Moso bamboo has large potential to alleviate global warming through carbon sequestration. Since soil respiration ( $R_s$ ) is a major source of CO<sub>2</sub> emissions, we analyzed the dynamics of soil respiration ( $R_s$ ) and its relation to environmental factors in a Moso bamboo (*Phyllostachys heterocycla* cv. *pubescens*) forest to identify the relative importance of biotic and abiotic drivers of respiration. Annual average  $R_s$  was 44.07 t CO<sub>2</sub> ha<sup>-1</sup> a<sup>-1</sup>.  $R_s$  correlated significantly with soil temperature ( $P < 0.01$ ), which explained 69.7% of the variation in  $R_s$  at a diurnal scale. Soil moisture was correlated significantly with  $R_s$  on a daily scale except not during winter, indicating it affected  $R_s$ . A model including both soil temperature and soil moisture explained 93.6% of seasonal variations in  $R_s$ . The relationship between  $R_s$  and soil temperature during a day showed a clear hysteresis.  $R_s$  was significantly and positively ( $P < 0.01$ ) related to gross ecosystem productivity and leaf area index, demonstrating the significance of biotic factors as crucial drivers of  $R_s$ .

**19 Abstract**

20 Moso bamboo has large potential to alleviate global warming through carbon sequestration. Since  
21 soil respiration ( $R_s$ ) is a major source of  $\text{CO}_2$  emissions, we analyzed the dynamics of soil  
22 respiration ( $R_s$ ) and its relation to environmental factors in a Moso bamboo (*Phyllostachys*  
23 *heterocycla* cv. *pubescens*) forest to identify the relative importance of biotic and abiotic drivers  
24 of respiration. Annual average  $R_s$  was  $44.07 \text{ t CO}_2 \text{ ha}^{-1} \text{ a}^{-1}$ .  $R_s$  correlated significantly with soil  
25 temperature ( $P < 0.01$ ), which explained 69.7% of the variation in  $R_s$  at a diurnal scale. Soil  
26 moisture was correlated significantly with  $R_s$  on a daily scale except not during winter, indicating  
27 it affected  $R_s$ . A model including both soil temperature and soil moisture explained 93.6% of  
28 seasonal variations in  $R_s$ . The relationship between  $R_s$  and soil temperature during a day showed a  
29 clear hysteresis.  $R_s$  was significantly and positively ( $P < 0.01$ ) related to gross ecosystem  
30 productivity and leaf area index, demonstrating the significance of biotic factors as crucial drivers  
31 of  $R_s$ .

**32 1. Introduction**

33 Soils are important sources and sinks in the global carbon budget (Sheng et al., 2010). Soil  
34 respiration ( $R_s$ ) is a major source of  $\text{CO}_2$  emissions from terrestrial ecosystem, and as the second  
35 largest carbon flux between the atmosphere and ecosystems it is surpassed only by gross primary  
36 production (Raich and Potter, 1995). Soils release approximately 75-100 Pg C per year globally  
37 (Bond-Lamberty and Thomson, 2010), nearly 10 times of the amount of  $\text{CO}_2$  released by the  
38 combustion of fossil fuels (Raich and Potter, 1995). Hence, slight shifts in  $R_s$  may cause profound  
39 changes in the atmospheric concentration of  $\text{CO}_2$  and in the accumulation of soil carbon

40 (Schlesinger and Andrews, 2000), thus subsequently affect global climate.

41 Considering the importance of forest ecosystems in the terrestrial carbon cycle and their response  
42 to global climate,  $R_s$  and its dependence on environmental drivers have been the focus of numerous  
43 studies. For instance, soil temperature and moisture of soils are two of the major environmental  
44 drivers regulating  $R_s$  (Liu et al., 2016). Additionally, disturbances, e.g. fire (Muñoz-Rojas et al.,  
45 2016; Köster et al., 2014), harvesting (Bahn et al., 2008), artificial warming and precipitation  
46 changes (Li et al., 2017a), or land use changes (Liu et al., 2011; Willaarts et al., 2016) can also  
47 have large effects on  $R_s$ .  $R_s$  is a complex biogeochemical process highly related to ecosystem  
48 productivity, leaf area index, and soil fertility (Hibbard et al., 2005), proving coupling between  
49  $CO_2$  assimilation by the vegetation and emissions from the soil (Bahn et al., 2008; Hibbard et al.,  
50 2005).  $R_s$  is also influenced by the amount of litter (Oishi et al., 2013; Wu et al., 2017), vegetation  
51 type (Mahecha et al., 2010; Wang et al., 2011), and composition of the soil microbial community  
52 (Luo et al., 2016). However, many of the environmental drivers are correlated with each other,  
53 making it difficult to distinguish and quantify the contribution of each environmental factor.

54 Bamboo forests are widely distributed in warm temperate, subtropical and tropical zones between  
55  $46^\circ N$ - $47^\circ S$  (Lu et al., 2014). Globally, bamboo forests cover 31.5 million ha (FAO, 2010). With  
56 more than 500 varieties and 39 species, China hosts the largest diversity of bamboo in the world,  
57 and the 6.16 million ha bamboo forests account for 2.97% of the total forest area in China  
58 (SFAPRC, 2015). Moso bamboo (*Phyllostachys heterocycla cv. pubescens*) is appreciated for its  
59 rapid growth and high rate of timber production (Guan et al., 2017). Moso bamboo forest is a major  
60 forest type of subtropical forests in subtropical China (Song et al., 2013). Currently, the area

61 covered by Moso bamboo forests increases annually by approximately 3%, mostly due to  
62 afforestation on wastelands (Chen et al., 2009), but also through conversion conifer and broadleaf  
63 forests and farmland (Cui et al., 2011; SFAPRC, 2015). Moso bamboo provides many benefits,  
64 including high income generation and other ecosystem services, to the forest owners.

65 Notably, the rate of carbon accumulation by Moso bamboo is high. Moso bamboo sequesters 4.91  
66 - 5.45 t C ha<sup>-1</sup> each year (Zhou and Jiang, 2004), showing great potential for alleviating global  
67 warming by carbon fixation. Previous studies on Moso bamboo have concentrated on carbon  
68 storage, balance and its distribution in the ecosystem (Li et al., 2013), productivity of bamboo  
69 forest (Cheng et al., 2015; Isagi et al., 1997), and the variation in soil organic carbon stocks (Guan  
70 et al., 2015). Previous studies reported a close relationship between R<sub>s</sub> and biotic factors in other  
71 forest types (Hibbard et al., 2005), suggesting a coupling between forest canopy assimilation and  
72 carbon emissions from soil. However, comparatively little is known about bamboo forests. Thus,  
73 given the ecological importance of Moso bamboo forests at regional scale, there is a need for  
74 understanding the relationships between biotic and abiotic factors and R<sub>s</sub> in this kind of ecosystem.  
75 In this study, we used soil respiration measurements from a Moso bamboo stand and combined  
76 these with measurements of abiotic and biotic factors. Our aims were to explore the temporal  
77 dynamics of soil respiration, and to identify the relative importance of the measured environmental  
78 factors.

## 79 **2. Methods**

### 80 **2.1. Study site**

81 The measurements were done in a Moso bamboo forest with an eddy covariance flux tower in

82 Anji, Zhejiang Province, southeast China (30°28'34.5"N, 119°40'25.7"E) at 380 m elevation. The  
83 study area has a typical subtropical monsoon climate with distinct seasons (Li et al., 2018; Peel et  
84 al., 2007). The average annual air temperature and precipitation in 1981-2010 was 15.6 °C and  
85 1413.2 mm, respectively. Monthly average rainfall and air temperature in the study period are  
86 shown in Fig.1. The soil type in this area is yellow red soil (Chinese system of soil classification),  
87 equivalent to Hapludult in USDA Soil Taxonomy (Soil Survey Staff of USDA, 1999), pH is from  
88 4.4 to 4.8, and soil bulk density is 1.5 g·cm<sup>-3</sup> (Chen, 2016).

