This paper is the last of a three-part series that investigates the architecture of cancellous bone in the main hindlimb bones of theropod dinosaurs, and uses cancellous bone architectural patterns to infer locomotor biomechanics in extinct non-avian species. Cancellous bone is highly sensitive to its prevailing mechanical environment, and may therefore help further understanding of locomotor biomechanics in extinct tetrapod vertebrates such as dinosaurs. Here in Part III, the biomechanical modelling approach derived previously was applied to two species of extinct, non-avian theropods, *Daspletosaurus torosus* and *Troodon formosus*. Observed cancellous bone architectural patterns were linked with quasi-static, three-dimensional musculoskeletal and finite element models of the hindlimb of both species, and used to derive characteristic postures that best aligned continuum-level principal stresses with cancellous bone fabric. The posture identified for *Daspletosaurus* was largely upright, with a subvertical femoral orientation, whilst that identified for *Troodon* was more crouched, but not to the degree observed in extant birds. In addition to providing new insight on posture and limb articulation, this study also tested previous hypotheses of limb bone loading mechanics and muscular control strategies in non-avian theropods, and how these aspects evolved on the line to birds. The results support the hypothesis that an upright femoral posture is correlated with bending-dominant bone loading and abduction-based muscular support of the hip, whereas a crouched femoral posture is correlated with torsion-dominant bone loading and long-axis rotation-based muscular support. Moreover, the results of this study

also support the inference that hindlimb posture, bone loading mechanics and muscular support strategies evolved in a gradual fashion along the line to extant birds.

29 **III.1 Abstract**

30

31 This paper is the last of a three-part series that investigates the architecture of cancellous bone in
32 the main hindlimb bones of theropod dinosaurs, and uses cancellous bone architectural patterns to
33 infer locomotor biomechanics in extinct non-avian species. Cancellous bone is highly sensitive to
34 its prevailing mechanical environment, and may therefore help further understanding of
35 locomotor biomechanics in extinct tetrapod vertebrates such as dinosaurs. Here in Part III, the
36 biomechanical modelling approach derived previously was applied to two species of extinct, non-
37 avian theropods, *Daspletosaurus torosus* and *Troodon formosus*. Observed cancellous bone
38 architectural patterns were linked with quasi-static, three-dimensional musculoskeletal and finite
39 element models of the hindlimb of both species, and used to to derive characteristic postures that
40 best aligned continuum-level principal stresses with cancellous bone fabric. The posture
41 identified for *Daspletosaurus* was largely upright, with a subvertical femoral orientation, whilst
42 that identified for *Troodon* was more crouched, but not to the degree observed in extant birds. In
43 addition to providing new insight on posture and limb articulation, this study also tested previous
44 hypotheses of limb bone loading mechanics and muscular control strategies in non-avian
45 theropods, and how these aspects evolved on the line to birds. The results support the hypothesis
46 that an upright femoral posture is correlated with bending-dominant bone loading and abduction-
47 based muscular support of the hip, whereas a crouched femoral posture is correlated with torsion-
48 dominant bone loading and long-axis rotation-based muscular support. Moreover, the results of
49 this study also support the inference that hindlimb posture, bone loading mechanics and muscular
50 support strategies evolved in a gradual fashion along the line to extant birds.

61 **III.2 Introduction**

62

63 The non-avian theropod dinosaurs include some of the most recognisable of extinct animals, and
64 with the carnivorous lifestyle and large body size of many species, they have received much
65 attention concerning various aspects of their palaeobiology (e.g., Alexander 1989; Bakker 1986;
66 Brusatte et al. 2010; Horner & Lessem 1993; Molnar & Farlow 1990). Locomotion in particular
67 is a well-studied (and sometimes controversial) topic, not only because of the interest in how a
68 giant, bipedal predator may have functioned, but also because it was likely intimately tied to the
69 evolution of the living decendants of non-avian dinosaurs, the volant birds (Allen et al. 2013;
70 Gatesy 1990; Gatesy 1995; Gatesy 2002; Gatesy & Middleton 1997; Hutchinson & Allen 2009).
71 A variety of different approaches and lines of evidence have been previously used to address
72 questions of locomotor biomechanics in non-avian theropods and its evolution on the line to
73 birds, including fossil footprints (Farlow et al. 2012; Gatesy et al. 1999; Thulborn 1990), external
74 bone shapes and proportions (Carrano 1998; Carrano 2000; Gatesy & Middleton 1997; Paul
75 1998), bone scaling (Carrano 2001; Christiansen 1999; Gatesy 1991), midshaft cortical geometry
76 (Alexander 1989; Christiansen 1998; Farlow et al. 1995) and muscle attachments and
77 significance (Carrano & Hutchinson 2002; Gatesy 1990; Hutchinson 2001a; Hutchinson 2001b).
78 These have been more recently augmented with various computational biomechanical models,
79 that have examined aspects such as speed capabilities (Gatesy et al. 2009; Hutchinson 2004;
80 Hutchinson & Garcia 2002; Sellers & Manning 2007), muscle moment arms (Bates & Schachner
81 2012; Bates et al. 2012; Hutchinson et al. 2005; Hutchinson et al. 2008) and mass properties
82 (Allen et al. 2013; Allen et al. 2009; Bates et al. 2012; Bates et al. 2009a; Bates et al. 2009b;
83 Henderson 1999; Henderson & Snively 2003; Hutchinson et al. 2011; Hutchinson et al. 2007)

84

85 The collective result of this prolonged and intensive research focus has been a much refined
86 understanding of how anatomy influenced non-avian theropod stance and gait, and how these
87 may have evolved on the line to extant birds. For instance, most non-avian species are inferred to
88 have used a largely upright hindlimb posture during normal locomotion, where the hips and knees
89 were flexed only to a minor degree; however, more crownward clades (e.g., paravians) may have
90 used a more crouched posture with greater flexion at the hip and knee (Hutchinson & Allen

91 2009). These postural changes are inferred to have occurred in association with changes in other
92 biomechanically important aspects, including an anterior shift in the location of the whole-body
93 centre of mass (COM; Allen et al. 2013), the muscular mechanisms of limb support and
94 propulsion (Gatesy 1990; Gatesy 1995; Gatesy 2002; Hutchinson & Gatesy 2000) and bone
95 loading mechanics (Carrano 1998). Yet, despite important advances in understanding, there is
96 still potential for further advances to be made, from investigation of hitherto unstudied lines of
97 evidence. One such line of evidence is the architecture of cancellous bone, which is well known
98 from studies of extant animals to be highly sensitive and well adapted to its prevailing
99 mechanical environment (cf. Part I of this series; Bishop et al. in review-b). Study of cancellous
100 bone architectural patterns in non-avian theropods may therefore provide new and unique insight
101 into various aspects of non-avian theropod locomotor biomechanics.

102

103 In Part I of this series, stark differences in hindlimb cancellous bone architecture were found
104 between humans and birds, the only obligate bipeds alive today. Many of these differences can be
105 associated with differences in the manner of striding, parasagittal, bipedal locomotion employed
106 by the two groups. In particular, the differences in cancellous bone architecture reflect differences
107 in their upright *versus* crouched postures and subsequent whole-bone loading mechanics, that is,
108 the prominence of bending and torsion. The different postures employed by humans and birds are
109 also associated with the mechanism of muscular control required to achieve limb support during
110 locomotion. In humans, mediolateral collapse of the stance phase limb is counteracted by hip
111 abduction, conferred predominantly by the gluteal muscles located dorsal to the hip (Pauwels
112 1980; Wall-Scheffler et al. 2010). However, in birds, anatomical, kinematic and
113 electromyographic evidence suggests that stance limb collapse is counteracted predominantly by
114 medial (internal) long-axis rotation of the subhorizontally oriented femur, conferred by the
115 iliopsoas muscles located anterior to the hip (Gatesy 1999b; Hutchinson & Gatesy 2000).
116 But what of extinct obligate bipeds, such as non-avian theropod dinosaurs?

117

118 In more stemward species of non-avian theropod, the architecture of cancellous bone in the main
119 hindlimb bones is similar to that of humans, in terms of both principal fabric directions in the hip
120 and knee and whole-bone architectural patterns. For instance, there exists a double-arcuate
121 pattern in the proximal femur, roughly parallel to the coronal plane; this was not observed in

122 more crownward non-avian species or extant birds (Part I; Bishop et al. in review-b). In species
123 more closely related to extant birds, cancellous bone architecture tends to be more similar to that
124 observed in birds. For instance, in the diaphysis-ward parts of the femoral metaphysis, primary
125 fabric vectors are disorganized and often oblique to the long-axis of the bone; and in Paravians
126 and extant birds at least, the distal tibiotarsus shows a distinctive and strongly anisotropic pattern
127 of sagittally aligned, often plate-like trabeculae (Part I; Bishop et al. in review-b). Given that
128 cancellous bone architectures in extant obligate bipeds appear to be linked to their different
129 locomotor biomechanics, these observations raise the following questions regarding non-avian
130 theropods:

- 131 1. Did the different species of non-avian theropods employ different limb postures?
- 132 2. Did the bones of the different species of non-avian theropods experience different loading
133 regimes?
- 134 3. Did the different species of non-avian theropods employ different strategies of muscular
135 support in counteracting stance limb collapse?
- 136 4. If the different species of non-avian theropods did employ different suites of hindlimb
137 locomotor biomechanics, how did these evolve on the line to extant birds?

138 Previously, the integration of anatomical, kinematic, bone strain and electromyographic data in
139 extant species led Carrano (1998) and Hutchinson & Gatesy (2000) to hypothesize that the
140 aforementioned aspects of bipedal locomotor biomechanics were intimately tied throughout
141 theropod evolution. The incremental change of external osteological features throughout theropod
142 evolution was also taken to indicate that the transformation in these particular biomechanical
143 aspects was a gradual occurrence (Hutchinson 2001a; Hutchinson 2001b; Hutchinson & Gatesy
144 2000). More broadly however, the exact history of theropod locomotor evolution, in terms of
145 whether it was long and gradual, or more punctuated at certain instances, remains to be fully
146 discerned (Allen et al. 2013; Hutchinson & Allen 2009).

147

148 A new approach that can quantitatively address the aforementioned questions was outlined in Part
149 II of this series (Bishop et al. in review-a). In this ‘reverse trajectorial approach’, the observed
150 three-dimensional (3-D) architecture of cancellous bone in the main bones of the hindlimb is
151 coupled with musculoskeletal and finite element models of the hindlimb. Under a quasi-static
152 situation, these models are used to derive a single ‘characteristic posture’, one in which

153 continuum-level principal stresses best align with cancellous bone fabric. This characteristic
154 posture is a time- and load-averaged posture across all loading regimes, and it is important to
155 recognize that it may or may not be an actual posture used at a particular instance in a particular
156 behaviour.

157

158 In Part II it was shown that when applied to an extant theropod (chicken, *Gallus gallus*), the new
159 approach was able to retrieve a posture that was quite comparable to that used by birds at around
160 the midstance of normal terrestrial locomotion. It could also provide a reasonable assessment of
161 bone loading in the proximal limb (i.e., femur, proximal tibia and proximal fibula) and muscle
162 control strategies for limb stabilization, although it had markedly lower accuracy in terms of bone
163 loading in the distal limb (tibial shaft and below) and muscle control strategies for limb
164 propulsion. Additionally, it was shown that the results of this approach were largely insensitive to
165 actual muscle size (manifest as force-generating capacity), a key unknown for extinct species.
166 When applied to extinct, non-avian theropods, the approach may therefore be used to investigate
167 posture, bone loading mechanics and muscle recruitment patterns in these species as well. Thus,
168 in this approach the architecture of cancellous bone constitutes an independent data set against
169 which one or more biomechanical hypotheses may be tested.

170

171 The present study aimed to quantitatively test the hypotheses of Carrano (1998) and Hutchinson
172 & Gatesy (2000) concerning the evolution of theropod locomotor mechanics. To do this, it
173 applied the reverse trajectorial approach to two species of non-avian theropod, the
174 phylogenetically basal coelurosaur *Daspletosaurus torosus* and the phylogenetically derived
175 paravian *Troodon formosus*, to derive a single characteristic hindlimb posture that best reflects
176 these species' architectural patterns of cancellous bone. These species show markedly different
177 cancellous bone architectures, with that of the former more similar to that of humans and that of
178 the latter bearing stronger resemblance to that of birds (Part I). Understanding limb posture in
179 these and other non-avian theropod species is in and of itself important, but it is also important
180 for understanding other aspects of locomotion. For instance, posture can influence maximum
181 speed capability in bipeds (Gatesy et al. 2009; Hutchinson 2004; Hutchinson & Allen 2009). In
182 concert with the results already derived from for an extant bird, the chicken (Part II), the results

183 of this study will also facilitate an examination of how locomotor biomechanics has evolved in
184 theropods on the line to extant birds.

185

186

187

188

189 **III.3 Materials and Methods**

190

191 The methodology employed in the present study followed that outlined previously in Part II
192 (Bishop et al. in review-a). Essentially, musculoskeletal models of the hindlimb in a static posture
193 were used to provide the force and boundary conditions for finite element modelling of the
194 individual limb bones, from which principal stress trajectories were determined and compared to
195 cancellous bone architectural patterns; the degree of correspondence between stress trajectories
196 and cancellous bone fabric was then used to inform a new test posture. This was repeated until no
197 further improvement in overall correspondence across the femur, tibiotarsus and fibula was able
198 to be gained; at this point the ‘solution posture’ was achieved. Only those differences from the
199 methodology of Part II, associated with the modelling of the two different species, will be
200 described in the present study. Also, as with the previous study, all assumptions and model
201 parameters were kept in their ‘best guess’ manifestation throughout the analyses; thus,
202 differences in model results directly reflected differences in limb postures in the extinct species.

203

204 All scripts, models and data used are held in the Geosciences Collection of the Queensland
205 Museum, and are available upon request to the Collections Manager. Additionally, a complete
206 copy of the raw data derived from the fossil specimens is accessioned with the respective
207 museums in which the specimens are housed.

208

209

210 ***III.3.1 Skeletal geometry acquisition***

211

212 The models developed in this study were derived through a combination of X-ray computed
213 tomographic (CT) scanning and photogrammetry of multiple fossil specimens; see Table 1 for the

214 specimens (and institutional abbreviations) and imaging parameters used. The CT scans for each
215 specimen were segmented using the software Mimics 17.0 (Materialize NV, Belgium), via a
216 combination of manual and automatic techniques, to produce initial surface meshes of each bone.
217 For photogrammetry, digital photographs were taken with a Lumix DMC-TZ40 (Panasonic,
218 Japan) and rendered to produce 3-D meshes using the software Agisoft Photoscan 1.0.4 (Agisoft
219 LLC, Russia), RealityCapture 1.0 (Capturing Reality s.r.o., Slovakia), Meshlab 1.3.3
220 (<http://meshlab.sourceforge.net/>) and CloudCompare 2.5.4 (<http://www.cloudcompare.org/>).

221

222 To maximize rigour, the models for each species were based primarily on single focal individuals
223 that were relatively complete and well-preserved, and for which information on cancellous bone
224 architecture was previously reported (Part I). These were TMP 2001.036.0001 for
225 *Daspletosaurus* and MOR 748 for *Troodon*. At the time the research was undertaken, the
226 specimens used to produce the model for *Troodon* were believed to represent a single species,
227 *Troodon formosus*. However, recent research has indicated otherwise, and furthermore has cast
228 doubt on the validity of the name *Troodon formosus* itself (van der Reest & Currie 2017); the
229 majority of specimens used in this study therefore belong to an unnamed taxon. Nonetheless, the
230 model constructed here is still considered to be an accurate reflection of the anatomy of a large,
231 phylogenetically derived, North American troodontid. Moreover, for the sake of simplicity in the
232 present study, the animal being modelled will herein be referred to as '*Troodon*'.

