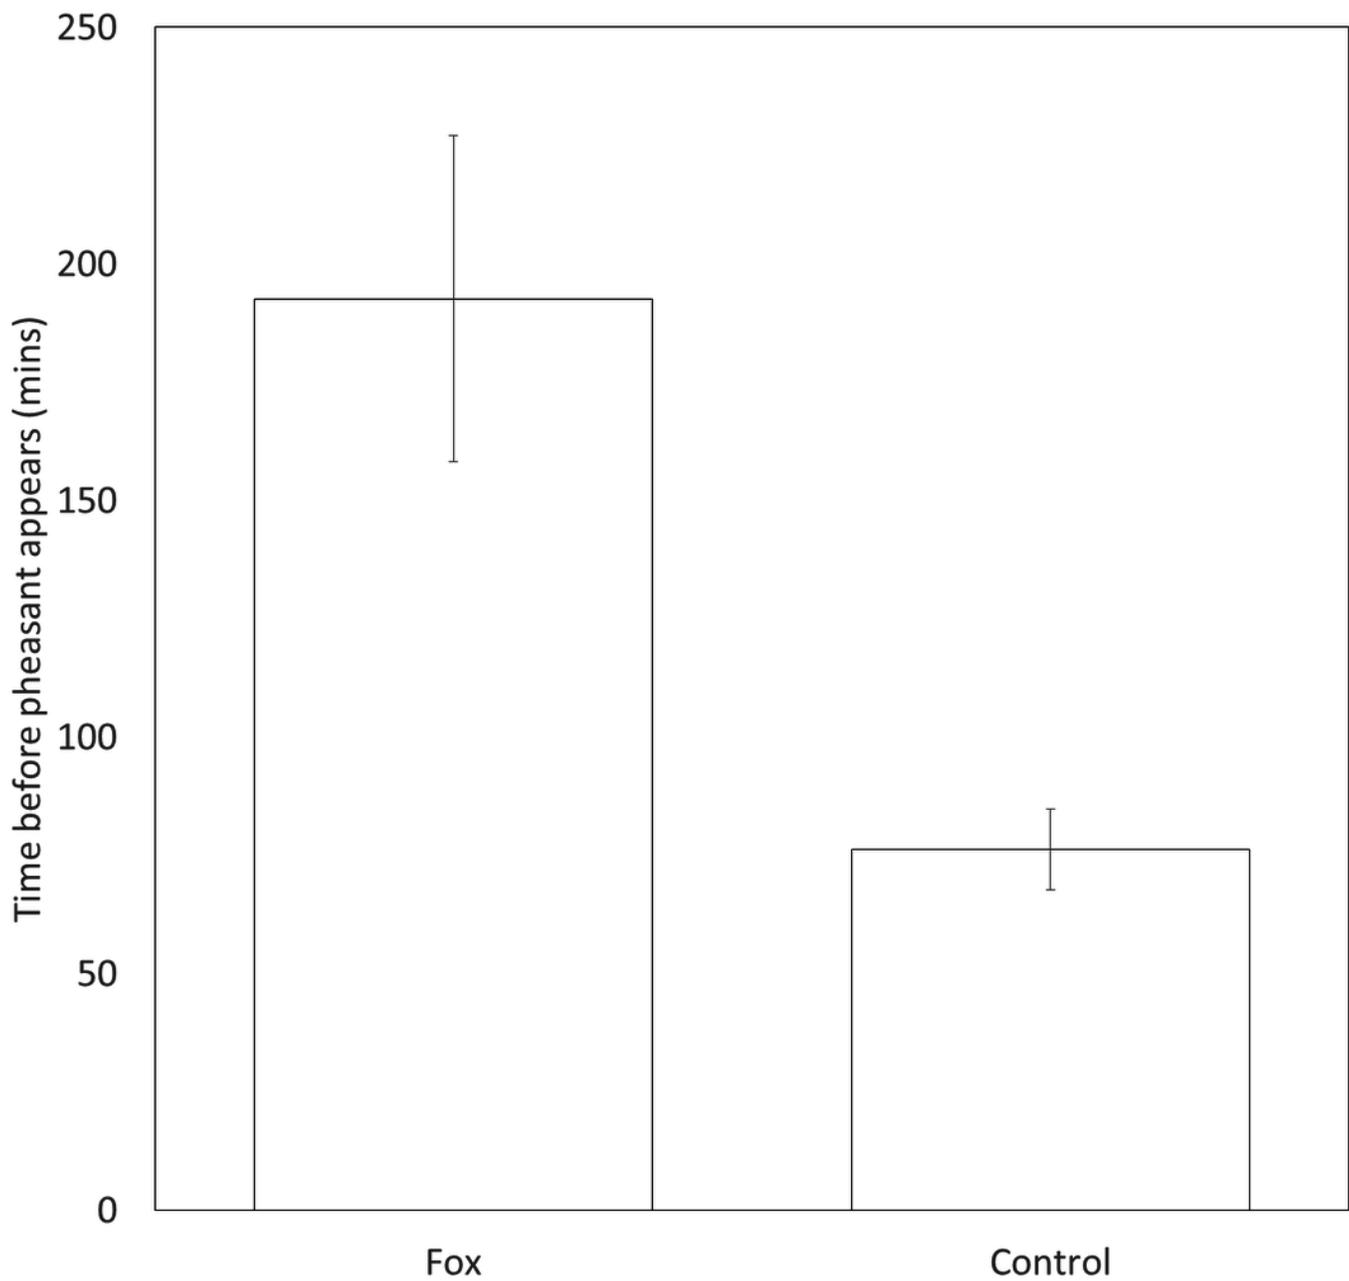

Figure 3

The mean mass of crop contents from birds shot in 2012. Error bars indicate ± 1 SE