89 The study area (1km around the eddy covariance flux tower) was covered by 86.1% of Moso  
90 bamboo forest (Xu et al., 2013). The total area of the forest was 1687 ha. Stand density was 3235  
91 culms per hectare, the average canopy height was 11 m with a mean diameter at breast height of  
92 9.3 cm. There was only a sparse understory in the study area. The main management activities  
93 were harvesting 6 or 7-year old bamboos, and a proportion of new bamboo shoots each year. The  
94 forest was not fertilized nor weeded during the study period. Further detailed information of the  
95 site is found in Mao et al. (2017). Moso bamboo has a biannual growth pattern. During “off years”  
96 (which are the even numbers in our site, i. e. 2012, 2014, 2016) few new bamboo shoots are  
97 produced, there is leaf senescence of old leaves, and new leaves grow vigorously (Qiu, 1984). In  
98 “on years” which are years with uneven numbers more new bamboo shoots are produced and leaf  
99 senescence is limited. In our study site, the study period in 2013 was an “on-year”.

## 100 **2.2. Experimental design and measurement**

### 101 **2.2.1. Soil CO<sub>2</sub> flux measurement**

102 The soil CO<sub>2</sub> flux was measured using an automated system consisting of a LI-8100 analyzer and

103 a LI-8100-104 chamber and a multiplexer (LI-8150) (all LI-COR Inc., Lincoln, NE, USA). Soil  
104 respiration measurements were done at two hour intervals between 0:00 and 22:00 on selected  
105 sunny days for approximately two weeks (usually from day 10 to day 23 of every month) of every  
106 month in 2013. The duration of each flux measurement was 2 minutes and the fluxes were  
107 calculated by an exponential fit of CO<sub>2</sub> against time by Soil Flux Pro, version. One 40 m × 40 m  
108 plot was established around the Flux tower within the forest. Sixteen sampling polyvinyl chloride  
109 (PVC) soil collars (20 cm inside diameter, 10 cm height, and 5 cm plugged into the soil ) were  
110 randomly placed within the plot. All collars remained permanently in place throughout the study  
111 period. There were few herbs in the Moso bamboo forest. To reduce the disturbance-induced  
112 carbon dioxide emission, the first measurement started at least 24 h after insertion. The areas inside  
113 collars were kept free of plants by cutting the plants carefully using scissors about monthly during  
114 the year. The data and the performance of the equipment were checked regularly to ensure the  
115 reliability of measurements throughout the year. Soil water content (SWC, m<sup>3</sup>·m<sup>-3</sup>) and soil  
116 temperature (T<sub>s</sub>, °C) were monitored adjacent to each collar at 5 cm depth with 2 theta probes  
117 inserted vertically (ML2x, Delta-T Inc., UK; Omega Inc., USA) provided with the system. We  
118 defined March to May as spring, June to August as summer, September to November as autumn,  
119 and January, February and December as winter.

### 120 **2.2.2. Measurements of environmental variables at the eddy covariance site**

121 T<sub>s</sub> and SWC were monitored by soil temperature sensors (109SS, Campbell Inc., USA) and soil  
122 moisture sensors (CS616, Campbell Inc., USA), respectively, at 5 cm, 50 cm and 100 cm depths  
123 (T<sub>S5</sub>, T<sub>S50</sub>, T<sub>S100</sub>, SWC5, SWC50, SWC100) close to the eddy covariance tower. Air temperature

124 and relative humidity were measured using HMP45C probes (Vaisala, Helsinki, Finland) at 1 m,  
125 7 m, 11 m, 17 m, 23 m, 30 m, and 38 m above the ground. All the data were recorded by a data  
126 logger (CR1000, Campbell Inc., USA) and saved as 30-min averages.

### 127 **2.2.3. Biological factors measurements**

128 Gross ecosystem productivity (GEP) was obtained by eddy covariance (EC) technique. An open-  
129 path infrared gas analyzer LI-7500 (Li-Cor Inc., Lincoln, NE, USA), in conjunction with a 3-  
130 dimensional sonic anemometer CSAT3 (Campbell Inc., Logan, UT, USA), was placed at 38 m  
131 above the ground. All the raw flux data were sampled at 10 Hz, and calculated and recorded by a  
132 CR1000 data logger (Campbell Inc., USA) as 30-min average values. The flux data was processed  
133 using the EdiRe software (University of Edinburgh). A double-coordinate rotation was applied and  
134 the Webb-Pearman-Leuning correction was conducted to remove the effects of air-density  
135 fluctuations. Daily net ecosystem exchange (NEE) was calculated as the daily sum of the measured  
136 CO<sub>2</sub> flux and the daily rate of change in CO<sub>2</sub> storage below the height of the EC system. Ecosystem  
137 respiration (RE) was calculated for each 30-min by extrapolating the exponential regressions  
138 between the night NEE at high-friction velocity and soil temperature at the 5 cm depth and summed  
139 into the daily values. Daily gross ecosystem productivity (GEP) was estimated as the difference of  
140 daily RE and daily NEE (Song et al., 2017).

141 The flux data were discarded when the following errors were observed (Yan et al., 2013; Yu et al.,  
142 2006; Song et al., 2017) (1) the CO<sub>2</sub> flux was beyond the range of  $-2.0$  to  $2.0$  mg CO<sub>2</sub> m<sup>-2</sup> s<sup>-1</sup>,  
143 CO<sub>2</sub> concentration was  $< 500$  or  $> 800$  mg m<sup>-3</sup>, and water vapor concentration was outside the  
144 range of  $0-40$  g m<sup>-3</sup>; (2) abnormal values, i.e. when the absolute value of the difference between

145 a numerical value and a continuous five points was  $> 2.5$  times of its variance; (3) the  
146 measurements occurred during precipitation events; (4) the number of valid samples was  $< 15,000$ ;  
147 (5) low friction velocity was low ( $u^* < 0.2 \text{ m s}^{-1}$ ). Gaps occurred more frequently at night than  
148 during the day. After data filtering, the annual flux data 64 % of the data were retained.

149 Gaps less than 2 h were linearly interpolated, gaps more than 2h were filled with the look-up-table  
150 method, which were built up based on the two-adjacent-month periods and two main  
151 environmental factors (photosynthetically active radiation and air temperature). For details  
152 information, please see the literature by Song et al. (2017).

153 Leaf area index (LAI) was measured at 6:00-10:00 and 15:00-17:50 of sunny, no cumulus days  
154 and with good visibility days. Measurements were done monthly using digital camera provided  
155 with a fish-eye lens in combination with MODIS LAI following the methods of Li et al. (2017b).  
156 LAI was reported as the average of three sample points chosen within the  $20 \text{ m} \times 20 \text{ m}$  plot on  
157 non-rainy days. The LAI data was calculated as mean values  $\pm$  SD (standard deviation).

### 158 **2.3. Data analysis**

159 We analyzed the soil respiration as a function of soil temperature assuming an exponential  $Q_{10}$   
160 type relationship.

$$161 \quad R_s = ae^{bt} \quad (1)$$

$$162 \quad Q_{10} = e^{10b} \quad (2)$$

163 Where  $R_s$  ( $\mu\text{mol}\cdot\text{m}^{-2}\cdot\text{s}^{-1}$ ) is soil respiration,  $T$  is soil temperate at 5 cm depth,  $a$  and  $b$  are fit  
164 parameters, Eq.1 (van't Hoff, 1884).The temperature sensitivity parameter,  $Q_{10}$ , was calculated by  
165 Eq.2 (Sheng et al., 2010;Song et al., 2013).

166 One-way analysis of variance (ANOVA) and the least significant difference were carried out to

167 test the statistical significance of differences in soil respiration, environmental (Table 1) and biotic  
168 factors (Table 2) between seasons. Regression (including nonlinear and linear regression) and  
169 correlation analysis was performed to analyze the relationship between soil respiration, biotic and  
170 abiotic variables. All analyses were conducted using the PASW software (PASW Statistics 18.0  
171 for windows, SPSS Inc., Chicago, IL, USA).

### 172 **3. Results**

#### 173 **3.1. Seasonal dynamics of environmental and biotic factors in Moso bamboo forest**

174 In 2013, the annual average air temperature was 1.2 °C higher and total precipitation 114.5 mm  
175 lower than the long-term averages. The 30.7 °C in July and 30.3 °C in August (Fig. 1) were as much  
176 as 7.9 and 2.8 °C higher, respectively, than the long-term averages. Precipitation was 57.2% and  
177 31.5% of the long-term average in July and August, respectively. The annual rainfall in 2013 was  
178 1298.7 mm, and occurred mostly from May to October. Additionally, it decreased by 57.18% in  
179 July compared with the corresponding period of long term (Fig. 1), showing exceptionally hot and  
180 dry conditions. Temperatures at different soil depths ( $T_{s5}$ ,  $T_{s50}$ ) and air temperature at 1m height  
181 ( $T_a$ ) exhibit a similar seasonal pattern (Fig.2A): a gradual increase from January to July, maximum  
182 in July, and a slow decrease till December.  $T_{s5}$  and  $T_{s50}$  changed comparatively more smoothly and  
183 steadily than  $T_a$ . Soil water content at 5 cm and 50 cm depths (SWC5 and SWC50) were obviously  
184 affected by rainfall, and were at the lowest in July and August.