233

234 Some bones, or parts thereof, were missing from these focal specimens, and in these cases their
235 geometry was modelled using other specimens of the same or closely related species (Table 1).
236 This was achieved by scaling the geometries of these other specimens appropriately to fit the
237 focal specimens' bones, accomplished using a combination of Mimics and the computer-aided
238 design software Rhinoceros 4.0 (McNeel, USA). Wholesale reconstruction was required for the
239 much of the pubis in *Daspletosaurus* and much of the ilium in '*Troodon*'. In *Daspletosaurus*, the
240 general shape of the pubis was evident from the focal specimen, but much of the boot, pubic
241 apron and ischiadic head were reconstructed based on comparison to other specimens that were
242 imaged (Table 1), personal observation of other specimens in the TMP and MOR collections, and
243 also the tyrannosaurid literature (e.g., Brochu 2003; Osborn 1917). In '*Troodon*', the acetabulum,
244 antitrochanter and pubic and ischiadic peduncles were present in the focal specimen, but the

245 anterior and posterior iliac blades were reconstructed based on comparison to other troodontids
246 described in the literature (e.g., Gao et al. 2012; Tsuihiji et al. 2014; Xu et al. 2002). The
247 assembly of the individual elements of the pelvis was based on the geometry of individual bones,
248 but also on specimens of other tyrannosaurids or paravians where the pelvic elements were
249 preserved *in situ* and intact with the sacrum (e.g., Brochu 2003; Gao et al. 2012; Lambe 1917;
250 Norell & Makovicky 1997; Osborn 1917; Tsuihiji et al. 2014; Xu et al. 2002), as well as personal
251 observation of other specimens in the TMP and MOR collections and displays. For completeness,
252 the vertebral column was represented by a single cylinder fixed with respect to the pelvis. In
253 addition to the pelvis, the distalmost fibular shaft was also reconstructed for ‘*Troodon*’; it was
254 essentially a continuation of the preserved part of the shaft, tapering towards the end, and gently
255 curving laterally as it approaches the distal tibia (cf. Norell & Makovicky 1999; Ostrom 1969).
256

257 Some of the individual bones used in the above procedure had undergone a variable amount of
258 taphonomic distortion. However, in all cases this appeared to be brittle deformation only, in the
259 form of fracturing and rigid displacement of the fragments relative to one another. In these
260 instances, the bones were retro-deformed in Rhinoceros, under the assumption of brittle
261 deformation (Lautenschlager 2016). This rigid retro-deformation restored the fossil geometry
262 closer to the original geometry by realigning fragments along apposing fracture surfaces, and also
263 taking into consideration the geometry of the bones in other specimens and other species,
264 including comparison to the literature (e.g., Brochu 2003; Tsuihiji et al. 2014). The retro-
265 deformed geometries were then ‘smoothed over’ in Mimics and 3-Matic 9.0 (Materialize NV,
266 Belgium). Additionally, cracks or abraded edges were filled in and reconstructed in Mimics; only
267 the minimal amount of filling in required was undertaken.

268

269 Once an initial surface mesh had been produced for the complete geometry of each bone for both
270 species, these were smoothed in 3-matic and then refined to produce a more isoparametric mesh
271 in ReMESH 2.1 (Attene & Falcidieno 2006; <http://remesh.sourceforge.net/>). Although the tibia,
272 astragalus and calcaneum typically remain as separate ossifications in tyrannosaurids, and the
273 tibia remains separate from the astragalus and calcaneum in troodontids, the meshes of the three
274 bones were fused together in this study to create a single tibiotarsus geometry. This was

275 undertaken for the sake of simplifying the models, as well as maintaining a greater degree of
276 consistency with the previously developed chicken model of Part II.

277

278

279

280

281

282 ***III.3.2 Musculoskeletal modelling***

283

284 Musculoskeletal models of the right hindlimb of *Daspletosaurus* and ‘*Troodon*’ were constructed
285 in NMSBuilder (Martelli et al. 2011; Valente et al. 2014) for use in OpenSim 3.0.1 (Delp et al.
286 2007), and are shown in Figs 1 and 2. Both comprised 12 degrees of freedom, as in the chicken
287 model of Part II, and 38 musculotendon actuators.

288

289

290 III.3.2.1 Definition of joints

291

292 Joint locations and orientations were defined in a similar fashion to the chicken model. However,
293 the location of the hip joint was left open-ended, so as to investigate the effects of different hip
294 articulations (see Section III.3.5 below). Initially, the centre of the joint in the femur was
295 determined by fitting a sphere to the femoral head in 3-matic, and the centre of the joint in the
296 acetabulum was determined by positioning the centre of femoral head sphere in the centre of the
297 acetabulum (in both lateral and anterior views). Hence, in this initial configuration, the
298 articulation of the femur with the acetabulum was consistent with the configuration used for the
299 chicken model. It was also consistent with the inference drawn in Part I from observations of
300 cancellous bone architecture (Section I.5.2.3), that the articulation was possibly centred about the
301 apex of the femoral head. The articulation of the tibia and fibula was guided by the relative
302 positions of the fibular crest on the tibiotarsus and the flared anteromedial process of the
303 proximal fibula, as well as the facet formed distally by the tibia, astragalus and calcaneum for
304 reception of the fibula. As with the chicken model, the pes was modelled as a rectangular prism,
305 with a width set to the mediolateral width of the distal tarsometatarsus and a length set to the total

306 length of digit III; the total length of digit III for the ‘*Troodon*’ model was based on the data of
307 Russell (1969) for *Latenivenatrix mcmastrae*, scaled to the individual modelled in the current
308 study.

309

310

311 III.3.2.2 Definition of muscle and ligament anatomy

312

313 The hindlimb myology of *Daspletosaurus* and ‘*Troodon*’ was reconstructed through analysis of
314 the muscle and ligament scarring patterns observed on the fossil bones, framed in the context of
315 the myology and scarring patterns of extant archosaurs (Bates & Schachner 2012; Bates et al.
316 2012; Carrano & Hutchinson 2002; Hutchinson 2001a; Hutchinson 2001b; Hutchinson 2002;
317 Hutchinson et al. 2005; Hutchinson et al. 2008). The 33 muscles and four ligaments
318 reconstructed, along with their origins and insertions, are listed in Table 2. As in the chicken
319 model, the collateral ligaments of the knee and ankle were represented by four musculotendon
320 actuators in both the *Daspletosaurus* and ‘*Troodon*’ models. Each muscle was represented by a
321 single musculotendon actuator in the models, with one exception; the iliotibialis 2 (IT2) was
322 represented by two actuators on account of its probable expansive origin on the dorsal ilium
323 (Bates et al. 2012; Hutchinson et al. 2005; Hutchinson et al. 2008). The 3-D courses of the
324 actuators were constrained to follow paths that are comparable to those reported for homologous
325 muscles in extant archosaurs, and also as reconstructed for other non-avian theropod species
326 (Bates & Schachner 2012; Bates et al. 2012; Hutchinson et al. 2005; Hutchinson et al. 2008).

327

328 In reconstructing the muscular and ligamentous components of the models, a number of
329 simplifying assumptions were made. Two muscles, the ambiens (AMB) and fibularis longus (FL)
330 may possibly have sent off secondary tendons to attach more distally in the limb, as can occur in
331 extant archosaurs (Carrano & Hutchinson 2002; Hutchinson 2002). However, these secondary
332 attachments were assumed to be of little importance for bone loading mechanics as far as the
333 present study is concerned, and so were not modelled. A distal accessory tendon was considered
334 to be absent from the caudofemoralis longus (CFL), as the fourth trochanter of both species lacks
335 a distally directed process or is of small size (Carrano & Hutchinson 2002; Hutchinson 2001a). It
336 is also possible that there may have been other flexor muscles of digits II–IV in both

337 *Daspletosaurus* and ‘*Troodon*’, in addition to the flexores digitorum longus (FDL) et brevis
338 (FDB), but currently it is too speculative to infer these (Carrano & Hutchinson 2002; Hutchinson
339 2002). It was assumed in the present study that if any such digital flexor muscles were present in
340 either species, they would have had a similar disposition to the FDL, and so their action could be
341 represented by the FDL actuator.

342

343

344

345

346

347 III.3.2.3 Definition of segment mass properties

348

349 To estimate the mass properties of each limb segment in the *Daspletosaurus* musculoskeletal
350 model, the segment soft tissue models of Allen et al. (2013) for *Tyrannosaurus* were modified to
351 fit the pelvic and limb elements of *Daspletosaurus*, by scaling each soft tissue segment in the x , y
352 and z directions to fit the relevant bone or bones (and in the case of the thigh segment, to also fit
353 the pelvis). This was accomplished in Rhinoceros. Likewise, the segment soft tissue models of
354 Allen et al. (2013) for *Velociraptor* were modified appropriately to fit the pelvic and limb
355 elements of ‘*Troodon*’ in the estimation of mass properties in its model. The application of the
356 soft tissue models developed for other species to the species studied here is justified, due to close
357 phylogenetic relationship and much similarity in the underlying skeletal structure between the
358 species involved. Assuming a bulk density of 1000 kg/m^3 for all body segments, the total mass of
359 the right hindlimb in the *Daspletosaurus* model was calculated to be 342.7 kg, and that in the
360 ‘*Troodon*’ model was 5.65 kg.

361

362 To completely define the musculoskeletal model, this also required the calculation of mass
363 properties for the remainder of the body, that is, the pelvis segment of the models. Based on
364 femoral mid-shaft circumferences, equation 7 of Campione et al. (2014) was used to estimate the
365 total body mass for the two models. This resulted in a mass of 2757 kg for the *Daspletosaurus*
366 model and 48.5 kg for the ‘*Troodon*’ model, and hence the mass of the pelvis segment in the two
367 models (including the mass of the left hindlimb) was 2414.3 kg and 42.85 kg, respectively. By

368 unintended coincidence, in both models the mass of the right hindlimb constituted approximately
369 12% of total body weight, which therefore increased consistency between two models. For
370 comparison, the mass of the hindlimb in the chicken model of Part II constituted approximately
371 10% of total body weight. Given the data reported by Allen et al. (2013), the combined COM of
372 the whole body, minus the right leg, in their ‘average’ model of *Tyrannosaurus* was 0.544 m
373 anterior to the hip joint. The femur length of the specimen upon which their model was based is
374 1.265 m, as reported by Hutchinson et al. (2011). Scaling isometrically to the *Daspletosaurus*
375 model, which has a femur length of 0.984 m, the COM of the pelvis segment was set at 0.423 m
376 anterior to the hip. Similarly, the combined COM of the whole body, minus the right leg, in the
377 ‘average’ *Velociraptor* model of Allen et al. (2013) was 0.090 m anterior to the hip joint, and the
378 femur length upon which their model was based is 0.163 m. Thus, scaling isometrically to the
379 ‘*Troodon*’ model, which has a femur length of 0.304 m, the COM of the pelvis segment was set
380 at 0.168 m anterior to the hip. The dorsoventral position of the COM of the pelvis segment was
381 assumed to be level with the hip. As noted in Part II, the dorsoventral position of the pelvis
382 segment COM will not influence the results so long as the pelvis segment’s orientation was fixed
383 in all simulations, and all simulations were quasi-static in nature.

384

385

386 III.3.2.4 Muscle activity

387

388 Not all of the 34 musculotendon actuators representing muscles were set to be active during the
389 musculoskeletal simulations, in both *Daspletosaurus* and ‘*Troodon*’ (Table 3). The inactive
390 muscles were set using the same criteria employed for the chicken model, and through
391 comparison to published electromyography data for homologous hindlimb muscles in extant
392 archosaurs (Gatesy 1990; Gatesy 1994; Gatesy 1997; Gatesy 1999b; Jacobson & Hollyday 1982;
393 Marsh et al. 2004; Reilly & Blob 2003; Roberts et al. 1998). One exception to this was the
394 iliofemoralis externus (IFE), which in both birds and crocodylians is mostly active during the
395 swing phase of locomotion. However, in the evolutionary scenario proposed by Hutchinson &
396 Gatesy (2000), abductor muscles such as the IFE are expected to have been crucial to maintaining
397 stance limb stability, if the femur was habitually held in the subvertical orientation hypothesized
398 for most, if not all, non-avian theropods (Hutchinson & Allen 2009). Moreover, the hypothesis of

399 Hutchinson & Gatesy (2000) explains the stance phase inactivity of the IFE (or its homologues)
400 in birds and crocodylians as a result of other hip muscles conferring stance limb support, namely,
401 medial long-axis rotators in birds (iliotrochanterici) and adductors in crocodylians (adductores
402 femoris 1 et 2). Thus, to test the hypothesis of Hutchinson & Gatesy (2000), among others, the
403 IFE was set as being active in both the *Daspletosaurus* and ‘*Troodon*’ simulations. All active
404 musculotendon actuators were assigned the same maximum force capacity, equal to two times
405 body weight, that is, each muscle was capable of exerting up to 54073.9 N for *Daspletosaurus*
406 and 951.2 N for ‘*Troodon*’.

407

408 As in the chicken simulations of Part II, a reserve actuator was applied to the
409 metatarsophalangeal joint in the musculoskeletal simulations. The maximum output of this
410 actuator in the *Daspletosaurus* and ‘*Troodon*’ simulations was scaled from that set for the
411 chicken (1,000 Nm), in proportion to the total body mass of each model: 1,767,308 Nm for
412 *Daspletosaurus* and 31,090 Nm for ‘*Troodon*’. This corresponds to a minimum of 27 times the
413 product of body weight and total hindlimb length (sum of interarticular lengths of femur,
414 tibiotarsus and tarsometatarsus). By providing ample control of the metatarsophalangeal joint,
415 this helped reduce excessively high recruitment of the FDL and FDB.

416

417

418 III.3.2.5 Initial posture

419

420 A general mid-stance posture was used as an initial starting point, which was modified in
421 subsequent modelling attempts, as per the process outlined in Part II of this study. This initial
422 posture was based on general interpretations of tyrannosaurid and troodontid appearance in the
423 literature (technical and popular). Additionally, the hip extension angle was initially set so that
424 the knee joint was near the line of the vertical ground reaction force in the x - z (sagittal) plane,
425 following previous interpretations of theropod hindlimb biomechanics (Gatesy et al. 2009;
426 Hutchinson & Gatesy 2006).

427

428

429 **III.3.3 Finite element modelling**

430

431 Finite element simulations of the *Daspletosaurus* and ‘*Troodon*’ models were developed and
432 solved in largely the same manner as the previously described chicken simulations of Part II,
433 using ANSYS 17.0 (Ansys, Inc., USA). Two minor differences were that (i) a graduated and finer
434 mesh was used around the cleft of the lesser trochanter of the *Daspletosaurus* femur, to reduce
435 stress artifacts, and (ii) connection between the tibiotarsus and fibula entities was modelled both
436 proximally and distally. The latter difference reflects that fact that both tyrannosaurs and
437 troodontids possessed a distinct furrow in the distal tibiotarsus for reception of the distal fibula,
438 whereas in birds the distal fibula is greatly reduced. In the *Daspletosaurus* model, the total
439 number of elements used across the various postures tested ranged from 961,023 to 975,544 in
440 the femur simulation and from 985,071 to 1,005,550 in the tibiotarsus + fibula simulation. In the
441 ‘*Troodon*’ model, the total number of elements used across the various postures tested ranged
442 from 668,033 to 684,547 in the femur simulation and from 583,228 to 598,556 in the tibiotarsus
443 + fibula simulation.

444

445 ***III.3.4 Results analysis***

446

447 In Part II, stress trajectories for the chicken model were compared to the observed cancellous
448 bone architecture in birds as a whole (reported in Part I), for reasons explained there. Here, stress
449 trajectories for the *Daspletosaurus* model were compared to observed cancellous bone
450 architecture in *Allosaurus* and tyrannosaurid fossils, and stress trajectories for the ‘*Troodon*’
451 model were compared to observed architectural patterns in troodontid fossils. Qualitative
452 comparisons of stress trajectories to fabric directions were made across all three bones: femur,
453 tibiotarsus and fibula. Supplementing these qualitative assessments, quantitative comparison of
454 stresses and architecture was undertaken for the femoral head and medial femoral condyle,
455 followed the procedure outlined for the chicken model in Part II. The direction of minimum
456 principal stress (σ_3) was determined as the mean direction of vectors within anatomically scaled
457 and positioned spheres placed within each region of the bone, with the mean principal fabric
458 direction in both regions taken as previously reported in Part I (figs 22, 29).

