Short title: Endophytes and foliar traits in oak

Keywords Phyllosphere, Bacteria, Leaf Traits, Seasonality, Forest, Biological Interaction

ABSTRACT

We studied the relationship between plant functional foliar traits and the endophytic bacterial communities associated in trees, taking the example of sessile oak (*Quercus petraea* (Matt.) Liebl). Forty-five samples of leaves were collected in spring, summer and autumn. Bacterial community diversity was analyzed via Automated Ribosomal Intergenic Spacer Analysis (ARISA). For each sample, the Specific Leaf Area (SLA), level of herbivory, stomatal number, stomatal length, carbon and nitrogen concentration were measured. For statistical analysis, the Canonical Correlation Analysis (CCA) and Non-Parametric Multivariate Analysis of Variance (NPMANOVA) were applied. Significant difference in herbivory, nitrogen and carbon concentration were found between summer and autumn (p value < 0.01). The seasonal differentiation of the bacterial community structure was explained by the first and second axes (29.7 % and 25.3 %, respectively) in the CCA. The most important foliar drivers resulted to be herbivory, nitrogen concentration and stomatal number.

INTRODUCTION

In biological sciences, besides specialization, integrating various scientific disciplines is a current major goal (Niklas, Owens & Wayne, 2013). One of the interfaces of biological interaction is between microbiota and plants. While many integrative studies exist, regarding description of bacterial taxa related to host plants and linking bacterial and plant communities across different spatial scales (e.g. symbiosis), temporal scales remain less unexplored. Plant functional traits are increasingly used in ecological research and are a promising avenue to link plant characteristics to environmental factor in interdisciplinary researches (Cornwell et al. 2008; Wellstein et al. 2011). In this sense, the leaf environment is characterized by foliar functional traits that are hypothesized to affect the hosted microbiome. In the context of the leaf environment of deciduous trees and inhabiting endophytic bacteria, intra-annual dynamics are of special interest.

Endophytic bacteria are ubiquitous inhabitants that colonize the inner parts of most terrestrial plant species beyond the epidermal cell layers (Lodewyckx et al. 2015; Santoyo et al. 2016). Inside the plant, there are diverse ecological niches in which endophytic bacteria can survive and grow, i.e. within cells, in the intercellular space. and in the vascular systems (Jacobs, Bugbee & Gabrielson, 1985; Bell et al. 1995; Kembel et al. 2014). Endophytic bacteria are very important to the host plant as they can contribute to the maintenance of its growth and health by,

e.g. promoting nutrient acquisition and defense against pathogens (Hirano *et al.* 1982; Afzal, Khan & Sessitsch, 2014). This is particularly true for long-lived plant species such as trees and consequently they could affect forest ecosystems (Tashi-Oshnoei, Harighi & Abdollahzadeh, 2017). Endophytic bacteria have often long-term ecological interactions with the host plants including symbiosis, mutualism and commensalism. They can either be obligate or facultative endophytes. Obligate endophytes have a strictly dependent association with the host plant and they are eventually transferred vertically through plant-host generations (Santoyo *et al.* 2016). Facultative endophytes originate from the surrounding environment and they are often included within epidermal cell layers (Hardoim, van Overbeek & van Elsas, 2008).

Different plant organs have diverse ways of colonization. Roots acquire endophytic bacteria from free-living organisms from the soil (Bulgarelli *et al.* 2012; Edwards *et al.* 2015). Leaf endophytic bacteria, especially in case of tall trees, can be acquired from the leaf surface via stomata that represent apertures in the foliar tissue connected to the intercellular space (Ou *et al.* 2014; Carrell, Carper & Frank, 2016). It has been hypothesized that leaves are a suitable surface for exchange with bacteria inhabiting the atmosphere (Bowers *et al.* 2009). Microbial communities inhabiting leaves, including endophytic bacteria, appear to be rather specialized, given that they share less than 1% of the bacterial species with soil (Kim *et al.* 2012).