185 Seasonal variation in net ecosystem exchange (NEE), ecosystem respiration (RE) and gross  
186 ecosystem productivity (GEP) showed several peaks during 2013. The lowest mean daily NEE  
187 was detected in August (0.76 g C m<sup>-2</sup>) (Fig. 2C), and highest in June and September. Additionally,  
188 NEE was positive on some rainy and cloudy days. Mean daily NEE, RE and GEP was -2.11 g C

189  $\text{m}^2 \text{ day}^{-1}$ ,  $5.36 \text{ g C m}^{-2} \text{ day}^{-1}$  and  $7.48 \text{ g C m}^{-2} \text{ day}^{-1}$ , respectively. Due to the impact of drought,  
190 GEP decreased significantly in July and August, being 59.9% and 80.0%, respectively, of GEP in  
191 the corresponding period in 2011 (Chen et al., 2016). LAI remained at approximately 3.6 in winter  
192 and spring, increased gradually starting from March, and reached a maximum (5.92) in July (Fig.  
193 2D). Thereafter, LAI decreased slowly, exhibiting the typical growth characteristic of Moso  
194 bamboo in an “on year” (Chen, 2016).

### 195 **3.2. Diurnal variation of soil $\text{CO}_2$ fluxes and its response to temperature**

196 Soil respiration ( $R_s$ ) in our forest presented similar diurnal dynamics across all seasons (Fig. 3A).  
197 After a daily minimum occurring between 05:00 to 07:00, it increased slowly reaching the  
198 maximum value between 14:00 to 16:00, and then decreased gradually. There were, however, big  
199 differences in  $R_s$  between months. Monthly maximum values of  $R_s$  ranged from 0.75 in January to  
200  $7.52 \mu\text{mol m}^{-2} \text{ s}^{-1}$  in August.

201 Monthly mean values of  $R_s$  correlated positively with both soil temperature at 5 cm depth ( $T_{s5}$ )  
202 measured by the EC system and air temperature ( $T_a$ ) ( $P < 0.01$ , not shown), with the correlation  
203 with  $T_{s5}$  being higher (Fig. 3B, Table 2). An exponential relationship was used to estimate  $R_s$  based  
204 on  $T_s$  (Table 1).  $T_s$  explained 69.7% variation of the variation in  $R_s$  at a diurnal scale, whereas  $T_{s5}$   
205 explained 63.9% (not shown). Both exponential regression models were statistically significant ( $P$   
206  $< 0.01$ ). Plotting the diurnal variation of  $R_s$  against  $T_s$ , and  $T_{s5}$  (Fig.4) showed a clear hysteresis.  
207 Additionally, there was slight discrepancy in the elliptic shape of  $T_s$  and  $T_{s5}$ , and the subtle  
208 difference in elliptic shape of both could explain the coefficient or determination ( $R^2$ ) of  
209 exponential regression in the relationship of  $T_s$  and  $T_{s5}$  (not shown).

### 210 3.3. Seasonal dynamics of soil CO<sub>2</sub> fluxes and its driving factors

211 Soil respiration followed a clear seasonal pattern in soil respiration (Fig. 3A), being highest in  
212 summer with 5.77  $\mu\text{mol CO}_2 \text{ m}^{-2} \text{ s}^{-1}$ , followed by autumn (3.50  $\mu\text{mol CO}_2 \text{ m}^{-2} \text{ s}^{-1}$ ), and spring (2.42  
213  $\mu\text{mol CO}_2 \text{ m}^{-2} \text{ s}^{-1}$ ), and lowest in winter (0.76  $\mu\text{mol CO}_2 \text{ m}^{-2} \text{ s}^{-1}$ ). The average annual soil CO<sub>2</sub> flux  
214 was 3.11  $\mu\text{mol CO}_2 \text{ m}^{-2} \text{ s}^{-1}$ , equating to an annual  $R_s$  of 44.07 t CO<sub>2</sub> ha<sup>-1</sup> a<sup>-1</sup>. Temperatures at  
215 different heights and depths presented similar seasonal dynamics, being highest in summer and  
216 lowest in winter (Fig. 3C). Furthermore,  $Q_{10}$  values were small in summer and large in winter  
217 (Table 1).

218 Monthly mean values of LAI, soil temperature and GEP were all significantly related to soil  
219 respiration (Table 2 and Fig. 5).

220 Within each seasonal, there was a complex linear relationship between SWC and  $R_s$ , with  
221 significant ( $P < 0.01$ ) negative correlation in summer ( $R = -0.796$ ,  $R_s = -19.101 * SWC + 10.368$ ),  
222 positive linear correlational in autumn ( $P < 0.01$ ,  $R = 0.552$ ,  $R_s = 47.663 * SWC - 7.012$ ) and spring  
223 ( $P < 0.05$ ,  $R = 0.331$ ,  $R_s = 36.661 * SWC - 6.708$ ), but no correlation ( $P > 0.05$ ) in winter ( $R = 0.008$ ),  
224 indicating that SWC played crucial role in  $R_s$  at the growing period of Moso bamboo. Soil  
225 temperature and soil moisture showed significant linear relationship in the summer ( $R = -0.939$ ,  
226  $T_s = -0.013 * SWC + 0.559$ ,  $P < 0.001$ ).

227 An exponential equation model was used to fit the relationship between different temperatures ( $T_s$ ,  
228  $T_{s5}$ ) and soil respiration (Fig.3C). The equations of  $T_{s5}$ - $R_s$  ( $R^2 = 0.954$ ) and  $T_{s50}$ - $R_s$  ( $R^2 = 0.929$ )  
229 both showed higher  $R^2$  than that of  $T_s$ - $R_s$  ( $R^2 = 0.915$ ), possible because of the relative stability of  
230 soil temperature profile measurement in eddy covariance system. Furthermore, due to the complex

231 relationship between SWC and  $R_s$ , as well as considering combination of temperature and soil  
232 moisture, six models were compared that predict  $R_s$  based on soil temperature and soil moistures  
233 (Table 3). Based on *RMSE* and  $R^2$ , the model ( $R_s = a + b \cdot \exp(c \cdot T_s) + d \cdot T_s \cdot \text{SWC}$ ) showed best  
234 result, suggesting  $T_s$  and SWC could explain 93.6% temporal variation of  $R_s$  in 2013. Compared  
235 with a soil temperature( $T_s$ )-soil respiration( $R_s$ ) equation (Fig.3C,  $R^2 = 0.915$ ), It showed a slight  
236 increase  $R^2$  (Table 3,  $R^2 = 0.936$ ).

#### 237 4. Discussion

238 Our work demonstrates the importance of three factors that affect soil respiration in Moso bamboo:  
239 temperature, soil water content and either productivity or LAI. The importance and interactions of  
240 the factors will be discussed subsequently.

241 Of the three factors, soil temperature was the dominant driver of soil respiration with an  $R^2$  of over  
242 0.8 (Fig. 3C and 5B). Seasonal change of  $R_s$  has been investigated in varying ecosystems. Soil  
243 temperature and soil water content are commonly considered to be two major determinants of  
244 seasonal variations in measured  $R_s$  (Davidson et al., 1998; Davidson et al., 2006a; Davidson et al.,  
245 2012; Sihi et al., 2018). In this study, soil respiration increased with the rising of soil temperature.  
246 Similar results were explored by Shi et al. (2012) on a global scale. However, soil temperature  
247 explained only 62.7% variation of soil respiration during summer (June, July and August). This  
248 was not only due to a lower variation of soil temperature during summer months, but also, as  
249 shown in Table 1, the temperature sensitivity of soil respiration was markedly lower in the summer,  
250 which was likely caused by low SWC values. Additionally, plots of soil respiration against daily  
251 temperature patterns show a rather flat relationship for the summer with a strong hysteresis. Similar

252 findings have been reported in Moso bamboo forest of subtropical China by Tang et al. (2016) and  
253 Song et al. (2013). Depth of the soil temperature measurement affected the explanatory power of  
254 soil temperature. The explanatory power of the temperature in the organic layer was highest and  
255 decreased with the depth of the measurements. This indicates that most of the respiration originates  
256 from the organic layer (Davidson et al., 2006b). Zhang et al. (2016) made similar observations in  
257 winter wheat ecosystems. While Dai et al. (2004) found soil respiration of wheat was highly  
258 correlated with soil temperature at 10 cm depth.

