

Top-down control involved in (turf) algae-mediated coral damage in coastal reefs of Belize, Central America

Many coral reefs in the Caribbean experienced substantial changes in their benthic community composition during the last decades, resulting in a shift from scleractinian corals to other benthic invertebrate and algae dominance and consequent degradation of coral reefs, but knowledge about the related role of coral-algae contacts that may negatively affect corals is scarce. Therefore, benthic community composition, abundance of algae grazers, and the abundance and character of coral-algae contacts were assessed at 13 Belizean reef sites distributed along a distance gradient to the Belizean mainland (12-70 km): Mesoamerican Barrier Reef (inshore), Turneffe Atoll (inner and outer midshore), and Lighthouse Reef (offshore). In-situ surveys revealed significantly higher benthic cover by scleractinian corals at the remote Lighthouse Reef (26 – 29 %) when compared to the other sites (4 - 19 %). The abundance of herbivorous fish and the sea urchin *Diadema antillarum* significantly increased towards the offshore reef sites, while the occurrence of direct coral-algae contacts consequently increased significantly with decreasing distance to shore. About 60 % of these algae contacts were harmful (exhibiting coral tissue damage, pigmentation change, or overgrowth) for corals (mainly genera *Orbicella* and *Agaricia*), particularly when filamentous turf algae were involved. These findings provide support to the theory that a top-down control is involved in primarily (turf) algae-mediated coral damage in Belizean coastal coral reefs.

10 **ABSTRACT**

Many coral reefs in the Caribbean experienced substantial changes in their benthic community composition during the last decades, resulting in a shift from scleractinian corals to other benthic invertebrate and algae dominance and consequent degradation of coral reefs, but knowledge about the related role of coral-algae contacts that may negatively affect corals is scarce. Therefore, benthic community composition, abundance of algae grazers, and the abundance and character of coral-algae contacts were assessed at 13 Belizean reef sites distributed along a distance gradient to the Belizean mainland (12-70 km): Mesoamerican Barrier Reef (inshore), Turneffe Atoll (inner and outer midshore), and Lighthouse Reef (offshore). In-situ surveys revealed significantly higher benthic cover by scleractinian corals at the remote Lighthouse Reef (26 – 29 %) when compared to the other sites (4 - 19 %). The abundance of herbivorous fish and the sea urchin *Diadema antillarum* significantly increased towards the offshore reef sites, while the occurrence of direct coral-algae contacts consequently increased significantly with decreasing distance to shore. About 60 % of these algae contacts were harmful (exhibiting coral tissue damage, pigmentation change, or overgrowth) for corals (mainly genera *Orbicella* and *Agaricia*), particularly when filamentous turf algae were involved. These findings provide support to the theory that a top-down control is involved in (turf) algae-mediated coral damage in Belizean coastal coral reefs.

Keywords: coral reef ecology, phase shift, coral algae contacts, coastal influence

INTRODUCTION

Phase shifts from scleractinian corals to other invertebrates such as sponges (Maliao et al. 2008), ascidians (Bak et al. 1996) or octocorals along with a strong increase in occurrence of benthic algae and cyanobacteria (Hughes 1996; Gardner et al. 2003; Andrefouet and Guzman 2005) are

particularly reported from coral reefs in the Caribbean Sea (Hughes 1994; Gardner et al. 2003). These reefs are highly affected by intense tourism, overfishing and coastal agriculture (Burke and Maidens 2004), but also by a wide diversity of severe coral diseases (Goreau et al. 1998; Aronson and Precht 2001; Patterson et al. 2001), and a previous pathogen-induced mass mortality of the sea urchin *Diadema spec.* (Lessios et al. 1984), the formerly dominant herbivorous invertebrate in Caribbean reefs.

In contrast, Caribbean coral reefs off Belize, Central America, have been described as pristine and undisturbed compared to reef locations in the Northern Caribbean (Lapointe et al. 1997), which was mainly attributed to low fishing pressure in Belize waters and a modest development of coastal development for agriculture and tourist industry. However, McClanahan and Muthiga (1998) and McClanahan et al. (1999) reported benthic community shifts from corals to fleshy macroalgae at reef locations along the Belizean Barrier Reef and Glovers Atoll off Belize, although fishing and inorganic nutrient concentrations were at relatively low levels. Thus, there is obviously some debate about the degradation status of Belizean coral reefs and the particular role of benthic algae that can damage corals if they are in direct contact to each other (Smith et al. 2006; Haas et al. 2010a).