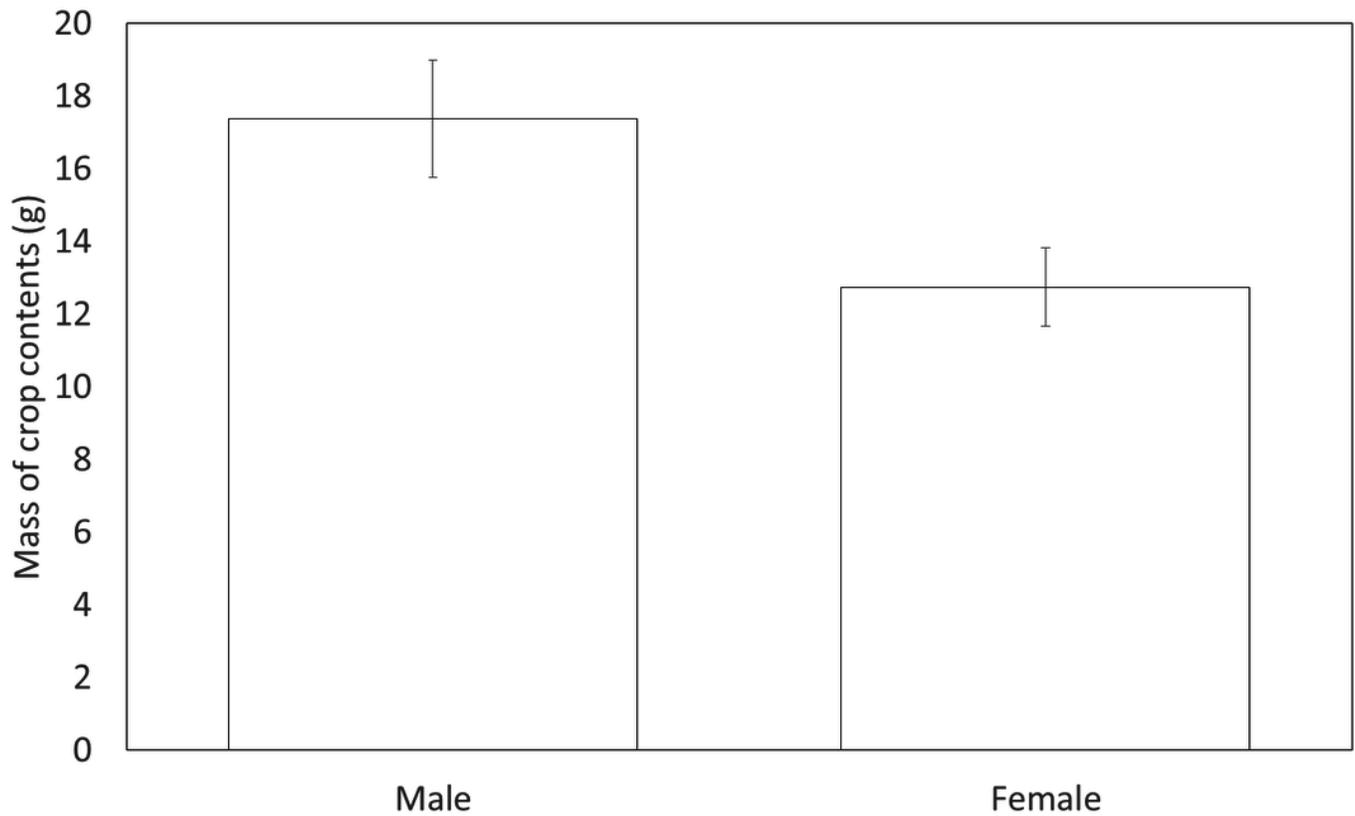

Table 1 (on next page)

A description, for each year, of the conditions each bird was reared under, the numbers per house, the release sex ratio along with what data was collected.

Representing a description, for each year, of the conditions each bird was reared under, the numbers per house, the release sex ratio along with what data was collected. The default environment was analogous to current industrial rearing conditions and acted as our control; a barren, spatially simple environment that offered a monotonous chick crumb diet that as *ad lib* and in excess. Within the parenthesis next to the measures denotes the sample size and which hypotheses it was used to test: FSH = Forage Selection Hypothesis; PRH = Predation Risk Hypothesis; ABH = Activity Budget Hypothesis.

Year	Rearing (day 1 – release day)	Release day (day 43-62)	Post release (release day until 1 March)	Shooting season (1 October - 1 February)
2012	10 replicates of 3 dietary treatments 1) 1% mealworms; 2) 5% mixed seed; 3) Control Rearing numbers = 30 per house Release sex ratio(f:m) = 50:50 Large release number (game keeper)	Mass (871) Tarsus (871)	Foraging behaviour (167: ABH) Mortality (13: PRH)	Mass (233) Tarsus (233) Gut morphology (129: FSH) Crop mass (159: FSH)