259 The relationship between soil carbon efflux and soil temperature showed a diurnal hysteresis (Fig.  
260 4). This indicates that there is a delayed effect of the rapidly varying temperature and diurnal  
261 variation of soil respiration, similar to the studies by Högberg et al. (2008), Abramoff et al. (2017)  
262 and Savage et al. (2009). One explanation is different diurnal temperature pattern at different  
263 depths and delays due to the transport of CO<sub>2</sub> from the sites of respiration to the soil surface (Graf  
264 et al., 2008). Furthermore, other research suggested that the length of the delay could vary among  
265 different species (Raich and Schlesinger, 1992). The hysteresis could also be an artifact for  
266 measuring soil temperature at a different depth than respiration is occurring. However, we tried  
267 different depths to measure soil temperature. Since the depth of the measurements of soil  
268 temperature varies between studies, it might be difficult to compare the sensitivity of soil  
269 respiration to soil temperature between studies (Zhang et al., 2016). Previous research suggested  
270 diurnal variation of R<sub>s</sub> was out of phase with corresponding T<sub>s</sub> at 2 cm depth, resulting in  
271 significant hysteresis (Gaumont-Guay et al., 2006). As discussed above, there may be two possible  
272 reasons (1) effects of diurnal variations of root respiration supplied by newly produced

273 photosynthetic products and (2) diurnal variations of soil water content near the critical value  
274 (Bahn et al., 2008; Davidson et al., 2012; Wang et al., 2015; Sihi et al., 2018), while further reasons  
275 for this (especially in winter) are needed controlled experiments to explore and demonstrate.  
276 The relationship between soil respiration and soil moisture was more complicated in our study.  
277 Soil moisture improved marginally our models of soil respiration with a better fit of the models  
278 particularly in the dry summer 2013. No significant correlation was found between soil respiration  
279 and soil moisture in 2013 (Fig. 3D). Similar findings had been reported for Moso bamboo forest  
280 in Zhejiang province (Song et al., 2013). However, soil moisture had a negative statistically  
281 significant ( $P < 0.001$ ,  $R = -0.796$ ,  $R_s = -19.101*SWC + 10.368$ ) correlation with soil respiration in  
282 summer while correlation in the other seasons was positive. Previous observation indicated a  
283 pronounced correlation between  $R_s$  and SWC in subtropical forests (Sheng et al., 2010; Liu et al.,  
284 2011). The negative correlation of soil respiration and soil moisture in our study was probably  
285 caused by a spurious correlation of soil temperature and soil moisture during summer ( $R = -0.939$ ,  
286  $T_s = -0.013*SWC + 0.559$ ,  $P < 0.001$ ). The cause of a nonexistent or negative linear correlation  
287 between SWC and  $R_s$  could be that natural variation of SWC covers only a part of response curve  
288 (at low to medium SWC,  $R_s$  depends positively on it because water is limiting, then there might  
289 be a plateau and at high SWC oxygen transport to the soil depth and transport of  $CO_2$  back might  
290 be blocked) (Linn and Doran, 1984; Xu et al., 2004). When we fitted non-linear models to soil  
291 respiration using temperature and soil moisture we got only a small increase in the  $R^2$  when soil  
292 moisture was included into the model. We have also checked the interaction between SWC and  
293 temperature (shown in Table 3) and our best model (last row in Table 3) shows that a model which

294 includes interactions was the best. This indicates that soil moisture was, even in the dry year of  
295 2013, not an important limitation of soil respiration.

296 The models of soil respiration suggest that the temperature sensitivity of soil respiration declines  
297 when soil moisture is decreasing (Almagro et al., 2009; Jassal et al., 2008; Wang et al., 2006), this  
298 may be due to the diurnal variation of soil moisture near the criticality value. Also,  $Q_{10}$  varied over  
299 the different seasons (Table 1). Due to smaller amplitude of soil temperature in deeper layers  
300 (Pavelka et al., 2007),  $Q_{10}$  values estimated from deeper soil layers tended to be larger than those  
301 of shallower layers. This can partly explain the discrepancy between  $T_a$ ,  $T_s$ , and  $T_{s5}$ .  $Q_{10}$  was about  
302 2.80 in our study, within range of 1.33~5.53 estimated for forests in China (Chen et al., 2008),  
303 lower than 4.09 in Moso bamboo forest of central Taiwan (Hsieh et al., 2016), but higher than  
304 median of 2.0~2.4 (Hashimoto, 2005).

305 Previous observation pointed out that annual  $Q_{10}$  value was not only an indicator of the response  
306 to soil temperature, but also a comprehensive response to variations of other factors (i.e. SWC,  
307 root biomass, root growth, amplitude of  $R_s$ , and other seasonal processes, Yuste et al., 2004).

308 Another driver of soil respiration is the phenology of Moso bamboo which shows a large variation  
309 in below ground activities. In the spring, carbon is allocated to the production of new bamboo  
310 shoots. After bamboo has completed its main growth period in summer and new leaves are fully-  
311 expanded, it accumulates nutrient substance and allocates its main growth to the rhizome. Then in  
312 autumn Moso bamboo starts to hatch bamboo shoots for the next year (Chen et al., 2016). In this  
313 growing phase, soil moisture was a key factor for soil respiration. Subsequently, the stand got into  
314 overwintering stage. Soil moisture became less important in this period. Consequently, the

315 importance of soil moisture for soil respiration varies among seasons and was more important  
316 during the time of active growth of Moso bamboo. However, soil temperature rather than soil  
317 moisture remained the most important drivers of soil respiration (Janssens and Pilegaard, 2003).  
318 The explanation for the differences in soil respiration and  $Q_{10}$  values are driven by the seasonal  
319 pattern of gross primary production which drives substrate supply to the root and rhizosphere  
320 (Bahn et al., 2008). Currently several authors have reported productivity should be considered to  
321 improve the prediction of soil respiration (Bahn et al., 2008; Hibbard et al., 2005; Vargas et al.,  
322 2011; Zhang et al., 2016). Numerous studies have shown close relations between soil respiration  
323 and canopy photosynthesis at different timescales. Högberg et al. (2008) reported that soil  
324 respiration was largely driven by recent primary production of the vegetation. Monthly soil  
325 respiration was significantly related to LAI and GEP in our study (Fig. 5A, 5C and 5D). The  
326 finding agreed with the view of a coupling of photosynthesis and soil respiration. Likewise, Yuste  
327 et al. (2004) found that seasonal  $R_s$  was positively related to LAI. Bahn et al (2008) suggested  $R_s$   
328 was closely related to LAI across grassland sites. In our study, LAI was closely related to the  
329 productivity of vegetation. There was similar monthly variation pattern of LAI and  $T_a$  in our study,  
330 which in turn increased the difficulty to detect relationships of  $R_s$  in relation to biological variable.  
331 Soil respiration is a complex biological process, composed of several processes from both  
332 autotrophic and heterotrophic organisms. Besides soil temperature and soil water content, it is  
333 known that soil respiration is partly explained by forest type, stand age and altitude in subtropical  
334 forests (Wang et al., 2011). Additionally, other variables such as management (i.e. fertilization,  
335 thinning and harvesting activities, Gao et al., 2014; Liu et al., 2011), litter, soil microbial (Linn

336 and Doran, 1984) and physical properties, root biomass and extreme weather (e.g. warming,  
337 precipitation events, short-term drought events), all have indirect and direct effects on soil  
338 respiration. However, how these influence autotrophic and heterotrophic processes is not well  
339 understood and should be a subject of further research.