Many benthic algae (Hay et al. 1987; Schmitt et al. 1995) and cyanobacteria (Nagle and Paul 1998) species produce toxic secondary metabolites that act as agents against herbivory and anti-fouling (Paul et al. 2001) and therefore may negatively affect corals. Additionally, abrasion-mediated polyp retraction (River and Edmunds 2001) or high production of labile dissolved organic matter (DOM) by reef algae, which can stimulate planktonic microbial metabolism with ensuing O₂ deficiency (Haas et al. 2010a; Haas et al. 2010b; Wild et al. 2010), may also negatively affect corals in direct contact with algae.

However, data about benthic community composition in combination with assessments of coral-algae interactions in reefs off Belize have not been described in the scientific literature.

59 The focus of the present rapid assessment pilot study therefore was to estimate live coral and reef
 60 algae cover along with grazer (sea urchin *Diadema antillarum* and herbivorous fish) abundance,
 61 and to quantify and characterize coral-algae contacts at different reef locations in Belize. Main
 62 objective of this study was to link abundance of herbivorous reef organisms with the occurrence
 63 and character of coral-algae interactions.

64 MATERIAL AND METHODS

65 Study site

66 All surveys were carried out during a Belize expedition of the research and media vessel
 67 *Aldebaran* between 12 and 23 March 2009. In total, 13 reef sites were investigated along a
 68 distance gradient to the Belize mainland (12-70 km). Surveys were conducted at sites located
 69 along the Mesoamerican Barrier Reef (inshore, n = 4), Turneffe Atoll (West side, i.e. inner
 70 midshore, n = 5; East side, i.e. outer midshore, n = 2) and Lighthouse Reef (offshore, n = 2).

71 Locations were mapped with GPS, and distances to Belize City were determined (Fig. 1 and
72 Table 1).

73 **Benthic cover**

74 At each site, two surveys (I. and II.) were carried out independently in water depths of 5 – 8 m by
75 SCUBA divers. I. During each of these surveys, two 50 m line point intercept transects (LPI) with
76 measuring points every 50 cm (n = 202 data points) were conducted to assess benthic community
77 composition. Test transects were carried out prior to select appropriate categories for benthic
78 cover and were then defined as: all present scleractinian corals and benthic alga genera as well as
79 turf algae (which were defined as a dense conglomerate of various diminutive and filamentous
80 algae growing up to a height of about 1 cm), hydrozoan fire corals, octocorals (soft corals and
81 gorgonians), sponges and seagrasses. According to Nadon and Stirling (2006), the conducted
82 transect methodology provides best combination of efficiency and accuracy.

83 II. Herbivore abundance was measured in a 2 m wide and 50 m long belt, with the transect line in
84 the middle (resulting area = 100 m²). In this area, abundances of the sea urchin *D. antillarum*
85 were quantified along with numbers of key herbivorous fishes (parrot fishes, surgeon fishes and
86 chubs) in the water column up to 3 m above this area using the following categories: 1. few (n =
87 1-5), 2. few-occasional (n = 6-10), 3. occasional (n = 11-50), 4. occasional-many (n = 51-100), 5.
88 many (n > 101). Photo documentation was used to verify taxonomic identification and to avoid
89 any observer bias.

90 **Coral-algae contacts**

91 Along with benthic cover, coral-algae contacts were recorded at each site in one LPI transect. All
92 scleractinian corals were carefully inspected for the occurrence of coral-algae contact, i.e. the
93 presence of macro or turf algae in direct contact to the coral. Coral-algae contacts were recorded

with photos, taken directly above the contact area using Panasonic LUMIX DMC-TZ5 and Canon PowerShot G10 digital cameras (resolution: 7 and 14 mega pixels, respectively). Subsequently, digital image analysis was used to identify both groups of organisms to the genus level and to evaluate the character of coral-alga contacts.