2013	3x2 design. 10 replicates of 3 dietary treatments 1) 1% mealworms; 2) 5% mixed seed; 3) Control 15 replicates of 2 structural treatments 1) access to perches; and 2) control (no perches) Rearing numbers = 30 per house Release sex ratio(f:m) = 46:54 Large release number (game keeper)	Mass (901) Tarsus (901)	Foraging behaviour (214: ABH) Vigilance behaviour (214: ABH) Resting behaviour (214: ABH) Walking behaviour (214: ABH) Mortality (18: PRH)	Mass (202) Tarsus (202) Crop samples (147: FSH)
2014	No environmental treatments. All had control environment with the addition of Supplementary mealworms and mixed seed and had access to perches Rearing numbers = 50 per house Release sex ratio(f:m) = 46:54 Small release number (no game keeper)	None	Feeder use relative to possible predation events (50: PRH)	None
2015	No environmental treatments. All had control environment with the addition of Supplementary mealworms and mixed seed and had access to perches Rearing numbers = 50 per house	Mass (194) Tarsus (194)	Mortality (42: PRH)	None

Release sex ratio(f:m) = 46:54

Small release number (no game keeper)

2 Table 1: Representing a description, for each year, of the conditions each bird was reared under, the numbers per house, the release
3 sex ratio along with what data was collected. The default environment was analogous to current industrial rearing conditions and acted
4 as our control; a barren, spatially simple environment that offered a monotonous chick crumb diet that as *ad lib* and in excess. Within
5 the parenthesis next to the measures denotes the sample size and which hypotheses it was used to test: FSH = Forage Selection
6 Hypothesis; PRH = Predation Risk Hypothesis; ABH = Activity Budget Hypothesis.