459

460

461 *III.3.5 Varying hip articulation*

462

463 Following the identification of a ‘solution posture’ for the *Daspletosaurus* model, a brief
464 exploratory exercise was undertaken to address the ambiguity surrounding the articulation of
465 non-avian theropod hips. Unlike birds, many non-avian theropods typically possessed a large
466 incongruence in size between the femoral head and the acetabulum; for example, in the
467 *Daspletosaurus* focal specimen studied, the diameter of the femoral head is about two-thirds that
468 of the acetabulum (Fig. 3). This has consequently created uncertainty in exactly how the femur
469 articulated with the acetabulum in these extinct species (see also Tsai & Holliday 2015; Tsai et al.
470 2018). It has been previously suggested that the main area of articulation on the femur occurred
471 on the roughly cylindrical part of the femoral head, lateral to the apex of the head (e.g., Hotton
472 1980; Hutchinson & Allen 2009). However, cancellous bone architectural patterns observed in
473 *Allosaurus* and tyrannosaurids (Part I) suggest that hip joint loads may have been transmitted
474 through the femoral head mainly from the apex of the head, not from the more lateral parts.

475

476 To examine the effect of different hip articulations in the *Daspletosaurus* model, the extent of
477 femur–acetabulum contact was varied to assess if any improvement in correspondence between
478 principal stress trajectories and cancellous bone architecture was possible beyond that of the
479 solution posture (Fig. 3). Two such variations were made. Firstly, the femur was moved 50 mm
480 medially with respect to the acetabulum, so that a sizeable proportion of the cylindrical part of the
481 femoral head was in close proximity to the acetabulum (Fig. 3D–F). The rest of the limb was also
482 moved medially along with the femur, including the coordinate systems of distal joints and all
483 musculotendon actuator origins, insertions and via points that were level with or distal to the hip.
484 So as to maintain a similar mediolateral foot placement as the original solution posture, the
485 amount of hip abduction-adduction was altered slightly. In the second variation, the femur and
486 limb distal to it was again moved 50 mm medially with respect to the acetabulum, but the hip was
487 also abducted by 14°, producing a net 10° abduction from the neutral posture (Fig. 3G–I). This
488 reflects the amount of hip abduction that has been supposed for tyrannosaurids in previous
489 modelling studies (e.g., Hutchinson et al., 2005, 2007), on account of the inclined disposition of
490 the femoral head relative to the long-axis of the femur. In order to bring the foot anywhere near
491 the body midline, this abducted posture also necessitated a large 27° of external long-axis

492 rotation of the hip, a value comparable to maximal external long-axis rotation in modern birds
 493 during straight-line locomotion (Kambic et al. 2015; Rubenson et al. 2007).

494

495

496 *III.3.6 Cross-species patterns*

497

498 Once solution postures were identified for both the *Daspletosaurus* and ‘*Troodon*’ models, a
 499 number of biomechanically relevant parameters were extracted. The same parameters were also
 500 extracted from the solution posture identified previously for the chicken model of Part II. By way
 501 of comparison across the three species, these parameters would allow a quantitative assessment
 502 of the evolutionary-biomechanical hypotheses of Carrano (1998) and Hutchinson & Gatesy
 503 (2000). Three sets of parameters were extracted:

- 504 1. *Postural parameters*, related to Question 1 posed in the Introduction: the location of the
 505 whole-body COM as normalized by total hindlimb length, joint angles for the hip and knee,
 506 and the ‘degree of crouch’, both actual and predicted from empirical data reported by Bishop
 507 et al. (2018).
- 508 2. *Bone loading parameters*, related to Question 2 posed in the Introduction: the orientation of
 509 principal stresses at the femoral mid-shaft, the ratio of maximum shear stress to bending
 510 stresses at the femoral mid-shaft, and the orientation of the neutral surface of bending at the
 511 femoral mid-shaft, relative to the mediolateral axis. To enable estimation of these parameters
 512 at mid-shaft, a local long-axis in the vicinity of the mid-point of the bone was determined.
 513 This was calculated by fitting a cylinder to the shaft in the immediate vicinity of the mid-
 514 point, using the in-built cylinder fitting tool in 3-matic; the long-axis of the cylinder defined
 515 the local long-axis of the bone, and the plane normal to this axis defined the plane of the
 516 mid-shaft cross-section. The orientation of principal stresses was defined as the orientation of
 517 the steepest inclined stress vector with respect to the local long-axis; this was calculated
 518 separately for both σ_1 and σ_3 , and then the mean orientation was taken. In pure bending the
 519 orientation would be 0° , that is, parallel to the long-axis, and in pure torsion it would be 45°
 520 (Beer et al. 2012). Additionally, mid-shaft bending stresses were calculated as

521

$$\sigma_{\text{bending}} = \frac{|\sigma_{\text{max}}| + |\sigma_{\text{min}}|}{2}, \quad (1)$$

522 where σ_{\max} is the maximum (tensile) stress at mid-shaft and σ_{\min} is the minimum
 523 (compressive) stress at mid-shaft. This assumes that planar strain conditions were in place
 524 (Biewener 1992), which was revealed by inspection of normal stress contours to be
 525 approximately true.

526 3. *Muscular support parameters*, related to Question 3 posed in the Introduction: the abduction
 527 moments of muscles that are predominantly suited to conferring hip abduction (i.e.,
 528 iliofemoralis externus), and the long-axis rotation moments of muscles that are
 529 predominantly suited to conferring hip long-axis rotation (i.e., iliotrochantericus caudalis and
 530 puboischiofemorales internus 1 et 2 in non-avian theropods; iliotrochanterici caudalis et
 531 medialis in the chicken). To give a size-independent, dimensionless measure of how much
 532 ‘effort’ a muscle exerts to stabilize a joint about a given axis, these moments are normalized
 533 by the product of the model’s body weight and hip height:

$$534 \quad M^* = \frac{a \cdot F_{\max} \cdot r_i}{m \cdot g \cdot h}, \quad (2)$$

535 where a is the activation level of the muscle, from 0 (inactive) to 1 (maximally active), F_{\max}
 536 is the maximum force capable of being produced (set at two body weights as per Part II), r_i is
 537 the muscle’s moment arm about joint axis i , m is body mass, g is the acceleration due to
 538 gravity (9.81 m/s^2) and h is hip height. It is worth noting that this analysis carries the caveat
 539 of ignoring biarticular muscles (e.g., iliotibiales) and co-contraction between agonistic and
 540 antagonistic muscles.

541

542 Given the small sample size of species examined here ($n = 3$), any assessment of the evolution of
 543 biomechanically relevant parameters is necessary a coarse one. Since the hindlimb anatomy of
 544 *Daspletosaurus* is close to that inferred for the ancestral state of Coelurosauria, its results may
 545 taken to be reasonably representative of the most recent common ancestor of it and ‘*Troodon*’;
 546 likewise, since the anatomy of the ‘*Troodon*’ model is close to that inferred for the ancestral state
 547 of Paraves, its results may taken to be reasonably representative of the most recent common
 548 ancestor of it and the chicken. That is, it is here assumed that – in the context of locomotor
 549 biomechanics – little important evolution occurred between the ancestral coelurosaur and
 550 *Daspletosaurus*, and likewise little important evolution occurred between the ancestral paravian
 551 and ‘*Troodon*’. By mapping results towards the most recent common ancestor of successive

552 clades, the differences observed between *Daspletosaurus*, ‘*Troodon*’ and the chicken are hence
553 taken to be a surrogate for the actual sequence (if not pattern) of evolution along the avian stem
554 lineage. This does not, however, escape the caveat of allometric effects on dimensional aspects of
555 hindlimb anatomy; the issue of size effects in theropod locomotor evolution will be returned to in
556 the Discussion.

557

558

559 **III.4 Results**

560

561 A total of five different postures for *Daspletosaurus*, and six postures for ‘*Troodon*’, were tested
562 before no further correspondence between principal stress trajectories and cancellous bone
563 architectural patterns was able to be achieved (Figs 4, 5). In the *Daspletosaurus* model, going
564 from the worst to best postures tested, the angular deviation between the minimum compressive
565 stress (σ_3) and the mean direction of the primary fabric orientation (\mathbf{u}_1) in the femoral head
566 decreased from 15.6° to 7.3°, a 53% reduction; likewise, the angular deviation between σ_3 and \mathbf{u}_1
567 in the medial femoral condyle decreased from 11.7° to 2.8°, a 76% reduction. In the ‘*Troodon*’
568 model, going from the worst to best postures tested, the angular deviation between σ_3 and \mathbf{u}_1 in
569 the femoral head decreased from 23.8° to 3.9°, an 84% reduction; likewise, the angular deviation
570 between σ_3 and \mathbf{u}_1 in the medial femoral condyle decreased from 28.3° to 24.2°, a 14% reduction.
571 The final solution posture for *Daspletosaurus* is illustrated in the centre of Fig. 4, and the solution
572 posture for ‘*Troodon*’ is illustrated in the centre of Fig. 5. As with the results for the chicken
573 model (Part II), only minimal correspondence between principal stress trajectories and cancellous
574 bone architecture was able to be achieved in the distal tibiotarsus of either species. Little
575 correspondence was also able to be achieved in the fibular crest of the *Daspletosaurus* model’s
576 tibia. Thus, the remainder of this section will focus on the more proximal parts of the hindlimb.

577

578

579 ***III.4.1 Daspletosaurus results***

580

581 In the solution posture, the principal stress trajectories in the femur showed a high degree of
582 correspondence with the observed cancellous bone architecture throughout the bone (Figs 6, 7).

583 Strong correspondence between σ_3 (compressive) and cancellous bone architecture occurred in
584 the femoral head and both medial and lateral femoral condyles. This correspondence included
585 that between the mean direction of σ_3 and \mathbf{u}_1 in the femoral head (Fig. 6G) and medial femoral
586 condyle (Fig. 7I). Correspondence between the maximum principal stress (σ_1 , tensile) and
587 cancellous bone architecture occurred in the distal half of the fourth trochanter. Additionally,
588 three instances of a double-arcuate pattern occurred, formed by σ_1 and σ_3 , largely in the coronal
589 plane. These correlate to three similar such patterns observed in the cancellous bone architecture
590 of tyrannosaurids: in the femoral head and proximal metaphysis, in the lesser trochanter, and in
591 the anterior and posterior parts of the distal femur proximal to the condyles. The double-arcuate
592 patterns of σ_1 and σ_3 sometimes also occurred in the results for other postures tested, but they
593 were often less developed compared to the solution posture.

594

595 Strong correspondence between principal stress trajectories and cancellous bone architecture also
596 occurred in the proximal tibia and fibula (Fig. 8). The trajectory of σ_3 corresponded closely with
597 the observed architectural patterns of both the medial and lateral condyles, including a more
598 lateral inclination in the lateral condyle. In the cnemial crest of the tibia, the trajectory of σ_1
599 largely paralleled the margins of the crest, as observed for cancellous bone fabric. Good
600 correspondence between σ_3 and cancellous bone architectural patterns was also observed in the
601 fibular head, particularly for in the medial aspect of the bone (Fig. 8K,L).

602 **III.4.2 'Troodon' results**

603

604 As with the *Daspletosaurus* model, in the solution posture identified for 'Troodon', the principal
605 stress trajectories in the femur generally showed strong correspondence to the observed
606 cancellous bone architecture (Figs 9, 10). Correspondence with σ_3 occurred in the femoral head,
607 under the greater trochanter and in both medial and lateral condyles; correspondence with σ_1
608 occurred in the lesser trochanter. The mean direction of σ_3 in the femoral head showed strong
609 correspondence to the mean direction of \mathbf{u}_1 (Fig. 9E). In the medial femoral condyle, the
610 directions of σ_3 and \mathbf{u}_1 are qualitatively similar, but σ_3 was notably more posteriorly inclined (by
611 about 20°) than the mean direction of \mathbf{u}_1 (Fig. 10E), as occurred in the chicken model of Part II.
612 Unlike the results for the *Daspletosaurus* model, no double-arcuate pattern of σ_1 and σ_3 was

613 present in ‘*Troodon*’; instead, their trajectories tended to spiral about the bone’s long axis, much
614 like the stress results for the chicken model.

615

616 Good correspondence between principal stress trajectories and cancellous bone architecture also
617 occurred in the proximal tibia and fibula (Fig. 11). In the medial and lateral condyles, σ_3
618 corresponded closely with observed architectural patterns, possessing a gentle posterior
619 inclination, with a slight lateral inclination under the lateral condyle. In the cnemial crest, the
620 trajectory of σ_1 largely paralleled the margins of the distal part of the crest. In the fibular head,
621 the principal stress trajectories showed good overall correspondence to the observed architectural
622 patterns (Fig. 11K–M). Greater correspondence occurred laterally with σ_1 , but some
623 correspondence was also present in the medial side with σ_3 .

624

625

626 ***III.4.3 Hip articulation results***

627

628 In both variations in hip articulation tested for the *Daspletosaurus* model, the resulting principal
629 stress trajectories of the proximal femur showed poorer correspondence with observed cancellous
630 bone architecture than that achieved with the initial solution posture (Fig. 12). In particular, σ_3 ,
631 was broadly directed towards the more cylindrical part of the femoral head, lateral to the apex,
632 rather than towards the apex itself. Additionally, the anterior inclination of σ_3 in the femoral head
633 was greater in both variations than that in the originally identified solution posture, and was
634 markedly greater than the anterior inclination of the mean direction of \mathbf{u}_1 .

635

636

637 ***III.4.4 Cross-species comparisons of biomechanical parameters***

638

639 In terms of posture, hip extension, hip adduction-abduction, hip long-axis rotation and knee
640 flexion angles all changed in a gradual fashion progressing from *Daspletosaurus* to ‘*Troodon*’ to
641 the chicken (Fig. 13). The same pattern also occurred for the anterior location of the whole-body
642 COM and the degree of crouch. Furthermore, the degree of crouch of the solution postures
643 matched closely with empirical predictions based on total leg length (Fig. 13C). In terms of bone

644 loading, all parameters also changed in a gradual fashion progressing from *Daspletosaurus* to the
645 chicken (Fig. 14 A,B). Thus, in *Daspletosaurus*, the femur was loaded predominantly in
646 mediolateral bending, whereas in the chicken the femur was loaded predominantly in torsion,
647 with bending predominantly in an anteroposterior direction. In ‘*Troodon*’, torsion was more
648 prominent compared to *Daspletosaurus*, but bending still remained the dominant loading regime.
649 As with the other parameters, muscular support also changed gradually progressing from
650 *Daspletosaurus* to the chicken Fig. 14C,D). In *Daspletosaurus*, the normalized hip abductor
651 moment was relatively high and the normalized hip medial rotator moment was relatively low,
652 whereas the situation was reversed in the chicken.

653

654

655 **III.5 Discussion**

656

657 Having previously demonstrated the validity and potential utility of the ‘reverse’ application of
658 the trajectorial theory (Part II; Bishop et al. in review-a), the aim of the present study was to
659 apply this approach to two extinct, non-avian theropods, *Daspletosaurus torosus* and ‘*Troodon*’
660 (*Troodontidae* sp.), to gain new insight into their hindlimb locomotor biomechanics. In addition
661 to deriving a ‘characteristic posture’ for both species, quantitative results were produced that
662 have bearing on various questions concerning theropod locomotor biomechanics and its
663 evolution, posed in Section III.2. In particular, the evolutionary-biomechanical hypotheses of
664 Carrano (1998) and Hutchinson & Gatesy (2000) were able to be quantitatively tested in a novel
665 way.