The following categories were used: I. no visible impact on corals (Fig. 2 a), II. overgrowth by algae (i.e. parts of the algae overbearing the interface between coral and algae and entering the coral zone) leading to reduced light availability or even coral tissue damage (Fig. 2 b, c), III. coral tissue pigmentation decrease at the interface (Fig. 2 d); categories II. & III. were considered as visibly harmful contact for corals.

Statistical analyses

Data were not normally distributed. Therefore, the two-sided Mann-Wilcoxon U-Test was conducted for direct comparisons of parameters between the remote locations and the other sites, both pooled for that purpose. All values are given as means \pm SE. The non-parametric Spearman correlation test was applied to relate shore distance to a) benthic cover (coral and algae), b) abundance of coral-algae contacts and c) *D. antillarum* occurrence. To check for correlation of herbivorous fish abundances and distance from shore, their frequency was set as rank order and the non-parametric Spearman correlation test was likewise conducted.

RESULTS

Benthic cover and grazer abundance

Benthic cover by scleractinian corals was low (4 - 19 %) at all investigated coral reef locations except at the remote Lighthouse Reef (26 – 29 %) where coral cover was significantly higher compared to Turneffe Atoll and the Barrier Reef (two-sided U-test, $p < 0.05$) (Table 2 and Fig. 3). Among the scleractinian corals, the genera *Agaricia* and *Orbicella* dominated (Table 2).

Specimens of the genus *Acropora*, namely *A. cervicornis*, were only observed at Lighthouse Reef, and *A. palmata* was not found at any site. Scleractinian corals were the most abundant benthic organisms only at the remote Lighthouse Reef. At eight other sites, algae dominated the benthic community, and at the remaining three sites octocorals were dominant. Coral cover was positively correlated with distance to shore (Table 3, non-parametric Spearman correlation, $p < 0.05$; Fig. 4).

Visible benthic sponge cover was relatively low with 2 - 12 %. Among the hydrozoans, only the fire corals *Millepora* could be observed, but its contribution to benthic community was minor (≤ 5 % benthic cover at all reef sites, if any present). The relative seafloor cover by benthic algae was highly variable among sites (Table 2). Consequently, there were no significant differences in algal cover between the three geographical groups of reef sites and no correlation along the distance gradient to the Belizean mainland (Fig. 4). The calcareous green algal genus *Halimeda* was the most abundant benthic algae at eight sites, but brown algae of the genus *Dictyota*, filamentous turf algae consortia and fleshy red or brown algae (*Jania*, *Wrangelia*, *Padina*, *Lobophora*) along with coralline red algae were also observed at all sites. Other green algae (*Udotea*, *Rhypocephalus*) and seagrasses (*Thalassia*) could be detected only at three stations along the Barrier Reef and at Southwest Turneffe Atoll.

Herbivorous fish were most abundant (more than 100 individuals per 100 m² reef area) at the remote Lighthouse Reef, where also the only specimens of *D. antillarum* could be observed. This coincided with lowest algal cover at the mentioned sites compared to all others (2-sided U-test, $p < 0.05$).

By contrast, all other sites exhibited low (less than 50 individuals per 100 m² reef area) herbivorous fish abundances, and no *D. antillarum* was present. *D. antillarum* abundance was significantly correlated with distance to shore, and herbivorous fish abundance showed a trend

141 for the same relationship (Table 3, non-parametric Spearman correlation, $p < 0.01$ and $p = 0.056$;
142 Fig. 4).

143 **Abundance and character of coral-algae contacts**

144 Corals were relatively often in direct contact with algae (10-78 % of all corals observed), with
145 significantly higher percentage of contact at sites of the Barrier Reef and the inner-midshore of
146 Turneffe Atoll (Table 2) compared to the more remote sites (2-sided U-test, $p < 0.01$). Coral-algae
147 contacts decreased with growing distance to shore (Table 3, non-parametric Spearman
148 correlation, $p < 0.01$). The percentages of contacts that were visibly harmful for the corals,
149 including coral tissue damage, coral pigmentation change and overgrowth by algae, exhibited no
150 correlation with distance to the mainland, and were very variable (0 - 100 %).