While numerous publications are focused on leaf epiphytic bacteria (Hirano *et al.* 1982; Balint-Kurti *et al.* 2010; Lopez-Velasco *et al.* 2011), leaf endophytic bacteria remain largely unexplored. Moreover, the possible role of plant functional traits for bacterial community dynamics represents a research gap. In detail, there are a few studies regarding the temporal dynamic and the environmental factors driving the endophytic bacterial communities associated with forest tree species. Previous works revealed that endophytes are subject to leaf age and leaf developmental stage in grapevine and in elm (Mocali *et al.* 2003; Bulgari *et al.* 2014). However, the potential drivers affecting the endophytic bacteria composition behind leaf aging are still not well understood, especially in forest plants.

In our study, we aimed to test (i) if there is a temporal gradient associating leaf aging with bacterial turnover and (ii) if foliar plant traits are linked to bacterial community dynamics across time.

MATERIALS AND METHODS

Study site and sampling

The study area is located in the Monticolo nature reserve on the hillslopes of the Mitterberg at 550 m a.s.l. in South Tyrol, Italy. The selected study site is representative of the present oak forest, dominated by sessile oak (*Quercus petraea* (Matt.) Liebl.) and admixed with few specimens of Scots pine (*Pinus sylvestris* L.) in the tree layer as well as of Sweet chestnut (*Castanea sativa* Mill.) and Manna ash (*Fraxinus ornus* L.) in the understory. The forest grows on acidic shallow soil above porphyry bedrock on a west-south-west oriented slope. We selected five individuals of sessile oak within the study site, i.e. a circular plot of 15 m radius (706 m²) representing relatively homogeneous site conditions within the slope. From each tree, we sampled three branches taking eight leaves from the same branch, which were used to assess the endophytic bacteria as well as the foliar functional traits. In detail, we used three leaves for the functional traits measurements and five leaves for the determination of the endophytic bacterial microbial community. We sampled three subsequent seasons in the year 2014, i.e. spring (June 5th), summer (August 25th) and autumn (October 20th). A total of 45 samples was collected.

For each season, we determined the Specific Leaf Area (SLA) of sampled leaves following standard protocols (*Pérez-Harguindeguy et al. 2013*). For each leaf, the leaf area was measured at the day of sampling using a scanner (CanoScan Lide, Canon, Cernusco sul Naviglio, Italy). Subsequently, leaves were oven dried at 70°C for 72 hours to obtain their dry weight and the SLA, measured in mm² mg⁻¹, was calculated (*Pérez-Harguindeguy et al. 2013*). Leaf nitrogen (N) and carbon (C) content was determined using an elemental analyzer (Flash 2000 Organic Elemental Analyzer, Thermo Scientific, Milan, Italy).

To measure the stomatal characteristics, epidermal impressions of the leaves were examined under an optical microscope connected to a digital microscope camera and the images were analyzed through an image processing software (DeltaPix InSight, DeltaPix, Smorum, Denmark). We used a standard counting area replicated three times on each leaf to determine the stomatal density as number of stomata (STNR) for each standard counting area. On each counting area, the length of the guard cells of stomata (SL) was measured for 15 randomly selected stomata per counting area. Additionally, the percentage of consumed leaf area was estimated to describe leaf-level herbivory. Mean values were calculated per branch, which were used in the statistical analyses.

DNA extraction and ARISA

Leaves used for microbiological analysis were processed within 4 hours as follows: Five leaves for each replicate were disinfected with 70% ethanol twice each for 3 min. Leaves were then washed with sodium hypochlorite (1.5%) and Tween 20 for ten minutes, three rinses in sterile, distilled shaking water. Disinfected leaves were grinded to a fine powder under liquid nitrogen using a sterile mortar and pestle. The disinfected samples were stored at -20°C. Triplicates of the water used in the last rise were used as negative for PCR amplification and plated on a LB and TSA medium to verify the disinfection protocol. Absence of PCR amplification products was observed. Furthermore, absence of bacterial colonies was observed in all the plates after 10 days of incubation at 30°C.