666

667

668 ***III.5.1 Postures***

669

670 In the ‘characteristic posture’ identified for both non-avian theropods, there was generally a
671 strong alignment between calculated principal stress trajectories and observed patterns in
672 cancellous bone architecture, across the femur, proximal tibia and proximal fibula. It is important
673 to note that this should not be presumed to be *the* posture used by these extinct species at any
674 particular point in the stance phase; rather, the posture identified here is a time- and load-

675 averaged characterization of the kinds of postures experienced on a daily basis. Nevertheless,
676 since the posture previously identified for the chicken corresponds well to the posture of a typical
677 avian hindlimb at around mid-stance in terrestrial locomotion (Part II), the postures derived for
678 *Daspletosaurus* and ‘*Troodon*’ are inferred to reflect the postures of these species at around the
679 mid-stance of normal locomotion. Thus, *Daspletosaurus* is inferred to have stood and moved
680 with a largely upright posture with a subvertical femoral orientation, whilst the limb posture of
681 ‘*Troodon*’ is inferred to have been more crouched, although not to the degree observed in extant
682 birds. It is worth noting that the femoral orientation of the *Daspletosaurus* posture, in terms of the
683 degree of hip extension, is very similar to that hypothesized for other large, phylogenetically
684 basal tetanuran species by previous workers such as *Tyrannosaurus* (Gatesy et al. 2009;
685 Hutchinson 2004; Hutchinson et al. 2005), *Allosaurus* and *Acrocanthosaurus* (Bates et al. 2012).
686 The inferences drawn in those studies were based on the posture that allowed for high locomotor
687 forces to be sustained (Gatesy et al. 2009; Hutchinson 2004), or that achieved a maximal total
688 moment arm of the hip extensor muscles (Bates et al. 2012; Hutchinson et al. 2005). The
689 rationale of the latter set of studies is in some respects similar to the approach of the present study
690 (which used static optimization in the musculoskeletal modelling stage), in that both approaches
691 are dependent on the moment arms of individual muscles (see Part II, section II.5.1).

692

693

694

695

696 ***III.5.2 Hip articulation in non-avian theropods***

697

698 The results of the exploratory analysis of hip articulations in the *Daspletosaurus* model supported
699 the inference made in Part I of this series: in non-avian theropods such as *Allosaurus* and
700 tyrannosaurids, the immediate articulation between the femur and acetabulum may have been
701 centred about the apex of the femoral head. Other articulations, involving greater contribution
702 from the cylindrical part of the femoral head lateral to the apex, did not result in as strong
703 correspondence between principal stresses and cancellous bone architecture. This is not to say
704 that these other articulations were not used during daily activity, rather that they may have been
705 used less frequently. Indeed, as the entire proximal surface of the non-avian theropod femur

706 typically bears a characteristic texture indicative of a hyaline cartilage covering (smooth on the
707 scale of millimetres, but wrinkled on the scale of centimetres; Tsai & Holliday 2015; Tsai et al.
708 2018), this suggests that articulation between the lateral proximal femur and the incipient
709 antitrochanter on the ilium would have occurred on occasion, but the relatively frequency of this
710 remains unknown (see also Kambic et al. 2014; Kambic et al. 2015). This interpretation of hip
711 articulation is also consonant with anatomical considerations of the non-avian theropod pelvis
712 and sacrum. Specifically, a more lateral articulation of the (non-abducted) femur with the
713 acetabulum places the femoral head more medially with respect to the pelvis, which could bring
714 it into contact with the centra of the sacral vertebrae (e.g., Gilmore 1920; Osborn 1917; Rauhut &
715 Carrano 2016).

716

717 Combined with the results of the exploratory analysis, the solution posture identified for the
718 *Daspletosaurus* model can help move toward resolving the question of how theropods with
719 proximomedially inclined femoral heads, such as tyrannosaurids and carcharodontosaurids, kept
720 their feet positioned close to the body midline, as indicated by fossil trackways (e.g., McCrea et
721 al. 2014). Previously, working on the assumption that the cylindrical part of the femoral head
722 articulated with the acetabulum, researchers had found that the femur inevitably becomes
723 markedly abducted from the body midline. Without further speculation about joint articulations
724 or the nature of the intervening soft tissues (cartilage, menisci) more distally in the limb, this
725 leads to an unnaturally wide foot placement (e.g., Bates et al. 2012; Hutchinson et al. 2005;
726 Hutchinson et al. 2007). Indeed, in the second variation of hip articulation tested for the
727 *Daspletosaurus* model, mediolateral step width was almost 47% of hip height (Fig. 3I), more than
728 three times the typical step width observed in theropods (Bishop et al. 2017). With the hip
729 articulation occurring at the apex of the femoral head, however, this allows for significant joint
730 movement in other directions besides abduction-adduction. In particular, the solution posture
731 identified for the *Daspletosaurus* model had a modest amount of external long-axis rotation, but
732 little abduction of the femur; in fact, the femur was adducted slightly. Moreover, the asymmetry
733 of the distal femoral condyles leads to a gently skewed orientation of the knee flexion-extension
734 axis in the coronal plane, such that the distal crus is angled in towards the body midline (see Part
735 II and Figs 1E and 2E). The combination of these features allows the pes to be positioned close to
736 the midline, yet the upper limb be kept clear of the pelvis.

737

738 Despite the potential that this new interpretation may have for understanding how non-avian
739 theropod hips may have articulated, it is worth emphasizing that it is based on a single posture,
740 which at best can only be regarded as a snap shot of the limb during the stance phase of
741 locomotion. A great deal more work is required if an understanding of dynamic joint articulations
742 throughout the stride is to be achieved. One potential avenue is by using forward dynamic
743 simulations (e.g., Sellers et al. 2017) to generate a variety of postures throughout the stance that
744 may be used to inform musculoskeletal and finite element models. This would require more
745 complex modelling of some joints than is currently done (e.g., three degrees of freedom for the
746 hip), and would in turn require substantially greater computational power.

747

748

749 ***III.5.3 Theropod locomotor evolution***

750

751 A second major objective of the current study was to test evolutionary-biomechanical hypotheses
752 concerning posture, bone loading mechanics and muscular control strategies in theropods. In
753 doing so, insight would be gained as to how such aspects of theropod locomotion may have
754 evolved on the line to birds. As only three species have thus far been investigated, current
755 assessments are necessarily coarse; yet, as these species span a broad part of the theropod family
756 tree, this is sufficient to detect gross phyletic change in the aspects of locomotor biomechanics
757 examined here. Indeed, that the results for the *Daspletosaurus* model are consistently quite
758 different from those for the chicken model (Figs 12, 13) is suggestive of pronounced evolutionary
759 change between Coelurosauria and Neognathae.

760

761 The results for the three theropod species modelled here demonstrate that, progressing through
762 theropod phylogeny towards more derived species, the following trends occurred:

- 763 1. The whole-body COM moved anteriorly; this was to be expected, given that model mass
764 properties were largely derived from models developed in the study of Allen et al. (2013),
765 who showed the same pattern.

- 766 2. Hindlimb posture became more crouched, at least as far as the hip and knee joints are
767 concerned. This is consonant with the findings of previous work (Carrano 1998; Gatesy
768 1990; Gatesy 1991; Gatesy 1995).
- 769 3. Torsion became more prevalent than bending as the dominant loading regime of the femur.
- 770 4. The direction of bending of the femur changed from being predominantly mediolateral to
771 being predominantly anteroposterior.
- 772 5. Hip abduction became overtaken by hip long-axis rotation as the main muscular control
773 mechanism of stance-limb support.
- 774 For a given parameter, the value for ‘*Troodon*’ was intermediate between that for *Daspletosaurus*
775 and that for the chicken. This supports the hypothesis of a gradual evolutionary change in
776 locomotor biomechanics along the line to birds, but more taxa from different parts of theropod
777 phylogeny would need to be modelled to definitively rule out punctuated change at any point
778 along the stem lineage. Regardless of the mode of evolution of these parameters, the above
779 results do suggest that hindlimb posture, bone loading mechanics and muscular support strategies
780 were tightly associated with each other, supporting the hypotheses of Carrano (1998) and
781 Hutchinson & Gatesy (2000). With the framework established in this series of studies, future
782 development of models for other species, from different theropod clades, will help further test
783 and clarify this interpretation.
- 784
- 785 The above trends identified in the present study are consilient with trends in other
786 biomechanically relevant aspects, as noted by previous studies. These other trends include:
- 787 1. Modifications of pelvic and hindlimb osteology and musculature (Carrano 2000; Hutchinson
788 2001a; Hutchinson 2001b; Hutchinson 2002).
- 789 2. Decrease in tail length and prominence of caudofemoralis musculature (Gatesy 1990; Gatesy
790 1995; Gatesy 2002; Pittman et al. 2013).
- 791 3. A shift from caudofemoralis-mediated, hip-based limb retraction to ‘hamstring’-mediated,
792 knee-based limb retraction during gait (Gatesy 1990; Gatesy 1995; Gatesy 2002).
- 793 4. Changes in gross limb proportions, in particular a decrease in relative femur length, which in
794 turn leads to an apparent increase in femoral diaphyseal robusticity (Carrano 1998; Gatesy &
795 Middleton 1997).

796 5. The acquisition of a more continuous locomotor repertoire, where walking and running are
797 not discrete gaits (Bishop et al. 2017).

798 The timing of some of these changes remains uncertain (see also Hutchinson 2006), but it appears
799 that all were underway prior to the origin of Paraves (i.e., birds and their closest maniraptoran
800 relatives such as ‘*Troodon*’), and that many, if not all, took place over a protracted period of time.
801

802 Most of the above changes also occurred in tandem with a progressive (Lee et al. 2014) or multi-
803 step (Benson et al. in press) reduction in body size along the theropod stem lineage. A decrease in
804 body size – either along the theropod stem lineage, or by directly comparing *Daspletosaurus*,
805 ‘*Troodon*’ and the chicken – might be expected in and of itself to bring about changes in posture,
806 since posture correlates with body size in extant parasagittal tetrapods (Biewener 1989; Biewener
807 1990; Bishop et al. 2018; Gatesy & Biewener 1991). However, since many other aspects of
808 theropod anatomy and locomotor biomechanics also change in tandem with body size along the
809 theropod stem lineage, it is presently not possible to disentangle the relative importance of body
810 size (or any other single feature) on posture. That many aspects of theropod locomotor anatomy
811 and biomechanics appear to have co-evolved over a protracted period of time, along with
812 additional features such as forelimb enlargement (Allen et al. 2013; Dececchi & Larsson 2013)
813 and elaboration of forelimb integument (Xu et al. 2014; Zelenitsky et al. 2012), is an interesting
814 phenomenon that warrants further investigation.

815

816 The results of this study may also have more general implications for understanding locomotor
817 biomechanics (and its evolution) in tetrapod species that employ a largely parasagittal stance and
818 gait. Previous *in vivo* strain gauge studies of parasagittal mammals that use a more crouched
819 femoral posture have shown that the femur experiences a sizeable amount of torsional loading, in
820 addition to bending (Butcher et al. 2011; Keller & Spengler 1989). Additionally, finite element
821 simulations of sit-to-stand and stand-to-sit behaviour in humans, behaviours that require limb
822 support during crouched femoral orientations, have revealed a marked increase in torsional
823 loading of the femur compared to normal locomotion (Villette 2016). In concert with the results
824 of this study, these observations suggest that there is a continuum in musculoskeletal mechanics
825 spanning from crouched to upright postures, of which birds and humans are ‘end members’. In
826 upright postures, hip abduction is the dominant mode of limb support, which results in bending

827 being the dominant mode of loading of the femur. However, as the femur becomes more
828 crouched, the efficacy of hip abduction in providing limb support decreases, whilst that of hip
829 long-axis rotation increases; this in turn loads the femur in a greater degree of torsion (see also
830 Butcher et al. 2011).

831

832

833 ***III.5.4 Methodological considerations***

834

835 A number of methodological considerations should be borne in mind when interpreting the
836 results of the present study. None are considered to be of any major importance for the main
837 interpretations made here, but they do highlight areas where future research efforts could be
838 focused, potentially yielding further insight into theropod hindlimb biomechanics.

839

840

841 III.5.4.1 Correspondence in the distal tibiotarsus

842

843 It is worth re-iterating that little correspondence was evident between principal stresses and
844 cancellous bone architecture in the distal parts of the tibiotarsus or fibula, in any posture tested
845 for all three theropod species modelled. Additionally, the architectural patterns observed in the
846 fibular crest of tyrannosaurid tibiae could not be replicated in the *Daspletosaurus* model. As
847 discussed in Part II, this could reflect an inadequate modelling formulation, adaptation of these
848 parts of the bones to many varied loading regimes, or a combination of both (or other) factors.
849 For the two extinct species at least, the normal *in vivo* loads experienced by the distal tibiotarsus
850 may have also been influenced by the derived arctometatarsalian structure of their metatarsus
851 (Holtz 1995; Snively & Russell 2003; Wilson & Currie 1985), a prospect requiring further
852 investigation. Nevertheless, the architecture of cancellous bone in the distal tibiotarsus of
853 theropods shows some strikingly different patterns between the various theropod groups. From a
854 phenomenological perspective at least, this is indicative of marked differences in bone loading
855 regimes, and by extension locomotor behaviour. It is therefore worthy of future modelling effort
856 to establish a more mechanistic link between cancellous bone architecture and musculoskeletal
857 loading mechanics in this part of the hindlimb.

858

859

860 III.5.4.2 Pelvic orientation

861

862 One aspect of theropod posture that was not investigated in this study was the orientation of the
863 pelvis. In all simulations, the pelvis of the three theropod species modelled was oriented
864 similarly, with the sacral vertebra oriented approximately horizontally and parallel to the x -axis
865 of the global coordinate system. However, it is known that extant birds can employ significant
866 amounts of pitch, roll or yaw during locomotion (Abourachid et al. 2011; Gatesy 1999a;
867 Rubenson et al. 2007). If the pelvis underwent side-to-side rolling during locomotion in non-
868 avian theropods, even by a small amount, this may have served to clear the pelvis and trunk
869 further out of the way of the thigh of the stance leg. The effect of this would have been most
870 obvious in species with well-developed pubic boots, such as large tyrannosaurids and
871 allosauroids. Future investigation could therefore be directed towards incorporating one or more
872 degrees of freedom in the pelvis segment of the models, as well as incorporating additional
873 degrees of freedom in other joints (e.g., knee). Caution would need to be exercised, however, as
874 the number of variable parameters could quickly grow to be very large, which may require a great
875 deal more posture variations be tested before a 'solution posture' is satisfactorily obtained.
876 However, as noted in Part II, the development of an automated optimization approach (in tandem
877 with more extensive quantification of cancellous bone architecture) could allow for more degrees
878 of freedom to be incorporated, and for more posture variations to be tested. This is a worthwhile
879 avenue for future research, one that could make the reverse approach more easily applicable to a
880 wider range of questions on tetrapod locomotor evolution.

881

882

883

884

885 III.5.4.3 Stresses in the medial femoral condyle

886

887 As noted in the results of this study, as well as those of Part II, the mean direction of the
888 minimum principal stress (σ_3) in the medial femoral condyle was notably more posteriorly

889 inclined than the mean direction of the primary fabric orientation of cancellous bone (\mathbf{u}_1), in both
890 the chicken and ‘*Troodon*’ models. This was the case regardless of the posture tested. The cause
891 for this discrepancy is probably twofold. Firstly, taking the mean direction of \mathbf{u}_1 in the medial
892 condyle will average out the ‘fan’ of individual fabric vectors (see Part I) that is ubiquitous in
893 theropods. Thus, there will be some parts of the condyle for which a greater correspondence
894 between fabric direction and the calculated principal stresses will indeed occur, namely, where
895 the fabric vectors are more posteriorly inclined than the overall orientation.

896

897 Secondly, it is quite possible that the individual \mathbf{u}_1 vectors throughout the medial condyle may
898 also ‘reflect’ the maximum principal stress (σ_1) in addition to σ_3 , and so do not fully align with
899 the calculated directions of either one. Given that motion of the theropod knee is inferred to have
900 predominantly occurred in the flexion-extension plane (but see Kambic et al. 2015), the main
901 loading regimes expected in the femoral condyles would be expected to be anteroposteriorly
902 oriented, as also suggested by the ‘butterfly pattern’ of the secondary fabric direction in the
903 condyles (see Part I). Hence, both σ_1 and σ_3 could be expected to be largely constrained to a
904 parasagittal orientation, which could influence the direction of \mathbf{u}_1 throughout the medial condyle.