151 In total, 203 different coral-alga contacts were investigated and revealed that 18 % of these
152 contacts involved more than one coral or algal genus. Among corals, the genera *Orbicella* and
153 *Agaricia* were most often involved in contacts with algae (31 and 29 % respectively), whereas the
154 genera *Porites* and *Siderastrea* showed low relative involvement (10 % each). Filamentous turf
155 (30 %), fleshy red (24 %, particularly genus *Jania*), the brown alga *Dictyota* spp. (21 %) and the
156 green alga *Halimeda* spp. (19 %) together accounted for 94 % of all algae representatives
157 involved in contact with corals.

158 Analysis of visibly harmful contacts revealed that in average among all sites 50 % of the
159 scleractinian corals were overgrown by algae and 11 % revealed pigmentation change, whereas
160 about 39 % of all coral-algae contacts showed no visible effect on corals. Harmful contacts were
161 primarily caused by filamentous turf algae consortia (35 %) and to a minor extent by fleshy red
162 algae (30 %), the calcifying green algae *Halimeda* spp. (26 %) and the fleshy brown algae
163 *Dictyota* spp. (19 %). Contact with *Halimeda* did only result in coral tissue pigmentation
164 decrease, but not in tissue damage.

DISCUSSION

This study indicates negative impacts on benthic coral reef communities close to the Belize mainland coast, manifested by rising coral-algae contact frequency and decreasing coral cover.

Main objective of the present study was to assess potential linkage between abundance of herbivores and abundance along with character of coral-alga contacts. The results of the present study indicate that there is a relationship between those two variables in Belizean reefs. This indicates that a top-down control is involved in (turf) algae-mediated coral damage in coastal reefs of Belize. We can however not rule out a potential bottom-up co-effect of coastal eutrophication, but unfortunately we were not able to measure inorganic nutrient concentrations parallelly on this expedition.

A crucial top down factor on reef degradation is the presence of herbivores, namely fish and sea urchins (Hughes 1994, Lapointe 1997), and in the present study the abundance of herbivorous fish and *D. antillarum* decreased with decreasing distance to shore. Therefore, grazing of algae by both benthic and pelagic herbivores likely contributes in shaping benthic community composition in the investigated reefs. Coral-algae contact abundance, as an indicator for degradation of coral reefs, showed negative correlation with herbivorous fish abundance, suggesting that a top-down scenario is involved in the algae-mediated degradation of Belizean reefs.

Even though the low number of Belizean fishers does apparently not target herbivorous fish (McClanahan and Muthiga 1998), herbivorous fish abundance was significantly higher in the remote reef sites (Lighthouse Long Caye, Lighthouse Long Caye West and Turneffe NW). The study by Williams et al. (2001) demonstrated that the presence of corals, i.e. their 3D-structure, attracts herbivorous fish. Coral reef decline, when linked to low abundances of grazing fish, may thus be a vicious cycle, which intensifies itself. Additionally, spatial heterogeneity in herbivore abundance and therefore grazing intensity may contribute to regional diversity among and within tropical reef habitats (Lewis 1986), and fishes do likely play a major role in structuring coral reef macrophyte communities (Morrison 1988; Reinthal and Macintyre 1994).

In the Caribbean, supplementary to herbivorous fish, *D. antillarum* and other sea urchins control benthic algae populations (Aronson et al. 2000, Aronson and Precht 2001, (McManus and Polsenberg 2004). McClanahan and Muthiga (1998) reported that population density of *D. antillarum* in Belizean reefs was less than 1 individual per 1000 m² 14 years after the die off in 1983-84. The present study showed that *D. antillarum* now occurs in actual numbers of 20 to 30 individuals per 1000 m² at some reef locations off Belize, i.e. at least one order of magnitude higher population density compared to about 10 years ago. These findings are supported by observations of *D. antillarum* at other reef locations along the Barrier Reef and Turneffe Atoll (M. McField, Smithsonian Institution Belize, pers. comm.) and is in agreement with other studies, who reported recovery of *D. antillarum* in reefs around Jamaica (Edmunds and Carpenter 2001) and St. Croix (Miller et al. 2003). The findings of the present study however indicate that combined herbivory by fishes and sea urchins was not sufficient in order to prevent a large number of coral-algae contacts particularly at reef sites close to the Belizean mainland.