## 340 **5. Conclusions**

341 Soil respiration ( $R_s$ ) in the Moso bamboo forest exhibited both daily and seasonal dynamic  
342 patterns, with its highest values in summer and lowest values in winter. Soil respiration correlated  
343 positively with soil temperature ( $P < 0.01$ ), which explained 69.7% of variation in  $R_s$  at a diurnal  
344 scale and 91.5% of variation in  $R_s$  for the whole year.  $R_s$  correlated positively with soil moisture  
345 in spring, autumn, and negatively in summer, implying that moisture played a crucial role in  
346 different growth phases, but did not correlate significantly on daily scale, this may result from soil  
347 carbon substrate supply limiting soil microbial respiration in summer, and enhancing soil  
348 respiration in winter given substrate diffusion to the reaction site, which is generally driven by the  
349 thickness of the soil water film. The model that included soil temperature and soil moisture  
350 explained 93.6% of the seasonal variation in  $R_s$ . The relationship between  $R_s$  and different soil  
351 temperature exhibited a clear hysteresis. Soil respiration correlated positively ( $P < 0.01$ ) with gross  
352 ecosystem productivity and LAI in our study, showing the significance of biotic factors in affecting  
353 soil respiration, and a need for future research to analyze the relationship between canopy  
354 photosynthesis and soil  $CO_2$  flux.

## 355 **Acknowledgements**

356 We thank Li Y for giving comments that greatly improved this manuscript. Tan Y provided field

357 assistance. And we also would like to thank Professor Jiang Hong ' s team for their invaluable  
358 support with the flux data collection. The authors also would like to thank the editor, three  
359 reviewers and Prof. Petri Penttinen for their contribution to the peer reviews of this study.

**Figure 1**(on next page)

Monthly and long-term average air temperature ( $T_a$ ) and precipitation at the study site