905

906

907 **III.6 Conclusion**

908

909 By applying the trajectorial theory in reverse, this study sought to identify a single, characteristic
910 posture for two extinct, non-avian theropods that can explain a considerable amount of the
911 architecture of cancellous bone observed in the hindlimb bones of these species. The postures
912 derived for *Daspletosaurus torosus* and ‘*Troodon*’ are inferred to reflect the postures used at
913 around mid-stance during normal terrestrial locomotion, but should not be presumed to have been
914 *the* postures used. The largely upright posture identified for *Daspletosaurus* is comparable to the
915 postures previously hypothesized for other large, phylogenetically basal tetanuran species of non-
916 avian theropod. The posture identified for ‘*Troodon*’ is more crouched than that of
917 *Daspletosaurus*, especially in regard to femoral orientation, but not to the degree observed in
918 extant birds. The results of this study also provide an alternative perspective on the manner of
919 articulation of the non-avian theropod hip joint, and suggest a solution to how non-avian

920 theropods with proximomedially inclined femoral heads maintained narrow mediolateral foot
921 placements.

922

923 In addition to improving understanding of posture in non-avian theropods, this study provides a
924 new approach for how evolutionary-biomechanical hypotheses of locomotion can be explicitly
925 and quantitatively tested. By using a previously underexplored line of evidence, cancellous bone
926 architecture, the results of this study have supported the hypotheses of Carrano (1998) and
927 Hutchinson & Gatesy (2000). Progressing from coelurosaurs through to extant birds, a number of
928 important changes are inferred to have occurred in concert with one another, involving whole-
929 body COM position, hindlimb posture, bone loading mechanics and muscular control strategies.
930 The pattern of the changes also supports a more gradual fashion of change (as opposed to more
931 punctuated), adding to the growing body of evidence suggesting that the unique locomotor
932 repertoire of extant birds was acquired over a long period of time. However, only three species
933 were modelled here, and so a more rigorous testing of the exact mode and tempo of evolutionary
934 change awaits the modelling of additional species.

935

936 The integrative biomechanical modelling approach developed in Part II provides useful insights
937 into non-avian theropod hindlimb locomotor biomechanics, as well as how this evolved along the
938 line to extant birds. The generality of the approach means that it could be useful for
939 understanding locomotor behaviour, and its evolution, in other extinct vertebrate groups as well.
940 Examples of future research that could apply the approach include: forelimb posture and use in
941 quadrupedal dinosaurs, such as ceratopsians (Fujiwara & Hutchinson 2012; Johnson & Ostrom
942 1995); the evolution of powered flight in birds, bats and pterosaurs (Bishop 2008; Heers & Dial
943 2012; Thewissen & Babcock 1992; Unwin 2005); the evolution of posture in synapsids on the
944 line to mammals (Blob 2001; Kemp 1982; Lai et al. 2018); and the evolution of terrestrial
945 locomotor capabilities in stem tetrapods (Clack 2012; Pierce et al. 2013). It may also prove to be
946 of use for questions of biomechanics not related to locomotion, such as the posture of sauropod
947 dinosaur necks (Stevens & Parrish 2005; Taylor et al. 2009).

948

949 **III.7 Acknowledgements**

950

951 The staff of the Geosciences Program of the Queensland Museum is thanked for the provision of
952 workspace and access to literature: A. Rozefelds, K. Spring, R. Lawrence, P. Tierney, J.
953 Wilkinson and D. Lewis. Much appreciation is extended to the staff and associated colleagues of
954 the institutions that provided access to the material studied here: D. Henderson, B. Strilisky, G.
955 Housego, R. Russel, T. Courtenay, B. Sanchez and F. Therrien (Royal Tyrell Museum of
956 Palaeontology, Drumheller); R. Irmis, C. Levitt-Bussian, C. Webb and P. Policelli (Natural
957 History Museum of Utah, Salt Lake City); J. Horner, J. Scannella, D. Varricchio, D. Strosnider,
958 C. Woodruff, D. Fowler and T. Carr (Museum of the Rockies, Bozeman). Many of the above
959 people also provided helpful discussion on various aspects of theropod biology, and also helped
960 transport specimens for CT scanning. Those who facilitated or performed the scanning itself are
961 also greatly thanked: S. Purdy and D. Wetter (Canada Diagnostic Centres, Calgary); K. Ugrin and
962 D. Van Why (Bozeman Deaconess Hospital, Bozeman); and S. Merchant, E. Hsu and J. Morgan
963 (HSC Cores Research Facility, University of Utah, Salt Lake City). The thorough and
964 constructive comments on earlier versions of the manuscript, provided by S. Gatesy, T. Ryan, D.
965 Henderson, E. Snively and an anonymous reviewer, are all greatly appreciated, and substantially
966 improved the clarity and content of the research presented here. All scripts and data used are held
967 in the Geosciences Collection of the Queensland Museum, and will be made available upon
968 request to the Collections Manager. Additionally, a complete copy of the fossil CT scan data
969 obtained in the present study is accessioned with the respective institutions in which the
970 specimens are housed.

1261

1262 **III.9 Figure captions**

1263

1264

1265 **Figure 1.** The musculoskeletal model of the *Daspletosaurus* hindlimb developed in this study.
1266 This is shown in the ‘neutral posture’ for all joints, that is, when all joint angles are zero. (A–C)
1267 Geometries of the musculotendon actuators in relation to the bones, in lateral (A), anterior (B)
1268 and oblique anterolateral (C) views. (D–F) Location and orientation of joint coordinate systems
1269 (red, green and blue axes), the centres of mass for each segment (grey and white balls) and the
1270 soft tissue volumes used to calculate mass properties; these are shown in the same views as A–C.
1271 Also reported in D are the masses for each segment; the pelvis segment represents the body as
1272 well as the contralateral limb. In D–F, the flexion-extension axis of each joint is the blue axis. For
1273 scale, the length of each arrow in the triad of the global coordinate system is 500 mm.

1274

1275

1276 **Figure 2.** The musculoskeletal model of the ‘*Troodon*’ hindlimb developed in this study. This is
1277 shown in the neutral posture for all joints. A–C, geometries of the musculotendon actuators in
1278 relation to the bones, in lateral (A), anterior (B) and oblique anterolateral (C) views. (D–F)
1279 Location and orientation of joint coordinate systems (red, green and blue axes), the centres of
1280 mass for each segment (grey and white balls) and the soft tissue volumes used to calculate mass
1281 properties; these are shown in the same views as A–C. Also reported in D are the masses for each
1282 segment; the pelvis segment represents the body as well as the contralateral limb. In D–F, the
1283 flexion-extension axis of each joint is the blue axis. For scale, the length of each arrow in the
1284 triad of the global coordinate system is 200 mm.

1285

1286

1287 **Figure 3.** Varying the articulation of the hip joint in the *Daspletosaurus* model. (A–C) The
1288 original ‘solution posture’ identified for the *Daspletosaurus* model. (D–F) The first variation in
1289 hip articulation, where the femur (and limb distal to it) is moved medially by 50 mm. (G–I) The
1290 second variation in hip articulation, where the femur (and limb distal to it) is moved medially by
1291 50 mm, also with a sizeable amount of hip abduction and external long-axis rotation. A, D and G
1292 are in oblique anterolateral view; B, E and H are in close-ups of the hip articulation in anterior
1293 view; C, F and I show the whole hindlimb in anterior view, to illustrate the effect of differing hip
1294 articulations on gross limb position. Intervening soft tissues used in the finite element simulations
1295 are shown in turquoise; for clarity, the ilium and pubis are shown translucent in B, E and H. Also
1296 illustrated in B are the relative diameters of the femoral head (solid lines) and the acetabulum
1297 (dashed lines).

1298

1299

1300 **Figure 4.** The postures tested for in *Daspletosaurus*. Around the periphery are the different
1301 postures tested, shown in lateral view, with the final solution posture in the centre box, shown in
1302 lateral, dorsal and anterior views; the whole-body COM location is also shown for the solution
1303 posture in lateral view. Joint angles for each posture are given in blue font; hip joint angles are
1304 given in the order of flexion-extension, abduction-adduction and long-axis rotation. Hip
1305 extension angle is expressed relative to the horizontal, whereas knee and ankle angles are
1306 expressed relative to the femur and tibiotarsus (respectively). For the other hip angles, positive
1307 values indicate abduction and external rotation, whereas negative values indicate adduction and
1308 internal rotation. The metatarsophalangeal joint angle is expressed relative to the neutral posture.
1309 The angular deviation between σ_3 and \mathbf{u}_1 for each posture is also given in red font (reported as
1310 femoral head, then medial femoral condyle). The solution posture resulted in the greatest degree
1311 of overall correspondence between principal stress trajectories and observed cancellous bone
1312 architectural patterns in birds, as assessed by qualitative comparisons across the femur,
1313 tibiotarsus and fibula, as well as quantitative results for the femoral head and medial femoral
1314 condyle.

1315

1316

1317 **Figure 5.** The postures tested for in ‘*Troodon*’. Around the periphery are the different postures
1318 tested, shown in lateral view, with the final solution posture in the centre box, shown in lateral,
1319 dorsal and anterior views; the whole-body COM location is also shown for the solution posture in
1320 lateral view. Joint angles for each posture are given in blue font, following the same conventions
1321 as Fig. 4. The angular deviation between σ_3 and \mathbf{u}_1 for each posture is also given in red font
1322 (reported as femoral head, then medial femoral condyle). The solution posture resulted in the
1323 greatest degree of overall correspondence between principal stress trajectories and observed
1324 cancellous bone architectural patterns in birds, as assessed by qualitative comparisons across the
1325 femur, tibiotarsus and fibula, as well as quantitative results for the femoral head and medial
1326 femoral condyle.

1327

1328

1329 **Figure 6.** Principal stress trajectories for the proximal femur in the solution posture of
1330 *Daspletosaurus*, compared with observed cancellous bone fabric. For easier visual comparison,
1331 the stress trajectories were ‘downsampled’ in a custom MATLAB script, by interpolating the raw
1332 stress results at each finite element node to a regular grid. (A) Vector field of σ_1 (red) and σ_3
1333 (blue) in a 3-D slice through the proximal femur, parallel to the coronal plane and through the
1334 middle of the femoral head, in anterior view. Note how the trajectory of σ_3 projects towards the
1335 apex of the femoral head (green braces). (B) Observed cancellous bone architecture in the
1336 proximal femur of *Allosaurus* and tyrannosaurids (cf. Part I), in the same view as A. (C) Vector
1337 field of σ_1 and σ_3 in a 3-D slice through the lesser trochanter, parallel to the plane of the
1338 trochanter, in anterolateral view. (D) Observed cancellous bone architecture in the lesser
1339 trochanter of *Allosaurus* and tyrannosaurids (cf. Part I), in the same view as C. (E) Vector field of
1340 σ_3 in the femoral head, shown as a 3-D slice parallel to the sagittal plane and through the apex of
1341 the head, in medial view. (F) Observed cancellous bone architecture in the femoral head of
1342 *Allosaurus* and tyrannosaurids (cf. Part I), in the same view as E. (G) Comparison of the mean
1343 direction of σ_3 in the femoral head (blue) and the estimated mean direction of \mathbf{u}_1 for *Allosaurus*
1344 and tyrannosaurids (red), plotted on an equal-angle stereoplot with northern hemisphere
1345 projection (using StereoNet 9.5; Allmendinger et al. 2013; Cardozo & Allmendinger 2013). Inset
1346 shows location of region for which the mean direction of σ_3 was calculated.

1347

1348

1349 **Figure 7.** Principal stress trajectories for the distal femur and fourth trochanter in the solution
1350 posture of *Daspletosaurus*, compared with observed cancellous bone fabric. (A) Vector field of
1351 σ_1 (red) and σ_3 (blue) in a 3-D slice, parallel to the coronal plane and through the anterior aspect
1352 of the distal metaphysis, in anterior view. (B) Observed cancellous bone architecture in the distal
1353 metaphysis of *Allosaurus* and tyrannosaurids (cf. Part I), in the same view as A. (C) Vector field
1354 of σ_1 in the fourth trochanter, in medial view. (D) Observed cancellous bone architecture in the
1355 fourth trochanter of *Allosaurus* and tyrannosaurids (cf. Part I), in the same view as C. (E) Vector
1356 field of σ_3 in the lateral condyle, shown as a 3-D slice parallel to the sagittal plane and through
1357 the middle of the condyle. (F) Observed cancellous bone architecture in the lateral condyle of
1358 *Allosaurus* and tyrannosaurids (cf. Part I), in the same view as E. (G) Vector field of σ_3 in the
1359 medial condyle, shown as a 3-D slice parallel to the sagittal plane and through the middle of the
1360 condyle. (H) Observed cancellous bone architecture in the medial condyle of *Allosaurus* and
1361 tyrannosaurids (cf. Part I), in the same view as G. (I) Comparison of the mean direction of σ_3 in
1362 the medial condyle (blue) and the estimated mean direction of u_1 for *Allosaurus* and
1363 tyrannosaurids (red), plotted on an equal-angle stereoplot with southern hemisphere projection.
1364 Inset shows location of region for which the mean direction of σ_3 was calculated.

1365

1366

1367 **Figure 8.** Principal stress trajectories for the tibia and fibula in the solution posture for
1368 *Daspletosaurus*, compared with observed cancellous bone fabric. (A) Vector field of σ_3 in the
1369 medial tibial condyle, shown as a 3-D slice through the middle of the condyle and parallel to the
1370 sagittal plane, in medial view. (B) Observed cancellous bone architecture in the medial tibial
1371 condyle of *Allosaurus* and tyrannosaurids (cf. Part I), in the same view as A. (C) Vector field of
1372 σ_3 in the medial and lateral tibial condyles, shown as 3-D slices through the middle of the
1373 condyles and parallel to the coronal plane, in posterior view. (D) Observed cancellous bone
1374 architecture in the medial and lateral tibial condyles of *Allosaurus* and tyrannosaurids (cf. Part I),
1375 in the same view as C. (E) Vector field of σ_3 in the lateral tibial condyle, shown as a 3-D slice
1376 through the middle of the condyle and parallel to the sagittal plane, in lateral view. (F) Observed
1377 cancellous bone architecture in the lateral tibial condyle of *Allosaurus* and tyrannosaurids (cf.
1378 Part I), in the same view as E. (G) Vector field of σ_1 in the cnemial crest, shown as a 3-D slice

1379 parallel to the coronal plane, in anterior view. (H) Observed cancellous bone architecture in
1380 cnemial crest of *Allosaurus* and tyrannosaurids (cf. Part I), sectioned in the plane of the crest,
1381 shown in the same view as G; blue section lines illustrate primary architectural direction. (I)
1382 Vector field of σ_1 in the cnemial crest, shown as a 3-D slice parallel to the sagittal plane, in
1383 medial view. (J) Observed cancellous bone architecture in cnemial crest of *Allosaurus* and
1384 tyrannosaurids (cf. Part I), sectioned in the plane of the crest, shown in the same view as I. (K)
1385 Vector field of σ_3 in the medial aspect of the fibular head, in medial view. (L) Observed
1386 cancellous bone architecture in the fibular head of *Allosaurus* and tyrannosaurids (cf. Part I), in
1387 the same view as K.

1388

1389

1390 **Figure 9.** Principal stress trajectories for the proximal femur in the solution posture of ‘*Troodon*’,
1391 compared with observed cancellous bone fabric. (A, B) Vector field of σ_3 in the femoral head,
1392 shown as 3-D slices parallel to the coronal plane (A, in anterior view) and sagittal plane (B, in
1393 medial view). (C, D) Observed vector field of u_1 in the femoral head, in the same views as A and
1394 B, respectively (cf. Part I). (E) Comparison of the mean direction of σ_3 in the femoral head (blue)
1395 and the mean direction of u_1 (red), plotted on an equal-angle stereoplot with northern hemisphere
1396 projection. Inset shows location of region for which the mean direction of σ_3 was calculated. (F,
1397 G) Vector field of σ_3 under the greater trochanter, shown as 3-D slices parallel to the coronal
1398 plane (F, in posterior view) and sagittal plane (G, in lateral view). (H, I) Observed vector field of
1399 u_1 under the greater trochanter, shown in the same views as F and G, respectively (cf. Part I). (J)
1400 Vector field of σ_1 in the lesser trochanter, shown in oblique anterolateral view. (K) Observed
1401 vector field of u_1 in the lesser trochanter, shown in the same view as J for both specimens studied
1402 (cf. Part I).