The observed coral-algae contacts can be the cause for manifold threats triggered directly or indirectly by algae in contact with corals. Overgrowth of coral tissue, tissue damage, and pigmentation decrease occurred most often in contact with turf algae. Considerable tissue damage

caused by the turfing filamentous red alga *Corallophila huysmansii* on the branching scleractinian coral *Porites cylindrica* was also observed by Jompa and McCook (2003a), which may be related to allelochemical mechanisms. The delicate filaments of turf algae are likely be able to colonise and kill coral tissue by direct chemical effects as suggested by Jompa and McCook (2003b). This assumption is supported by results from Titlyanov et al. (2007), who demonstrated that the cyanobacterium *Lyngbya bouillonii*, often associated with algae turf, acts as a poison against scleractinian corals and is able to kill live coral tissue. Turf algae can also trap organic matter by their delicate branches (Stewart 1989), which was frequently observed in the present study. Thus, while overgrowing coral colonies, turf algae may form dense algal-sediment mats causing a localized smothering and shading of coral colonies (Nugues and Roberts 2003). This increases energy expenditure for cleaning mechanisms and leads to a reduced energy acquisition due to shading of photosynthetically active parts of the coral (Potts 1977). Additionally, the proximity of macroalgae may further lead to the alteration of water flow, not only causing a change in the rate of sedimentation (Eckman and Duggins 1991), but also an alteration in the rate of gas exchange (Hurd and Stevens 1997) and an inhibition of particle capture rates of corals (Morrow and Carpenter 2008). The combination of light reduction through shading, reduced gas exchange, a decrease in nutrient supply through the inhibition of particle capture rates and increased energy expenditure for cleaning mechanisms may weaken the competitive ability of corals. Weakened or dead coral tissue may then be more easily overgrown by more persistent secondary settlers such as fleshy red or brown algal species tightening the algal predominance following the first invasion of the relatively short-lived turf algal assemblages. The result of the present study that comparably less coral tissue damage was observed in direct contact with calcifying green algae of the genus *Halimeda* may be explained by the morphology of these algae that in contrast to turf and fleshy red algae do not exhibit such delicate filaments. However, Nugues et al. (2004) reported that pigment decrease of corals in

contact with *Halimeda* may be explained by the role of this particular alga in introducing white plague disease to reef corals. This is confirmed by the finding of the present study that most pigment decrease of coral tissue was associated with *Halimeda* contacts.

In summary, the observed negative correlation between abundance of coral-algae contacts and occurrence of herbivores may thus be a further piece of a puzzle supplementing recent studies (Stevenson et al. 2007; Sandin et al. 2008) that found negative correlation between coastal pressures (overuse of resources, but also eutrophication that was not assessed in the present study) and coral reef health.

ACKNOWLEDGEMENTS

We thank Dr. M. Mc Field and E. M. Zetsche for background information about Belize coral reefs and their valuable advice prior to this study. S. Bendixen, S. Duewel, A. Wittenzellner, and particularly captain F. Schweikert, are acknowledged for their help during the ALDEBARAN cruise, and A. Haas and S. Becker are acknowledged for their help during data analysis and figure preparation.

Table 2_(on next page)

Table 2

Table 2. Benthic cover and major organisms at the sites of investigation. “Coral-algae contact (%)” is the relative proportion of corals in direct contact with benthic algae. “Visibly harmful (%)” illustrates which of these interactions resulted in coral overgrowth or pigmentation change (see Fig. 2b-d). Herbivorous fish (parrot fishes, surgeon fishes and chubs) abundance in the water column up to 3 m above the surveyed 100 m² area was estimated using the following categories: few (n = 1-5), few-occasional (n = 6-10), occasional (n = 11-50), occasional-many (n = 51-100), many (n > 101). “N.a.” indicates that values are not available.

Table 3

Table 3. Correlation of measured parameters with distance to shore.

Table 3. Correlation of measured parameters with distance to shore.