DNA was extracted using the Qiagen DNeasy PowerPlant Pro Kit (Qiagen, Milan, Italy) accordingly to the user's manual. Extracted DNA was stored at -80°C. The quality and the size of the soil DNA were checked by electrophoresis on 1.2% agarose gel with a marker (Eurogentec Smart Ladder, Belgio). The absorbance (260 nm) of 2 µl of DNA was used to evaluate the concentration of DNA by NanoVue Spectrophotometer (GE Healthcare, Little Chalfont, UK).

PCR was performed using the primers ITSF and ITSReub labeled with 6-FAM according to the chemical and thermal amplification protocol of Cardinale et al. (2004). Capillary electrophoresis was done by STAB Vida Lda. (Caparica, Portugal). Data were investigated via Peak Scanner Software 1.0 (Applied Biosystems, Monza, Italy) and the downstream matrix was normalized and analyzed according to Borroso et al. (2015).

Data analysis

PAST software (Hammer, Harper & Ryan, 2001) was used for the statistical analysis. ANOVA was used to test for differences in the functional leaf traits and the endophytic bacterial richness between seasons. Canonical correspondence analysis (CCA) of the endophytic microbial community structure in dependence of functional leaf traits and season was performed. Non-Parametric Multivariate Analysis of Variance (NPMANOVA) with Bonferroni corrected *p*-value was applied to investigate differences among the endophytic bacterial communities across the three seasons using Bray-Curtis dissimilarity distance.

RESULTS

Functional leaf traits

Figure 1 shows the functional leaf traits investigated in this study across the three sampling seasons. Leaf nitrogen and carbon concentration was significantly lower in autumn than in spring and summer ($p < 0.05$). The C:N ratio and the level of herbivory were significantly higher in autumn than in spring and summer ($p < 0.05$). Stomatal length, stomatal number and specific leaf area did not show significant differences across the seasons ($p > 0.05$).

Bacterial community structure

An average of 82 ± 15 peaks per sample representing bacterial richness, ranging from 200 bp to 1200 bp, were found. No significant results in terms of number of peaks across the three seasons were found (spring 82 ± 9 ; summer 86 ± 19 and autumn 79 ± 14 ; ANOVA p -value: n.s.). NPANOVA showed significant differences between the bacterial community structure of spring and of autumn ($p < 0.001$), while the bacterial community structures of summer did not cluster apart (Table 1).

Canonical correspondence analysis (CCA)

Canonical correspondence analysis (CCA) was used to investigate the effects of functional leaf traits and the level of herbivory on endophytic bacterial communities across the seasons. Differentiation is illustrated by the first and second axes in the CCA (29.7% and 25.3%, respectively) and the leaf features fitted into the CCA. The CCA ordination diagram (Figure 2) revealed first, that community structure variation appeared along season (temporal sequence) and, second, the existence of relationships between plant foliar traits and endofoliar microbiota across the temporal sequence. In detail, the community variation is related mainly to the level of herbivory, leaf nitrogen content and stomatal length, and less to stomatal number, leaf carbon content and specific leaf area (length of vectors in the ordination diagram; Figure 2).

DISCUSSION

We explored the seasonal diversity behavior via fingerprinting ARISA of the of leaf endophytic bacterial communities. ARISA is a corroborate technique used to investigate bacterial structure variations and the correlations with environmental parameters (*Esposito et al. 2013; Borruso, Zerbe & Brusetti et al. 2015; Pioli et al. 2018*) with a comparable robustness as Next Generation