1403

1404

1405 **Figure 10.** Principal stress trajectories for the distal femoral condyles in the solution posture of
1406 ‘*Troodon*’, compared with observed cancellous bone fabric. (A) Vector field of σ_3 in the lateral
1407 condyle, shown as a 3-D slice parallel to the sagittal plane. (B) Observed vector field of u_1 in the
1408 lateral condyle, shown in the same view as A (cf. Part I). (C) Vector field of σ_3 in the medial
1409 condyle, shown as a 3-D slice parallel to the sagittal plane. (D) Observed vector field of u_1 in the

1410 medial condyle, shown in the same view as C (cf. Part I). (E) Comparison of the mean direction
1411 of σ_3 in the medial condyle (blue) and the mean direction of \mathbf{u}_1 (red), plotted on an equal-angle
1412 stereoplot with southern hemisphere projection. This shows that in the solution posture the mean
1413 direction of σ_3 was of the same general azimuth as the mean direction of \mathbf{u}_1 , but was markedly
1414 more posteriorly inclined. Inset shows location of region for which the mean direction of σ_3 was
1415 calculated.

1416

1417

1418 **Figure 11.** Principal stress trajectories for the tibia and fibula in the solution posture for
1419 ‘Troodon’, compared with observed cancellous bone fabric. (A) Vector field of σ_3 in the medial
1420 tibial condyle, shown as a 3-D slice through the middle of the condyle and parallel to the sagittal
1421 plane, in medial view. (B) Observed vector field of \mathbf{u}_1 in the medial tibial condyle, in the same
1422 view as A (cf. Part I). (C) Vector field of σ_3 in the medial and lateral tibial condyles, shown as 3-
1423 D slices through the middle of the condyles and parallel to the coronal plane, in posterior view.
1424 (D) Observed vector field of \mathbf{u}_1 in the medial and lateral tibial condyles, in the same view as C
1425 (cf. Part I). (E) Vector field of σ_3 in the lateral tibial condyle, shown as a 3-D slice through the
1426 middle of the condyle and parallel to the sagittal plane, in lateral view. (F) Observed vector field
1427 of \mathbf{u}_1 in the lateral tibial condyle, in the same view as E (cf. Part I). (G) Vector field of σ_1 in the
1428 cnemial crest, shown as a 3-D slice parallel to the coronal plane, in anterior view. (H) Observed
1429 vector field of \mathbf{u}_1 in the cnemial crest, in the same view as G (cf. Part I). (I) Vector field of σ_1 in
1430 the cnemial crest, shown as a 3-D slice parallel to the sagittal plane, in medial view. (J) Observed
1431 vector field of \mathbf{u}_1 in the cnemial crest, in the same view as I (cf. Part I). (K) Vector field of σ_1 in
1432 the lateral fibular head, in lateral view. (L) Vector field of σ_3 in the medial fibular head, in medial
1433 view (reversed). (M) Observed vector field of \mathbf{u}_1 in the fibular head, in the same view as K (cf.
1434 Part I).

1435

1436

1437 **Figure 12.** Principal stress trajectories for the proximal femur of *Daspletosaurus* in the two
1438 variations in hip articulation tested. (A) Vector field of σ_3 in the first variation tested, shown as a
1439 3-D slice parallel to the coronal plane and through the middle of the femoral head. (B) Vector
1440 field of σ_3 in the first variation tested, shown as a 3-D slice parallel to the sagittal plane and

1441 through the apex of the femoral head. (C) Vector field of σ_3 in the second variation tested, shown
1442 as a 3-D slice parallel to the coronal plane and through the middle of the femoral head. (D)
1443 Vector field of σ_3 in the second variation tested, shown as a 3-D slice parallel to the sagittal plane
1444 and through the apex of the femoral head. A and C are in anterior view, B and D are in medial
1445 view. Note in particular how the trajectory of σ_3 projects towards the more cylindrical part of the
1446 femoral head, lateral to the apex (green braces); compare to Fig. 6A,B,E,F. Also note in C how σ_3
1447 has a strong medial component near the apex of the head.

1448

1449

1450 **Figure 13.** Comparison of parameters related to posture, extracted from the solution postures of
1451 the three species modelled: *Daspletosaurus* ('D'), '*Troodon*' ('T') and the chicken ('C'). (A)
1452 Schematic illustration of the solution postures obtained for the three species, along with the
1453 location of the whole-body centre of mass (black and white disc). (B) Whole-body centre of mass
1454 location anterior to the hips, normalized to total leg length. (C) Degree of crouch for each species,
1455 both as measured from the solution posture, as well as empirically predicted from the data
1456 reported by Bishop et al. (2018). (D) Angles of the hip and knee joints. The hip extension angle is
1457 expressed relative to the horizontal, whereas the knee flexion angle is expressed relative to the
1458 femur. (E) Long-axis rotation and adduction-abduction of the hip joint. Positive values indicate
1459 external rotation and abduction (respectively), whereas negative values indicate internal rotation
1460 and adduction (respectively).

1461

1462

1463 **Figure 14.** Comparison of parameters related to bone loading mechanics and muscular support,
1464 extracted from the solution postures of the three species modelled: *Daspletosaurus* ('D'),
1465 '*Troodon*' ('T') and the chicken ('C'). (A) Orientation of the neutral surface of bending and the
1466 orientation of principal stresses (σ_1 and σ_3) relative to the femur long-axis, both measured at mid-
1467 shaft. Insets show the neutral surface with respect to the mid-shaft cross-section, as well as
1468 anatomical directions ('A', anterior; 'P', posterior; 'M', medial; 'L', lateral). (B) Ratio of
1469 maximum shear to bending stress in the femoral mid-shaft. (C) Normalized moments of hip
1470 abductor and medial rotator muscles. The hip abductor for all species is the iliofemoralis externus
1471 (activation set to zero in the chicken; see Part II). In *Daspletosaurus* and '*Troodon*', the medial

1472 rotators are the iliotrochantericus caudalis and puboischiofemorales internus 1 et 2; in the
1473 chicken, they are the iliotrochanterici caudalis et medius. (D) Oblique anterolateral view of the
1474 hip of *Daspletosaurus*, showing the abductor and medial rotator muscles (colours as in C).

Table 1 (on next page)

The specimens utilized in building the models of *Daspletosaurus torosus* and ' *Troodon* '.

Also listed are the settings used in acquiring CT scans; the geometry of specimens that were not CT scanned was captured via digital photogrammetry.

*Collection number abbreviations: MOR, Museum of the Rockies; TMP, Royal Tyrrell Museum of Palaeontology; UMNH VP; Natural History Museum of Utah.

Table 2 (on next page)

The origins and insertions of each of the muscles and ligaments represented in the *Daspletosaurus* and ' *Troodon* ' musculoskeletal models.

Specific differences between the two theropods are noted where appropriate.

Table 2. The origins and insertions of each of the muscles and ligaments represented in the *Daspletosaurus* and ‘*Troodon*’ musculoskeletal models. Specific differences between the two theropods are noted where appropriate.

Muscle or ligament	Abbreviation	Origin	Insertion
Iliotibialis 1	IT1	Anterior rim of lateral ilium	Cnemial crest
Iliotibialis 2	IT2	Dorsal rim of ilium, lateral surface	Cnemial crest
Iliotibialis 3	IT3	Dorsal rim of postacetabular ilium	Cnemial crest
Ambiens	AMB	Preacetabular process on proximal pubis	Cnemial crest
Femorotibialis externus	FMTE	Lateral femoral shaft	Cnemial crest
Femorotibialis internus	FMTI	Anteromedial femoral shaft	Cnemial crest
Iliofibularis	ILFB	Lateral postacetabular ilium, between IFE and FTE; posterior to median vertical ridge of the ilium in <i>Daspletosaurus</i>	Fibular tubercle
Iliofemoralis externus	IFE	Lateral ilium, anterodorsal to acetabulum; anterior to median vertical ridge of the ilium in <i>Daspletosaurus</i>	Trochanteric shelf of femur
Iliotrochantericus caudalis	ITC	Lateral preacetabular ilium	Lesser trochanter
Puboischiofemoralis internus 1	PIFI1	Iliac preacetabular fossa; also descending onto lateral surface of pubic peduncle in <i>Daspletosaurus</i>	Anteromedial aspect of proximal femur
Puboischiofemoralis internus 2	PIFI2	Near PIFI1 origin, probably anterior to it (iliac preacetabular fossa)	Distal to lesser trochanter; on accessory trochanter in <i>Daspletosaurus</i>
Flexor tibialis internus 1	FTI1	Low tubercle on posterolateral ischial shaft in <i>Daspletosaurus</i> ; distal end of ischium in ‘ <i>Troodon</i> ’	Medial proximal tibia
Flexor tibialis internus 3	FTI3	Ischial tuberosity on posterolateral proximal ischium in <i>Daspletosaurus</i> ; proximal ischial shaft in ‘ <i>Troodon</i> ’	Medial proximal tibia
Flexor tibialis externus	FTE	Lateral postacetabular ilium	Medial proximal tibia
Adductor femoris 1	ADD1	Lateral surface of obturator process	Medial posterodistal surface of femoral shaft; large scarred region in <i>Daspletosaurus</i>
Adductor femoris 2	ADD2	Posterodorsal rim of ischium	Lateral posterodistal surface of femoral shaft; large scarred region in <i>Daspletosaurus</i>
Puboischiofemoralis externus 1	PIFE1	Anterior surface of pubic apron	Greater trochanter
Puboischiofemoralis externus 2	PIFE2	Posterior surface of pubic apron	Greater trochanter
Puboischiofemoralis externus 3	PIFE3	Lateral ischium, between ADD1 and ADD2	Greater trochanter
Ischiotrochantericus	ISTR	Medial surface of ischium	Lateral proximal femur

2

Table 2 (continued).

Muscle or ligament	Abbreviation	Origin	Insertion
Caudofemoralis longus	CFL	Caudal vertebral centra, probably from caudal vertebrae 1–15 in <i>Daspletosaurus</i> and caudal vertebrae 1–10 in 'Troodon'	Medial surface of fourth trochanter in <i>Daspletosaurus</i> , posteromedial surface of proximal femur in 'Troodon'
Caudofemoralis brevis	CFB	Brevis fossa of ilium	Lateral surface of fourth trochanter in <i>Daspletosaurus</i> , posterolateral surface of proximal femur in 'Troodon'
Gastrocnemius lateralis	GL	Posterolateral surface of distal femur	Posterior surface of metatarsals II-IV
Gastrocnemius medialis	GM	Medial proximal tibia	Posterior surface of metatarsals II-IV
Flexor digitorum longus	FDL	Posterior surface of distal femur	Ventral aspect of digit II-IV phalanges
Flexor digitorum brevis	FDB	Posterior surface of metatarsals II-IV	Ventral aspect of digit II-IV phalanges
Flexor hallucis longus	FHL	Posterior surface of femur	Ventral aspect of digit I phalanges
Extensor digitorum longus	EDL	Distal anterolateral femur; possibly also proximal anterior tibia in <i>Daspletosaurus</i> , and possibly also distal anterolateral femur in 'Troodon'	Dorsal aspect of digit II-IV phalanges
Extensor digitorum brevis	EDB	Anterior surface of metatarsals	Dorsal aspect of digit II-IV phalanges
Extensor hallucis longus	EHL	Distal fibula	Dorsal aspect of digit I ungual
Tibialis anterior	TA	Anterior surface of proximal tibia	Anteroproximal metatarsals II-IV
Fibularis longus	FL	Anterolateral surface of tibia and/or fibula	Posterolateral ankle region (e.g., metatarsal V)
Fibularis brevis	FB	Distal to FL on fibula	Anterolateral ankle region (e.g., metatarsal IV)
Knee medial collateral ligament	KMCL	Depression on medial surface of medial femoral condyle	Medial proximal tibiotarsus, proximal to FCLP and FCM insertions
Knee lateral collateral ligament	KLCL	Lateral surface of lateral femoral condyle	Lateral fibular head
Ankle medial collateral ligament	AMCL	Depression on medial surface of astragalus	Medial proximal tarsometatarsus
Ankle lateral collateral ligament	ALCL	Depression on lateral surface of calcaneum	Lateral proximal tarsometatarsus

Figure 1

The musculoskeletal model of the *Daspletosaurus* hindlimb developed in this study.

This is shown in the 'neutral posture' for all joints, that is, when all joint angles are zero. (A-C) Geometries of the musculotendon actuators in relation to the bones, in lateral (A), anterior (B) and oblique anterolateral (C) views. (D-F) Location and orientation of joint coordinate systems (red, green and blue axes), the centres of mass for each segment (grey and white balls) and the soft tissue volumes used to calculate mass properties; these are shown in the same views as A-C. Also reported in D are the masses for each segment; the pelvis segment represents the body as well as the contralateral limb. In D-F, the flexion-extension axis of each joint is the blue axis. For scale, the length of each arrow in the triad of the global coordinate system is 500 mm.