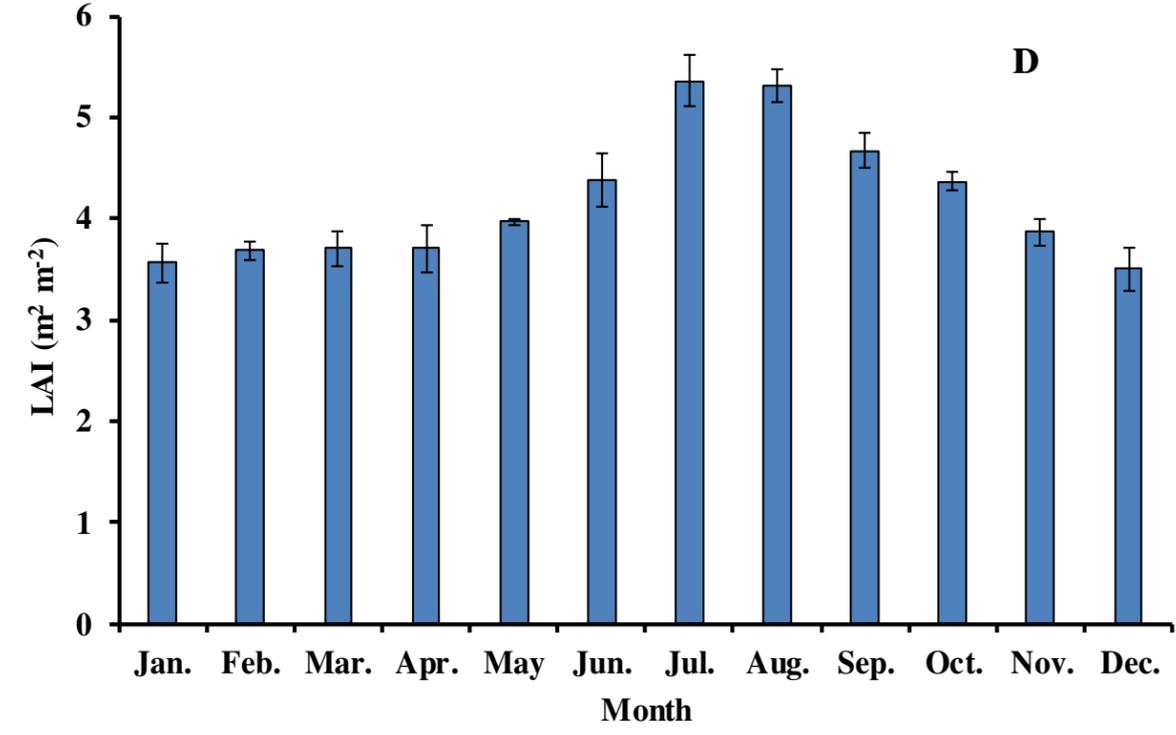

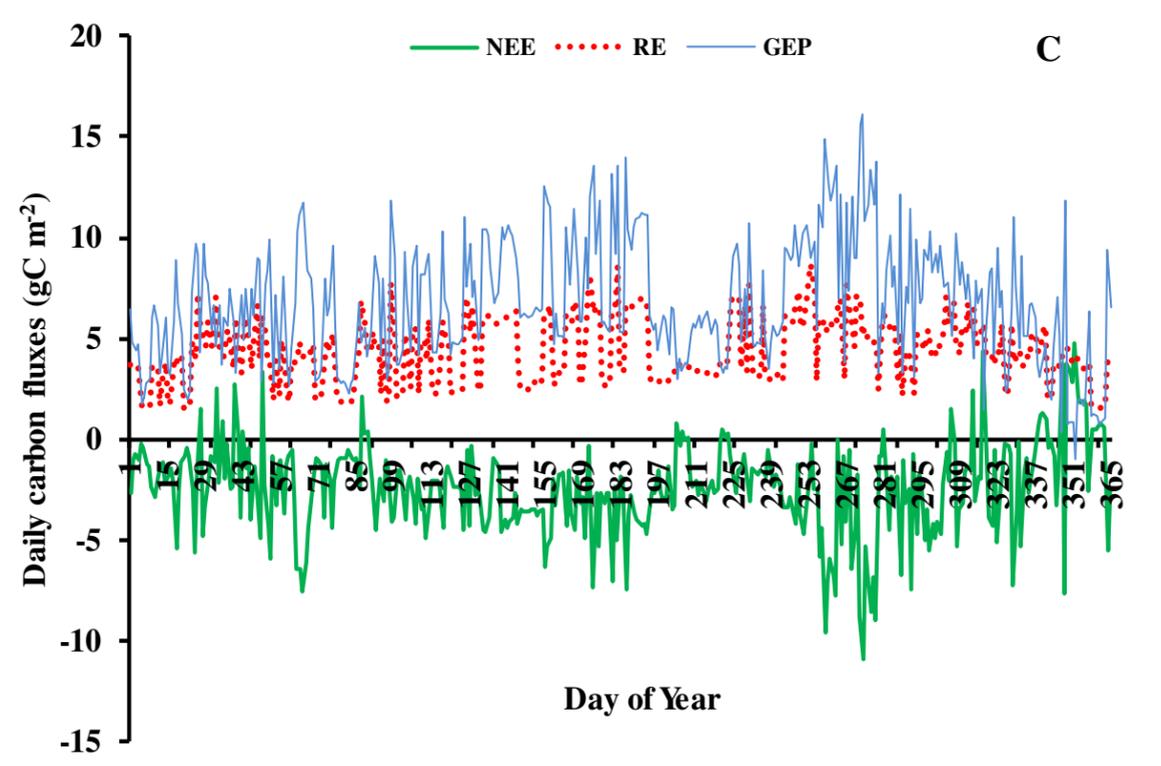

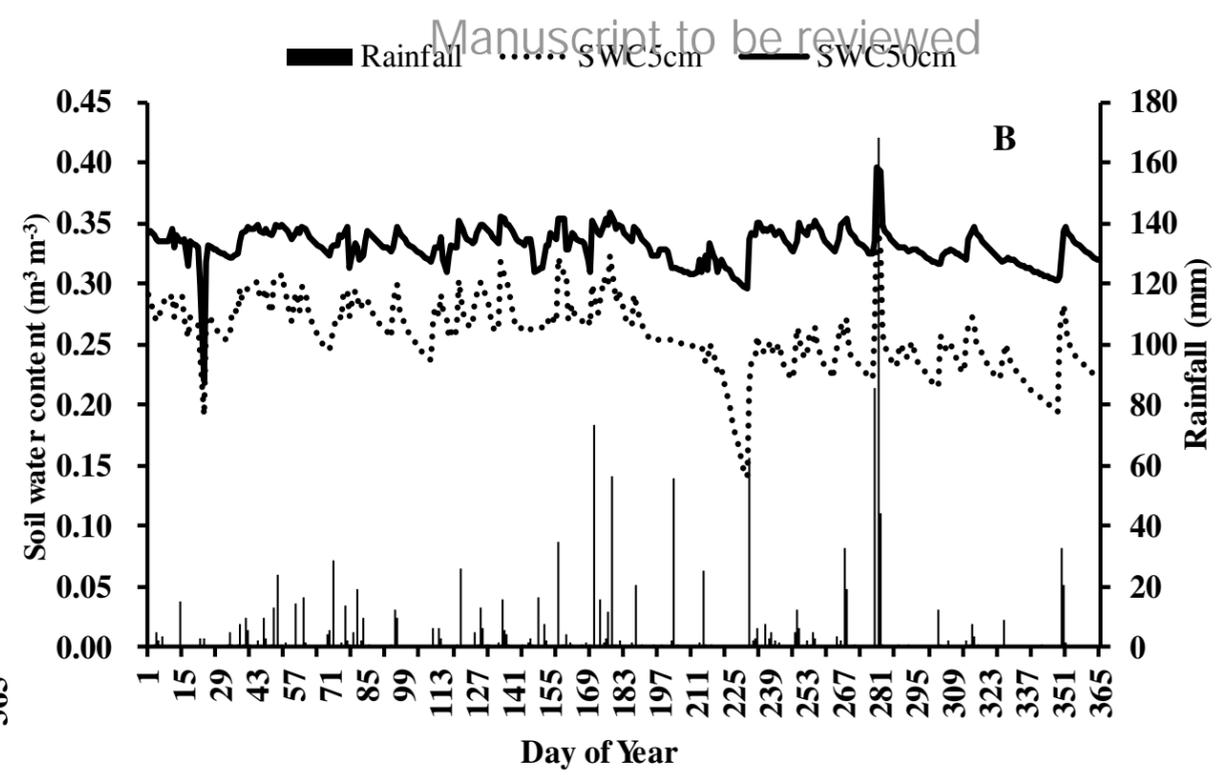

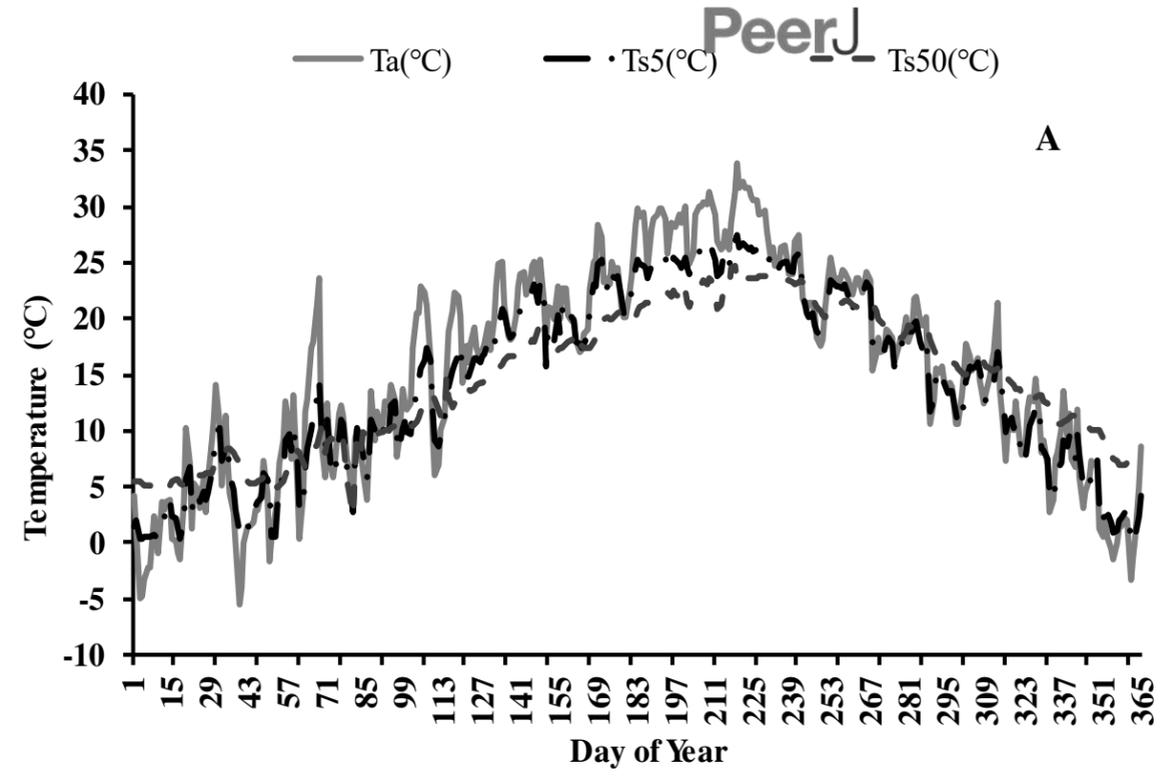

White circles are monthly air temperature in 2013, black triangles denote long-term average air temperature; grey rectangles are monthly precipitation in 2013, white ones denote long-term average precipitation.

**Figure 2**(on next page)

Seasonal variation of abiotic and biotic factors of Moso bamboo forest in 2013.