Table 2 (on next page)

The distribution, response variables, explanatory variables and random factors for all GLM and GLMMs used in the study

<i>Question</i>	<i>Distribution</i>	<i>Response</i>	<i>Explanatory Factors</i>	<i>Random Factors</i>
<i>Do sexes differ in mass upon release into the wild?</i>	Normal	Mass	Sex of focal Rearing treatment (2012 and 2013 only)	House
<i>Do sexes differ in tarsus length upon release into the wild?</i>	Normal	Tarsus length	Sex of focal Rearing treatment (2012 and 2013 only)	House
<i>Do sexes differ in mass when shot as an adult?</i>	Normal	Mass	Sex of focal Age when shot Rearing treatment	
<i>Do sexes differ in tarsus length when shot as an adult?</i>	Normal	Tarsus length	Sex of focal Age when shot Rearing treatment	
<i>Do sexes differ in their gut morphology when shot as adults</i>	Normal	Length/ Mass/ Volume	Sex of focal Age when shot Rearing treatment	
<i>Do sexes differ in the mass of food found in their crop?</i>	Normal	Mass	Sex of focal Age when shot	
<i>Do sexes differ in the time spent foraging (2012)?</i>	Normal	Percentage of time spent	Sex of focal Time of day	

		foraging (logit transformed)	(am/pm) Rearing treatment Degree of aerial protection (Open/Closed canopy)
<i>Do sexes differ in foraging, walking and resting behaviours (2013)?</i>	Binomial	Likelihood performing behaviour	Sex of focal Time of day (am/pm) Rearing treatment Degree of aerial protection (Open/Closed canopy)

3 GLM and GLMMs used in the study

Table 3 (on next page)

The mean mass in grams (range) of males and females released into the wild for three rearing seasons and the mass of adult birds shot in 2012 and 2013

<i>Year (age)</i>	<i>Male mass (g)</i>	<i>Female mass (g)</i>	<i>df (df-error)</i>	<i>F</i>	<i>P</i>
2012 (50 days)	643.69 (400-800)	536.32 (300-760)	1 (865)	688.29	< 0.001
2013 (43 days)	489.42 (350-630)	412.07 (220-540)	1 (889)	169.90	< 0.001
2015 (62 days)	738.31 (556-936)	607.82 (466-726)	1 (192)	233.37	< 0.001
2012 (Adult)	1577.18 (1140- 2200)	1220.32 (1010- 1510)	1 (124)	830.03	< 0.001
2013 (Adult)	1574.63 (1170- 2000)	1223.66 (920-1500)	1 (223)	503.33	< 0.001

1

2 **Table 3** The mean mass in grams (range) of males and females released into the wild for three
3 rearing seasons and the mass of adult birds shot in 2012 and 2013

4

Table 4(on next page)

The mean tarsus length in mm (range) of males and females released into the wild for three rearing seasons and the tarsus length of adult birds shot in 2012 and 2013

<i>Year (age)</i>	<i>Male tarsus (mm)</i>	<i>Female tarsus (mm)</i>	<i>df (df-error)</i>	<i>F</i>	<i>P</i>
2012 (50 days)	69.01 (55-79.2)	63.28 (52.7-78)	1 (865)	144.09	< 0.001
2013 (43 days)	62.70 (51.2-69.9)	58.56 (45.7-65)	1 (873)	392.11	< 0.001
2015 (62 days)	72.57 (67.2-81.1)	65.48 (67.2-81.1)	1 (192)	312.50	< 0.001
2012 (Adult)	79.97 (72.95-88.2)	70.41 (63.2-76.15)	1 (221)	590.53	< 0.001
2013 (Adult)	80.79 (75.25-89.4)	71.34 (61.05-78.1)	1 (186)	547.3	< 0.001

1

2 **Table 4** The mean tarsus length in mm (range) of males and females released into the wild for
3 three rearing seasons and the tarsus length of adult birds shot in 2012 and 2013

4

Table 5 (on next page)

Mass (g) and lengths (mm) of male and female gut morphologies (degrees of freedom = 1,128) for birds shot as adults in 2012

<i>Dependent Variable</i>	<i>Sex</i>	<i>Mean</i>	<i>Std. Error</i>	<i>Relative difference</i>	<i>F</i>	<i>P</i>
Oesophagus Length	Female	111.75	1.82	1.10	23.720	< 0.001
	Male	123.00	1.43			
Oesophagus Mass	Female	1.79	0.08	1.27	23.227	< 0.001
	Male	2.28	0.06			
Crop Mass	Female	3.67	0.16	1.22	16.318	< 0.001
	Male	4.48	0.12			
Gizzard Mass	Female	22.55	0.53	1.18	33.098	< 0.001
	Male	26.45	0.42			
Intestine Length	Female	1146.23	15.78	1.09	25.942	< 0.001
	Male	1248.35	12.37			
Intestines Mass	Female	15.73	0.41	1.17	25.475	< 0.001
	Male	18.34	0.32