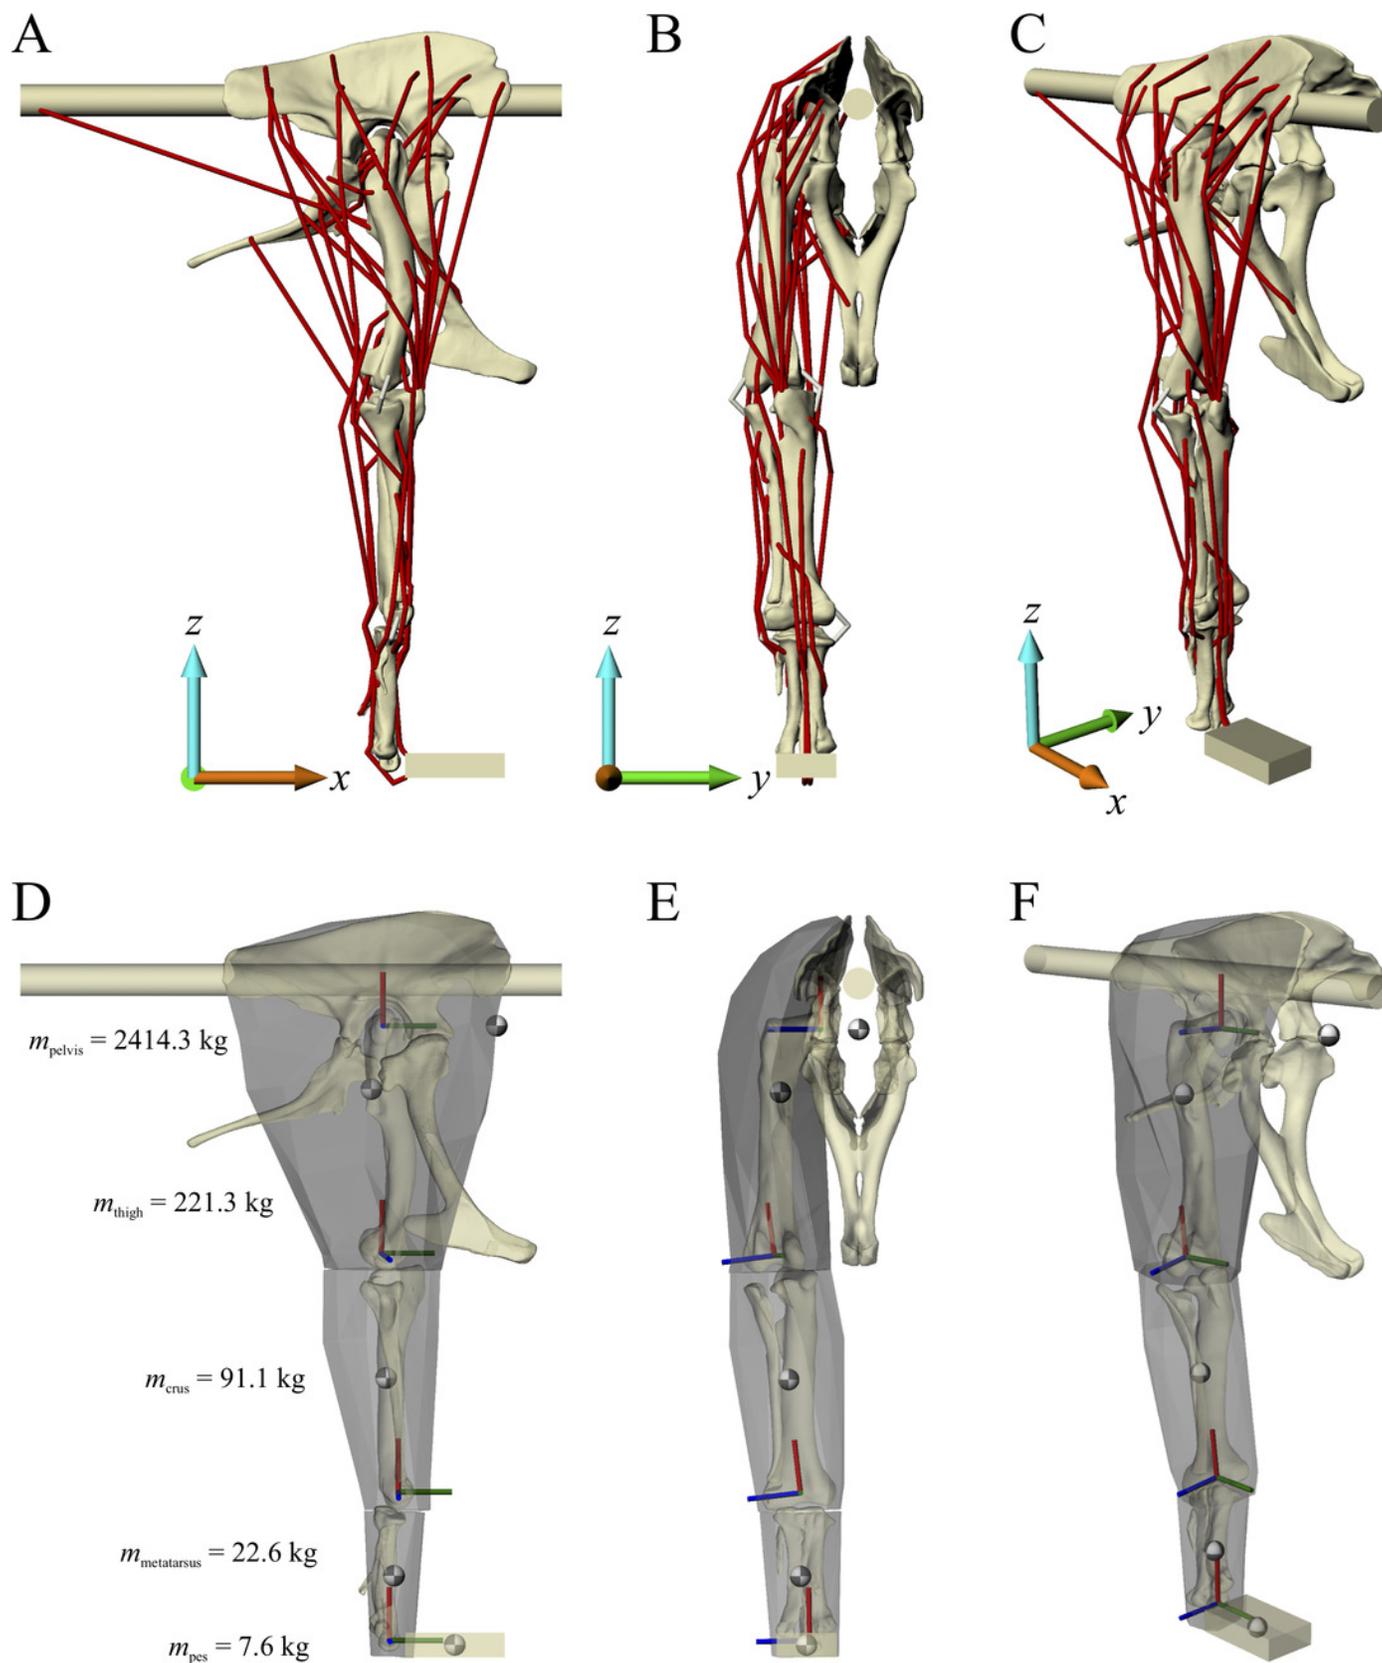

Figure 2

The musculoskeletal model of the '*Troodon*' hindlimb developed in this study.

This is shown in the neutral posture for all joints. A-C, geometries of the musculotendon actuators in relation to the bones, in lateral (A), anterior (B) and oblique anterolateral (C) views. (D-F) Location and orientation of joint coordinate systems (red, green and blue axes), the centres of mass for each segment (grey and white balls) and the soft tissue volumes used to calculate mass properties; these are shown in the same views as A-C. Also reported in D are the masses for each segment; the pelvis segment represents the body as well as the contralateral limb. In D-F, the flexion-extension axis of each joint is the blue axis. For scale, the length of each arrow in the triad of the global coordinate system is 200 mm.

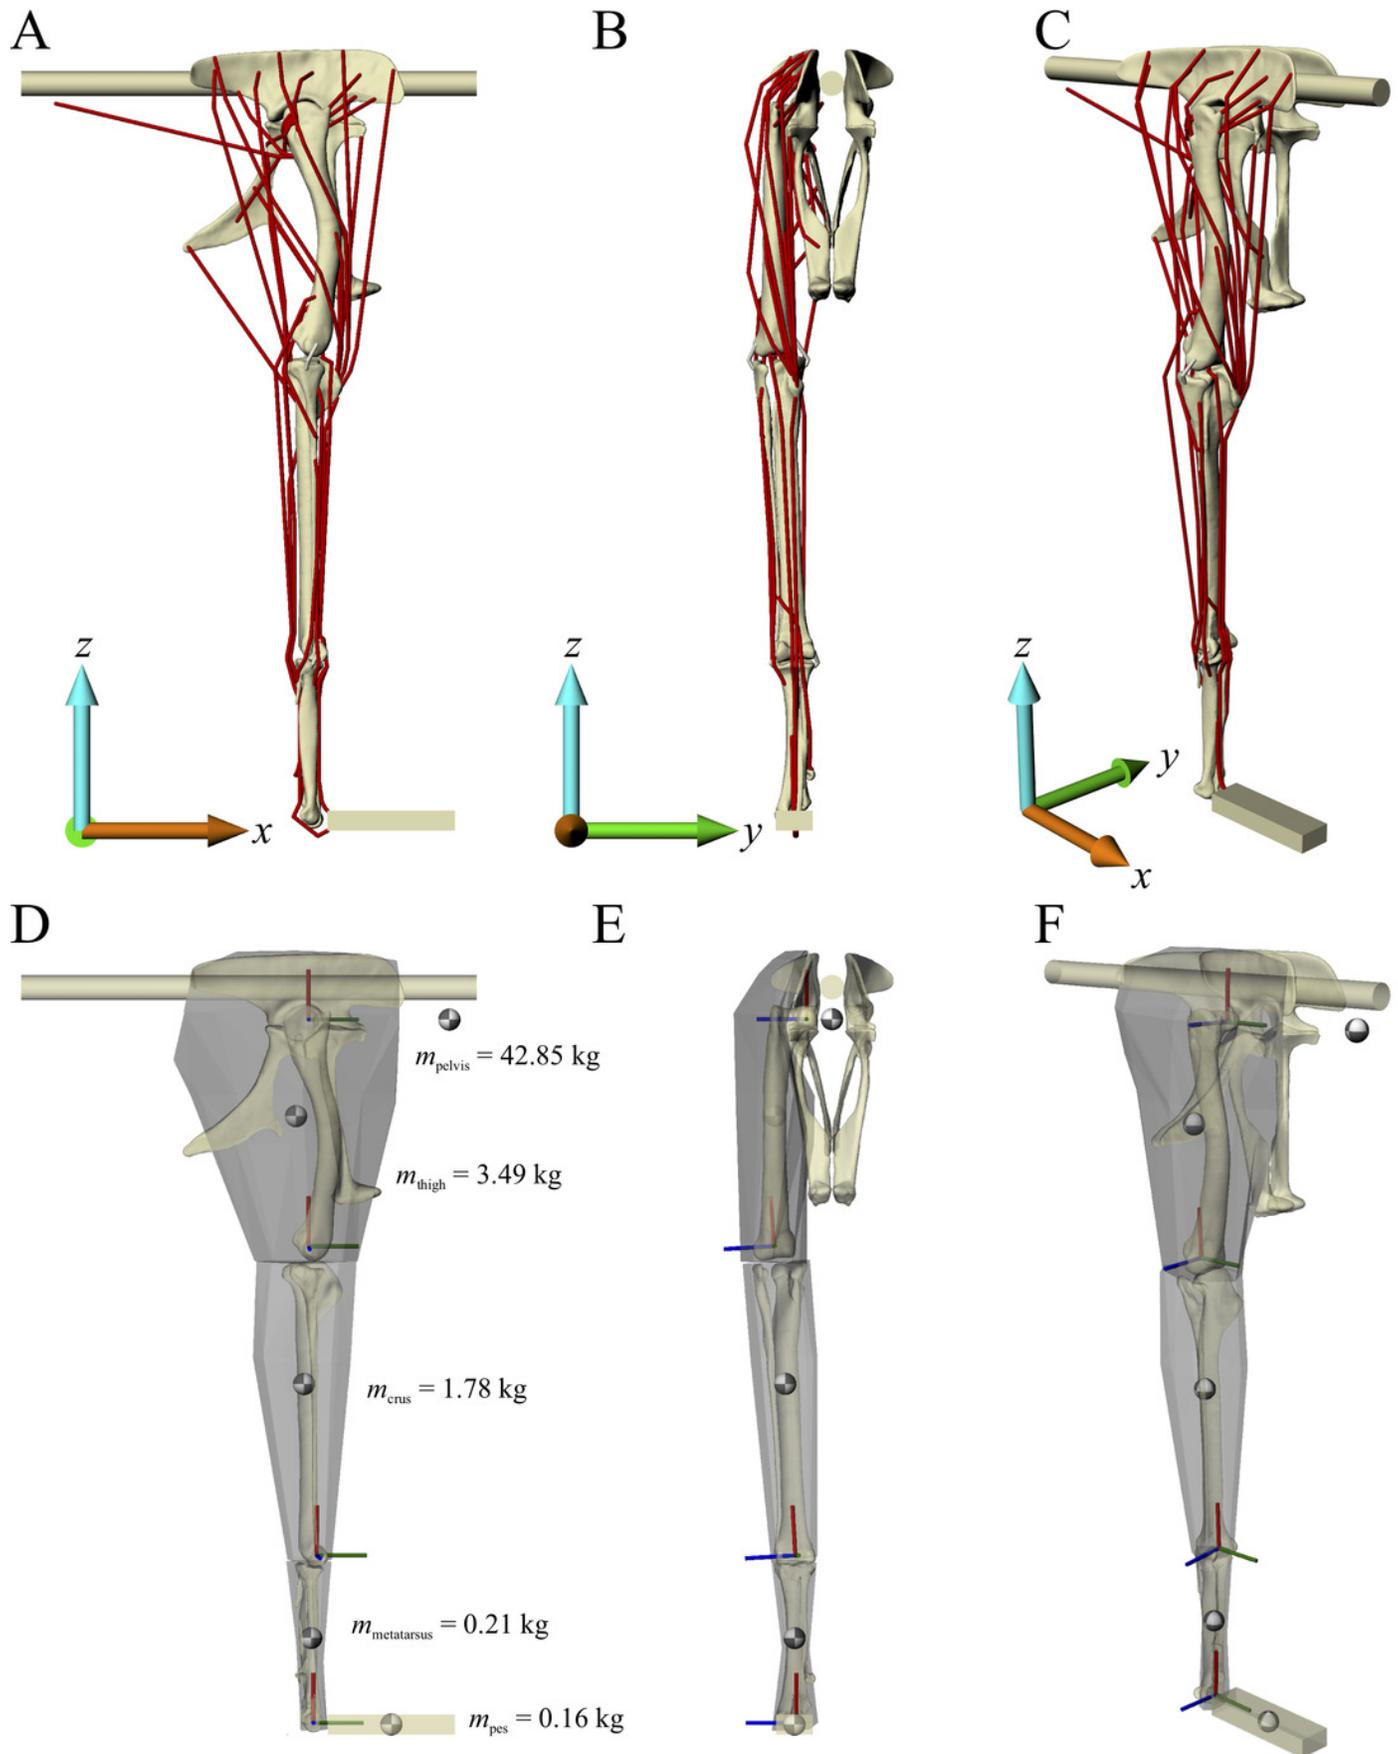

Figure 3

Varying the articulation of the hip joint in the *Daspletosaurus* model.

(A-C) The original 'solution posture' identified for the *Daspletosaurus* model. (D-F) The first variation in hip articulation, where the femur (and limb distal to it) is moved medially by 50 mm. (G-I) The second variation in hip articulation, where the femur (and limb distal to it) is moved medially by 50 mm, also with a sizeable amount of hip abduction and external long-axis rotation. A, D and G are in oblique anterolateral view; B, E and H are in close-ups of the hip articulation in anterior view; C, F and I show the whole hindlimb in anterior view, to illustrate the effect of differing hip articulations on gross limb position. Intervening soft tissues used in the finite element simulations are shown in turquoise; for clarity, the ilium and pubis are shown translucent in B, E and H. Also illustrated in B are the relative diameters of the femoral head (solid lines) and the acetabulum (dashed lines).

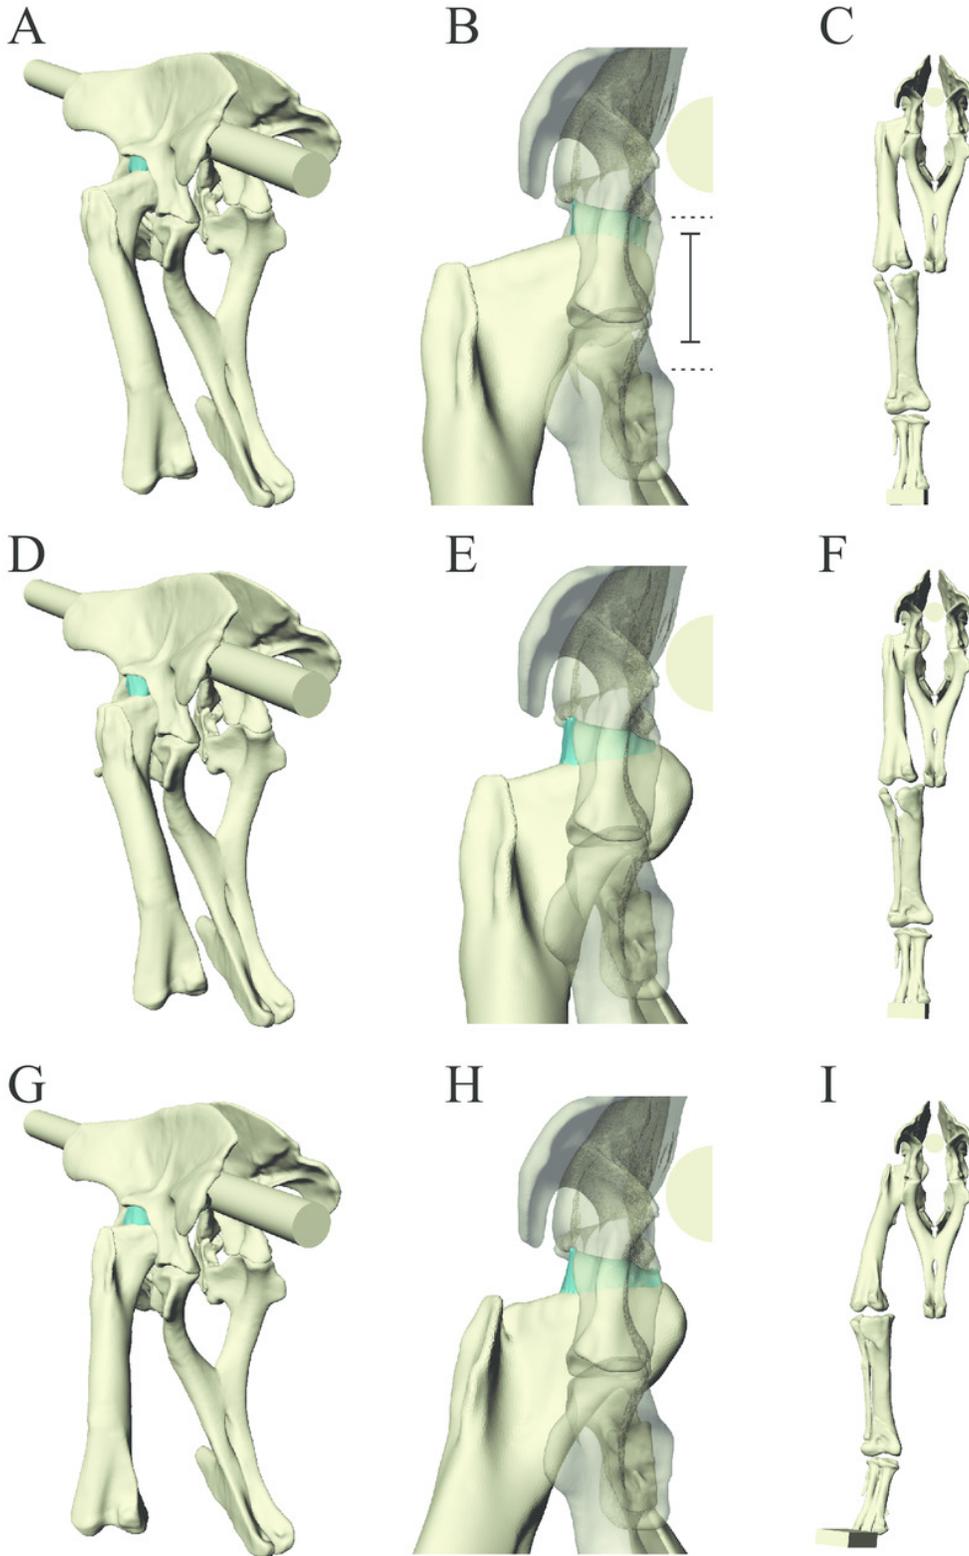

Figure 4

The postures tested for in *Daspletosaurus* .