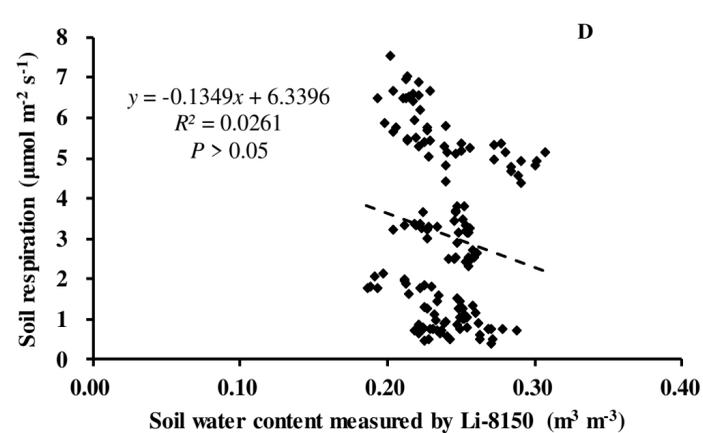

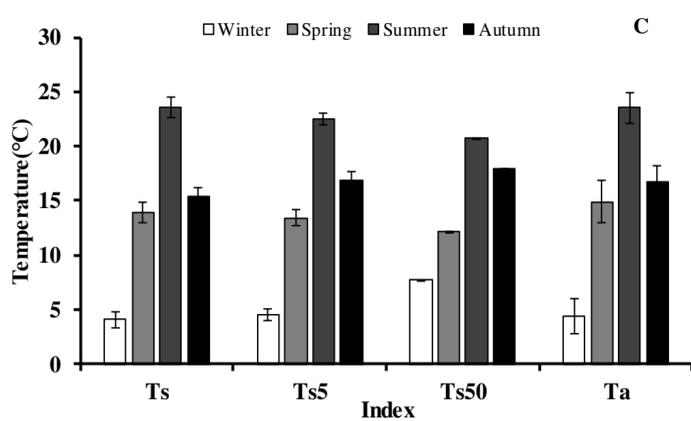

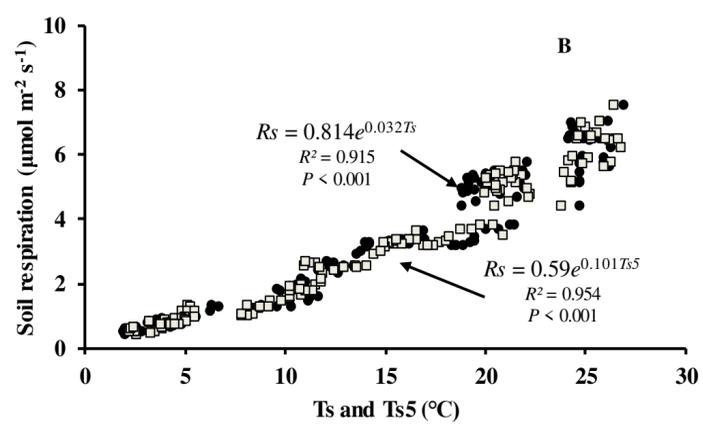

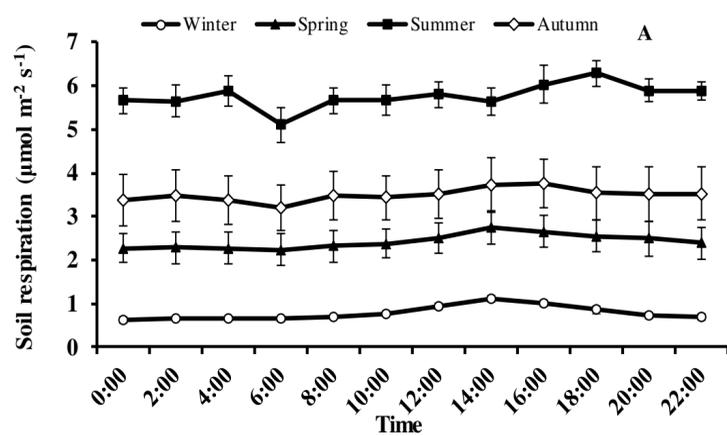

(A) daily temperature ( $^{\circ}\text{C}$ ) of air ( $T_a$ ) and soil at 5 cm( $T_{s5}$ ), 50cm( $T_{s50}$ ) depth, (B) Daily rainfall amount (mm) and soil water content ( $\text{m}^3 \text{m}^{-3}$ ) at 5 cm depth ( $\text{SWC}_5$ ) and 50 cm depth ( $\text{SWC}_{50}$ ), (C) daily carbon fluxes (NEE, RE, GEP,  $\text{gC m}^{-2}$ ), (D) mean monthly LAI ( $\text{m}^2 \text{m}^{-2}$ ) during the study period Mean  $\pm$  SD (n=3).

**Figure 3**(on next page)

Diurnal, seasonal dynamic of soil respiration and the relationship between related factors and soil respiration in Moso bamboo forest.

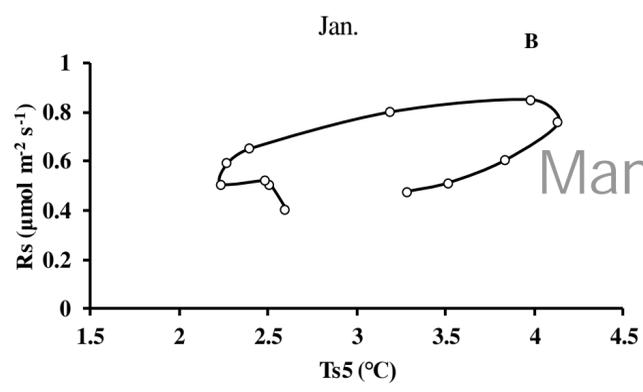

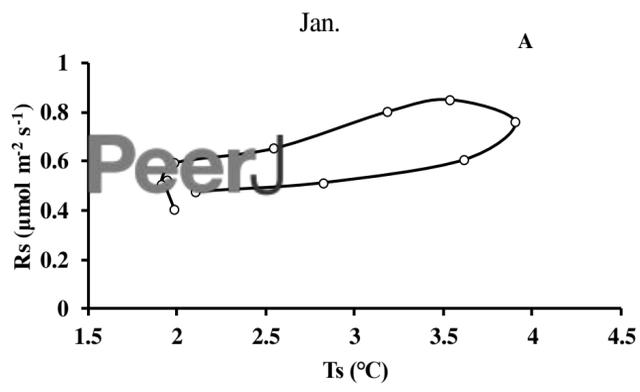

(A, error bars denote standard error of means,  $n=12$ ). Seasonal variation of soil respiration (B,  $T_s$ , black circle,  $T_{s5}$ , white diamond,  $n=144$ ), and (C) seasonal variation of different temperatures; (D) relationship between soil water content and soil respiration ( $n=144$ ) error bars indicate standard deviation of the means ( $n=12$ ).

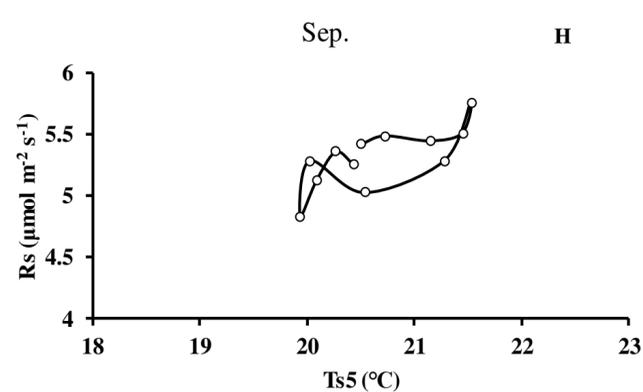

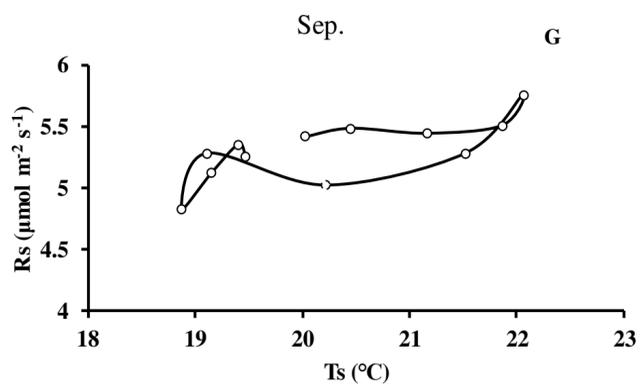

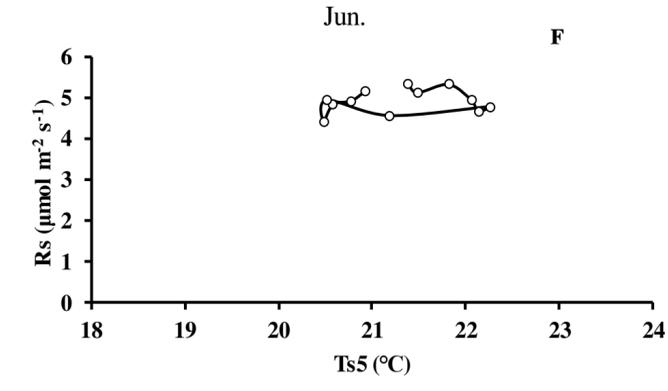

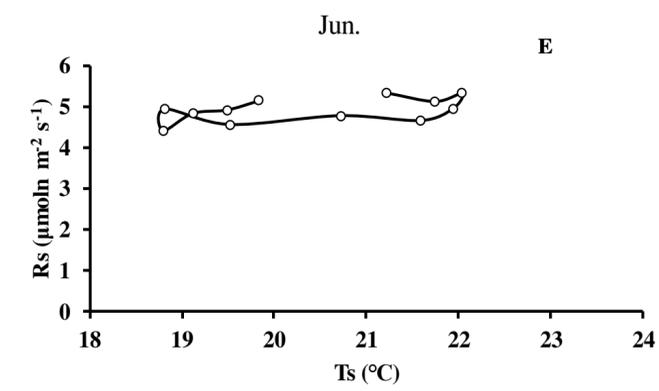

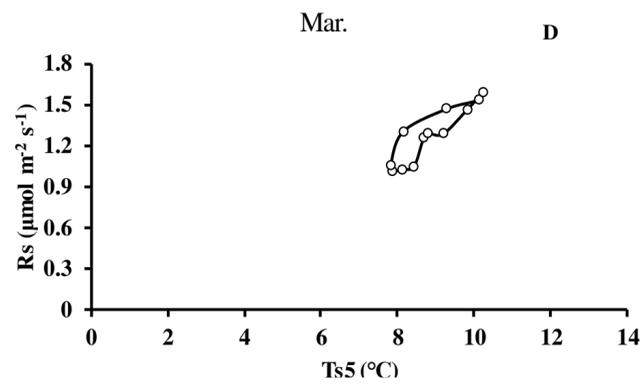

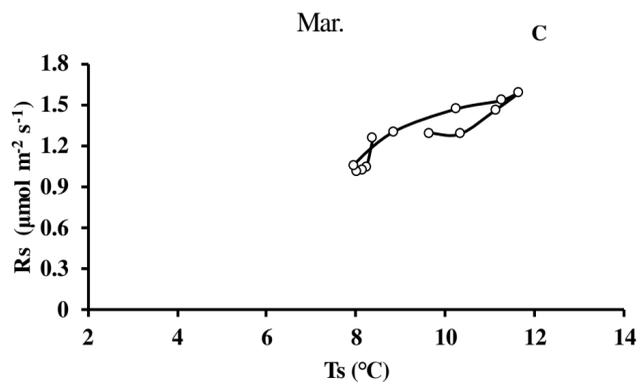

**Figure 4**(on next page)

Mean diurnal changes of  $R_s$  in response to  $T_s$  and  $T_{s5}$  in different months of Moso bamboo forest.