Benthic cover		Significance level	p	Rsp
Corals	(%)	(*)	0.046	0.508
Algae	(%)	-	0.274	-0.328
Coral-algae-contact	(%)	**	0.001	-0.810
Octocorallia	(%)	-	0.656	-0.137
Fire corals	(%)	-	0.19	0.388
Sponges	(%)	-	0.814	0.072
<i>D. antillarum</i>	(individuals	*	0.028	0.606
abundance	100 m ⁻²)			
Herbivorous fish	(ranks)	*	0.045	0.564

Figure 1

Figure 1

Figure 1. Summary of transect sites. The numbers next to dots refer to order of station names (Table 1), along a distance gradient to shore; distance groups: inshore (site 1-4), inner midshore (site 5-8, 13), outer midshore (site 9-10), offshore (site 11-12).

Figure 2

Figure 2

Figure 2. Exemplary photographs of coral-algae contacts observed during the transect surveys; (a) no visible harmful impact of *Halimeda* sp. on *Orbicella* sp., (b) overgrowth of *Agaricia agaricites* by the brown alga *Dictyota*, (c) overgrowth of *Orbicella* sp. by filamentous algae, (d) or pigment change of *Siderastrea* sp. next to red algae.

Figure 3

Figure 3

Figure 3. Benthic cover of scleractinian corals and algae along with their contact frequency and *D. antillarum* abundances (per 100 m² seafloor area) at the three reef complexes (Barrier Reef, inshore; Turneffe Atoll, midshore; Lighthouse Reef, offshore) in increasing distance to shore. Values are means \pm SE.

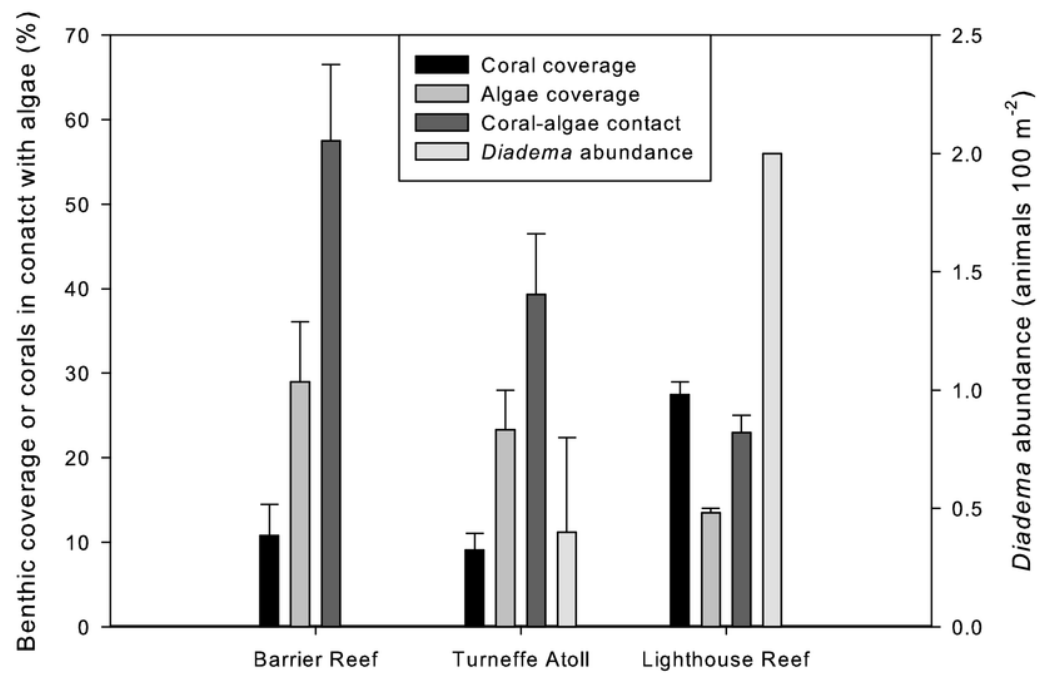

Figure 4

Figure 4

Figure 4. Benthic cover of corals and algae, including herbivorous fishes (in ranks) and number of coral-algae contacts in relation to shore distance (measured as relative distance to population centre Belize City).