Sequencing (*van Dorst et al. 2014*). Although the bacterial community did not show significant differences in alpha diversity across the three seasons, a general trend of the bacterial community structure differentiation mainly between spring and autumn was found (Table 1 and Figure 2). These results support the idea of an intimate association between endophytes and the leaf, seen as a dynamic micro-ecosystem that selects for different specific microbial communities along time. Leaves have been traditionally considered as “short-lived environment”, where specialized bacteria can dynamically colonize new niches and leave others according to the leaf continuous modifications over seasons (*Vorholt 2012*). Bulgari et al. (*2014*) hypothesized that the endophytic communities in *Vitis vinifera* should remain stable across the seasons in absence of bacterial plant pathogens such as phytoplasma. However, this is in contrast with our findings and those of other researchers. Influence of the seasonality on endophytic microbial community composition associated with different tree species (i.e. *Acer negundo*, *Ulmus pumila*, and *U. parvifolia*) were also found by Shen & Fulthorpe (*2015*). Moreover, others observed that the bacterial community composition in the phyllosphere was primarily driven by temporal changes and community succession (*Copeland et al. 2015*). In order to shed light on the processes behind community changes, we explored the role of leaf functional traits in bacterial structure dynamics. In fact, previous studies investigated the effect of migration and community succession in the phyllosphere microbiome and suggested that colonization, persistence, and succession of the community may be key-factors driving the phyllosphere microbiome (*Redford & Fierer 2009; Shade, McManus & Handelsman, 2013; Maignien et al. 2014; Copeland et al. 2015*). The relevance of environmental conditions such as temperature optima of the bacteria or the changing physiology of tree host species have been discussed for their possible effects (*Jansson & Douglas 2007*). However, previous studies did not look deeper into possible drivers in terms of plant functional characteristics behind the observed dynamical processes of the microbiome.

Given that we found a clear endophytic seasonal variation, it is highly interesting to understand better the potential leaf-level drivers behind the compositional variation. In fact, based on our results, we suggest that foliar characteristics related to leaf-level herbivory, nutrient contents and stomatal aperture affect directly the bacterial community composition over time. Indeed, there is evidence that plants regulate to some extent the access of bacteria through stomata (*Gimenez-Ibanez et al. 2017*). In addition, leaf nutrient contents and their changes can influence bacteria. It has been shown that endophytic bacterial taxa able to fix nitrogen occur in oak species

(Tashi-Oshnoei, Harighi & Abdollahzadeh, 2017) and in *Pinus flexilis* needles (Moyes et al. 2016) and, eventually, a drop in leaf nitrogen content could challenge bacterial shifts towards nitrogen-fixing taxa and in contrast to denitrifying bacteria.

Our results of diminishing nutrients such as C and N with leaf aging is in line with other studies (Li et al. 2017), while other functional traits related to the stomata, such as stomatal length and stomatal density and specific leaf area did not vary significantly along season. Another study on leaf traits showed that even such traits could show seasonal variation (Römermann et al. 2016). However, these results are based on different tree species growing in different environments. In comparison, our species *Q. petraea* might have relatively stable stomatal and specific leaf area trait levels based on the relatively rigid leaf. Moreover, herbivory that increases along season due to elongated exposure time, can have direct impact on endophytic bacteria as well as indirect impact influencing other leaf characteristics. For example, the open structures of the leaf, limited to the size and number of stomata in intact leaves, are largely modified by herbivory that exposes further leaf tissue. Due to the increasing rate of changes that can be assumed with aging, we expect that leaf characteristics exert a differential impact during aging on the bacterial community.

Conclusions

Based on our findings, we suggest that leaf-level of herbivory, nitrogen content, and size of stomatal aperture are main drivers affecting the endophytic bacterial community composition in oaks growth in alpine forest environments.

Figure and Tables captions

Figure 1 Differences of foliar traits (N = nitrogen, C = carbon, C:N = carbon/nitrogen ratio, SLA = specific leaf area, STL = stomatal length, STNR = stomatal number per reference area, HERB = level of herbivory) among three seasons (spring, summer, autumn). Significant differences according to ANOVA followed by post-hoc test are indicated by different lower case letters. Graphics without letters were not significant.

Figure 2 CCA analysis of endophytic communities across a temporal sequence (spring: blue dots; summer: green dots; autumn: red dots) and plant foliar traits. CCA was calculated with the following plant foliar traits: HERB = level of herbivory; STNR = number of stomata; SLA = specific leaf area; SL = length of stomata; N = leaf nitrogen content; C = leaf carbon content.

Table 1 *P* value results from Non-Parametric MANOVA (NPMANOVA) with Bonferroni corrected *p* value among endophytic bacterial communities across the three seasons (Bray-Curtis dissimilarity).

Figure 1(on next page)

Differences of foliar traits among three seasons.