$R_s$  denotes soil respiration,  $T_s$  denotes soil temperature measured by Li-8150,  $T_{s5}$  denotes soil temperature at 5 cm depth measured by eddy covariance technique. one month of the season was chosen.

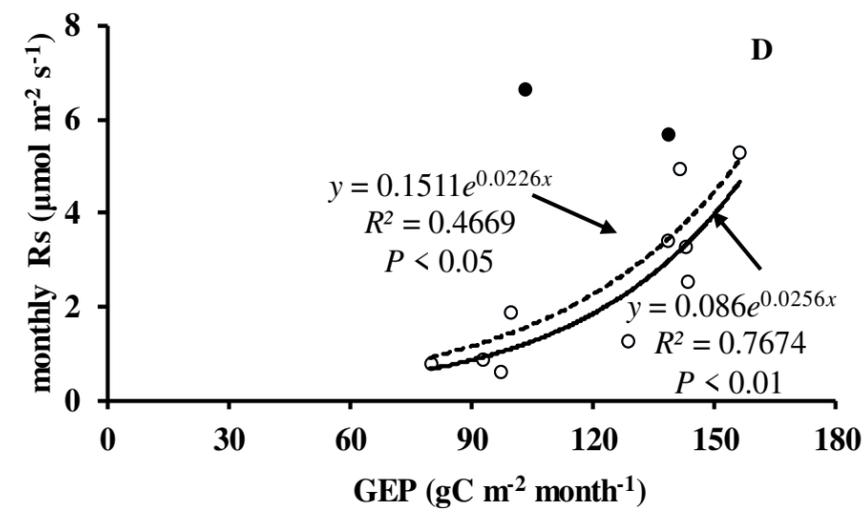

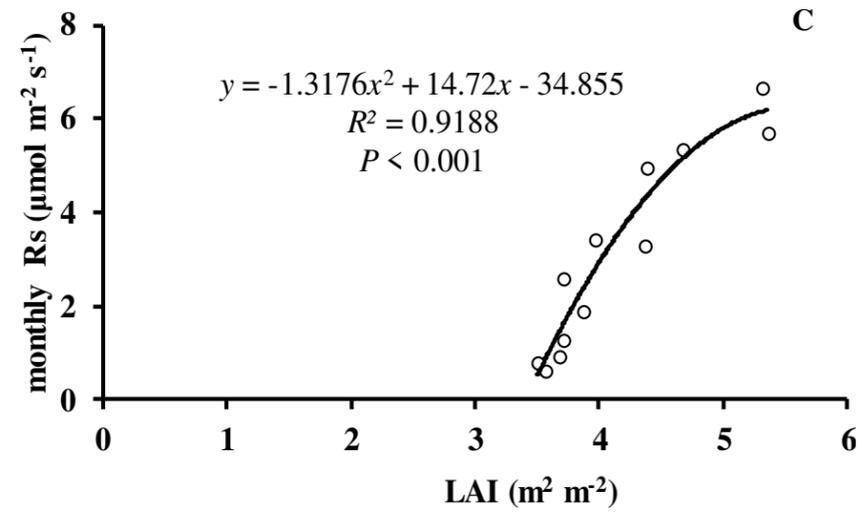

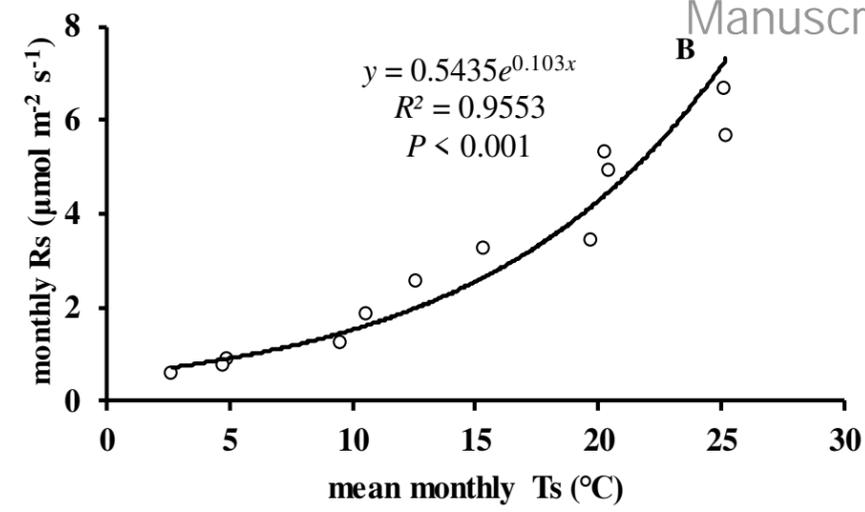

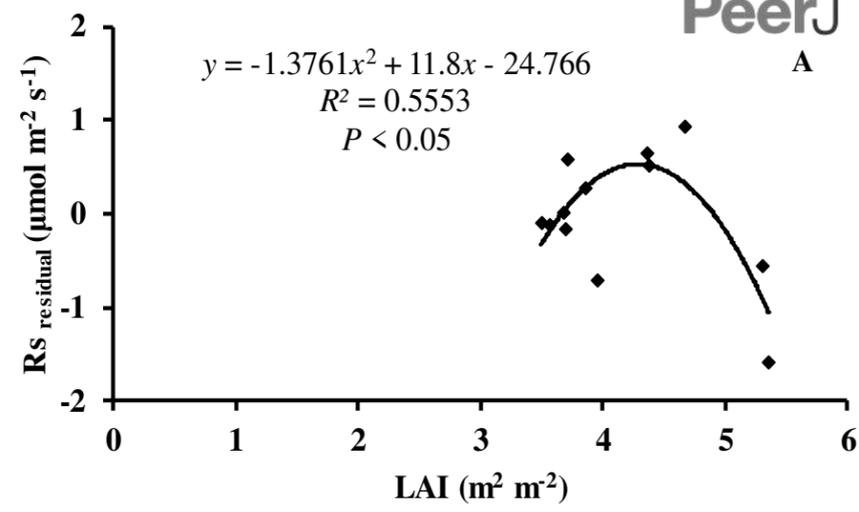

Manuscript to be reviewed

**Figure 5**(on next page)

Relationship between monthly soil respiration and leaf area index ,gross ecosystem productivity.

(A) Residuals of observed minus predicted (calculated by the best model in the last row of Table 3) values of  $R_s$  in relation to monthly values of LAI . monthly  $R_s$  in relation to (B) mean monthly soil temperature, (C) LAI, and (D) monthly GEP .Black circles denote GEP of July and August, hollow circles are months excluding July and August; Dotted line is relationship including all the months in 2013, whereas solid line is excluding  $R_s$  of July and August.

**Table 1** (on next page)

Relationships between mean diurnal soil respiration ( $R_s$ ) and soil temperature measured by Li-8150 ( $T_s$ ) in 2013.

$R_s$  is soil respiration,  $T_s$  is soil temperature measured by Li-8150.

1 **Table 1.** Relationships between soil respiration ( $R_s$ ) and soil temperature measured by Li-8150  
2 ( $T_s$ ).  
3

Time	Equation	$R^2$	$Q_{10}$	$F$	$P$
Dec.~Feb.	$R_s=0.279\exp(0.241*T_s)$	0.684	11.08	73.74	0.000
Mar.~May	$R_s=0.629\exp(0.095*T_s)$	0.819	2.59	154.39	0.000
Jun.~Aug.	$R_s=1.427\exp(0.058*T_s)$	0.627	1.79	57.08	0.000
Sep.~Nov.	$R_s=0.594\exp(0.107*T_s)$	0.983	2.92	1976.33	0.000