Around the periphery are the different postures tested, shown in lateral view, with the final solution posture in the centre box, shown in lateral, dorsal and anterior views; the whole-body COM location is also shown for the solution posture in lateral view. Joint angles for each posture are given in blue font; hip joint angles are given in the order of flexion-extension, abduction-adduction and long-axis rotation. Hip extension angle is expressed relative to the horizontal, whereas knee and ankle angles are expressed relative to the femur and tibiotarsus (respectively). For the other hip angles, positive values indicate abduction and external rotation, whereas negative values indicate adduction and internal rotation. The metatarsophalangeal joint angle is expressed relative to the neutral posture. The angular deviation between σ_3 and u_1 for each posture is also given in red font (reported as femoral head, then medial femoral condyle). The solution posture resulted in the greatest degree of overall correspondence between principal stress trajectories and observed cancellous bone architectural patterns in birds, as assessed by qualitative comparisons across the femur, tibiotarsus and fibula, as well as quantitative results for the femoral head and medial femoral condyle.

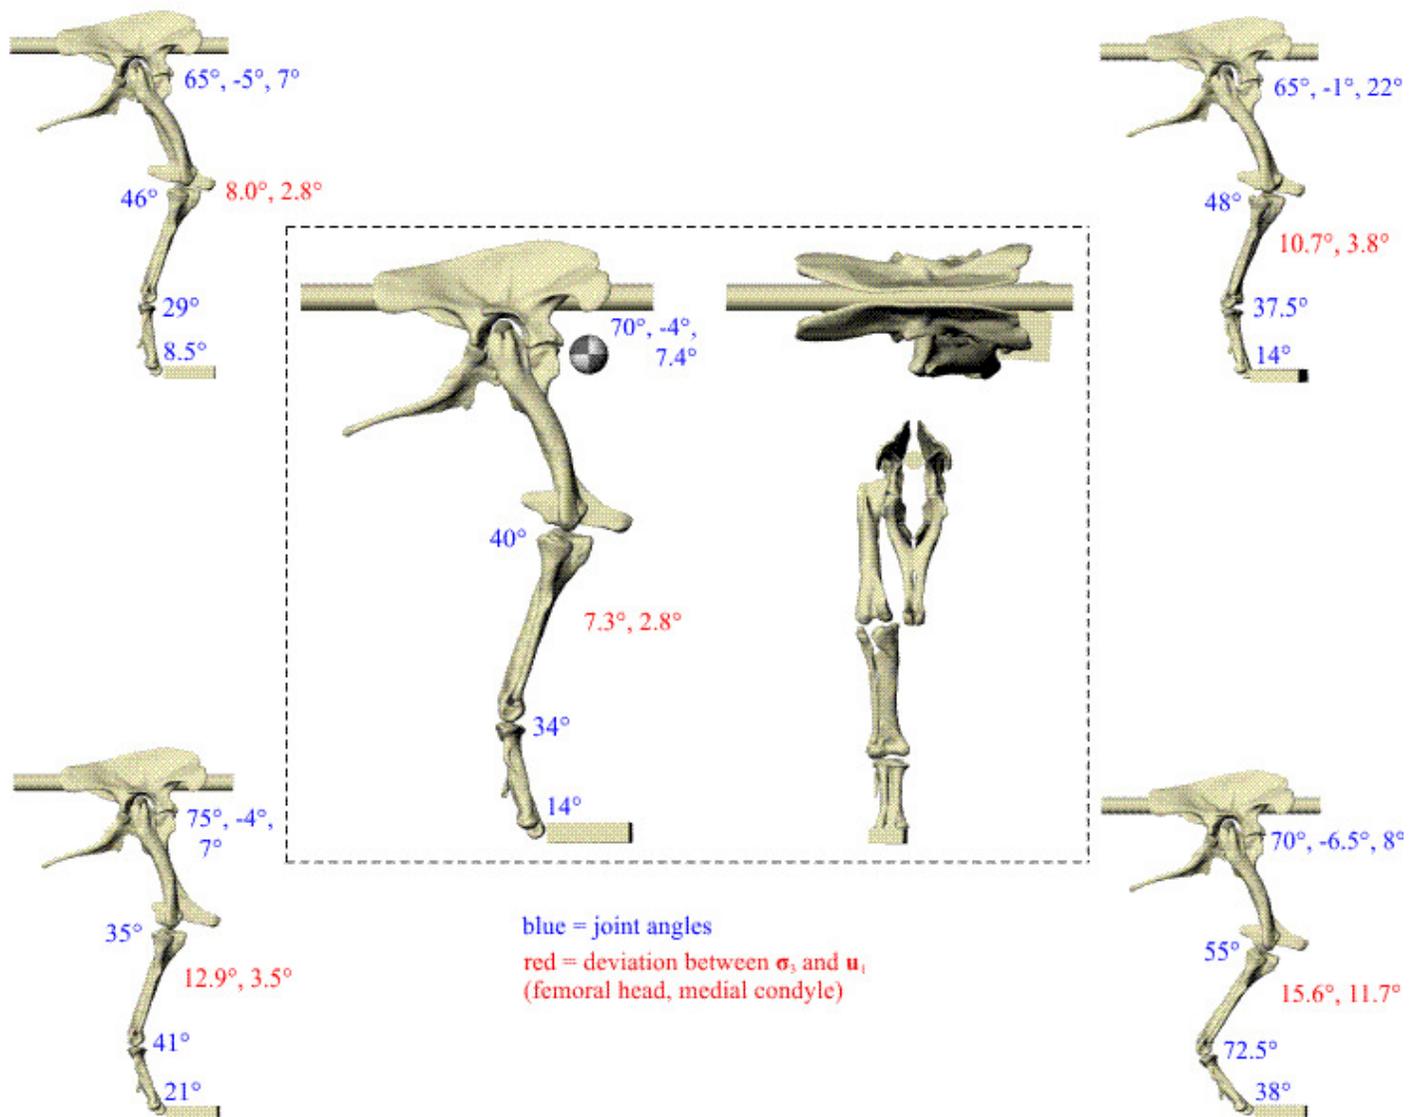

Figure 5

The postures tested for in '*Troodon*'.

Around the periphery are the different postures tested, shown in lateral view, with the final solution posture in the centre box, shown in lateral, dorsal and anterior views; the whole-body COM location is also shown for the solution posture in lateral view. Joint angles for each posture are given in blue font, following the same conventions as Fig. 4. The angular deviation between σ_3 and u_1 for each posture is also given in red font (reported as femoral head, then medial femoral condyle). The solution posture resulted in the greatest degree of overall correspondence between principal stress trajectories and observed cancellous bone architectural patterns in birds, as assessed by qualitative comparisons across the femur, tibiotarsus and fibula, as well as quantitative results for the femoral head and medial femoral condyle.

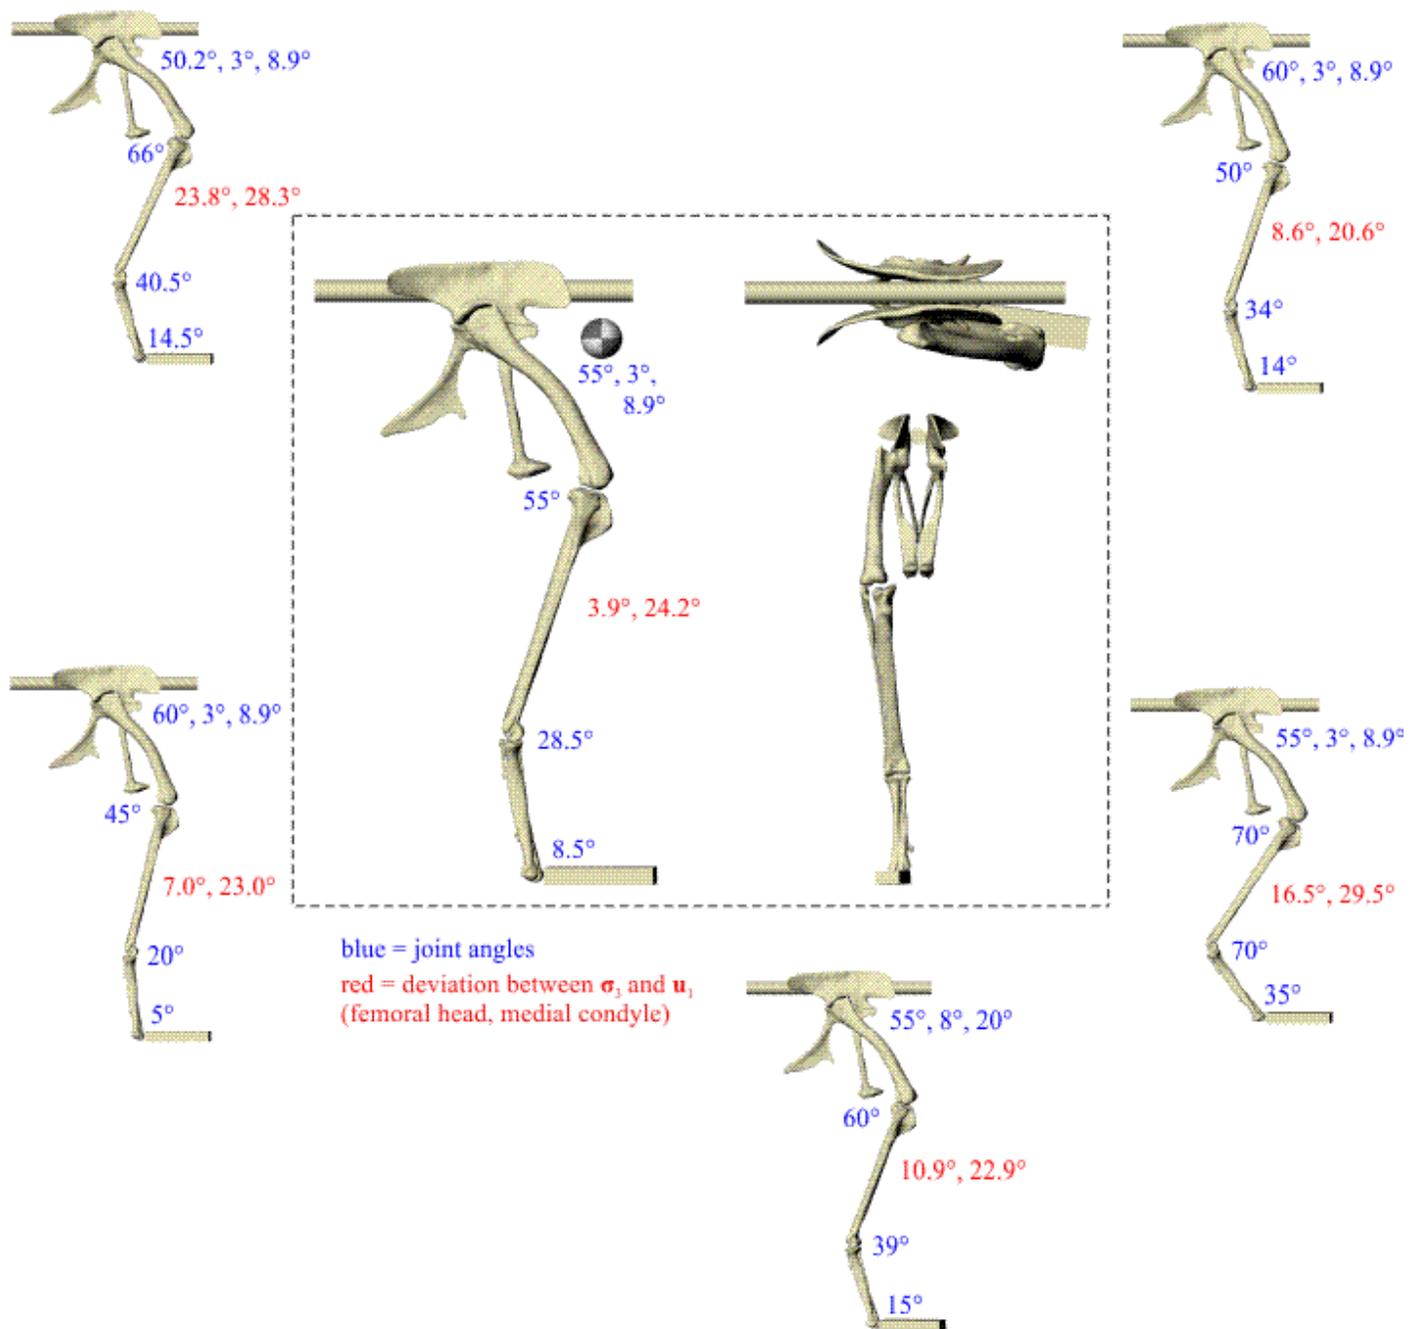

Figure 6

Principal stress trajectories for the proximal femur in the solution posture of *Daspletosaurus*, compared with observed cancellous bone fabric.

For easier visual comparison, the stress trajectories were ‘downsampled’ in a custom MATLAB script, by interpolating the raw stress results at each finite element node to a regular grid. (A) Vector field of σ_1 (red) and σ_3 (blue) in a 3-D slice through the proximal femur, parallel to the coronal plane and through the middle of the femoral head, in anterior view. Note how the trajectory of σ_3 projects towards the apex of the femoral head (green braces). (B) Observed cancellous bone architecture in the proximal femur of *Allosaurus* and tyrannosaurids (cf. Part I), in the same view as A. (C) Vector field of σ_1 and σ_3 in a 3-D slice through the lesser trochanter, parallel to the plane of the trochanter, in anterolateral view. (D) Observed cancellous bone architecture in the lesser trochanter of *Allosaurus* and tyrannosaurids (cf. Part I), in the same view as C. (E) Vector field of σ_3 in the femoral head, shown as a 3-D slice parallel to the sagittal plane and through the apex of the head, in medial view. (F) Observed cancellous bone architecture in the femoral head of *Allosaurus* and tyrannosaurids (cf. Part I), in the same view as E. (G) Comparison of the mean direction of σ_3 in the femoral head (blue) and the estimated mean direction of u_1 for *Allosaurus* and tyrannosaurids (red), plotted on an equal-angle stereoplot with northern hemisphere projection (using StereoNet 9.5; Allmendinger et al. 2013; Cardozo & Allmendinger 2013). Inset shows location of region for which the mean direction of σ_3 was calculated.

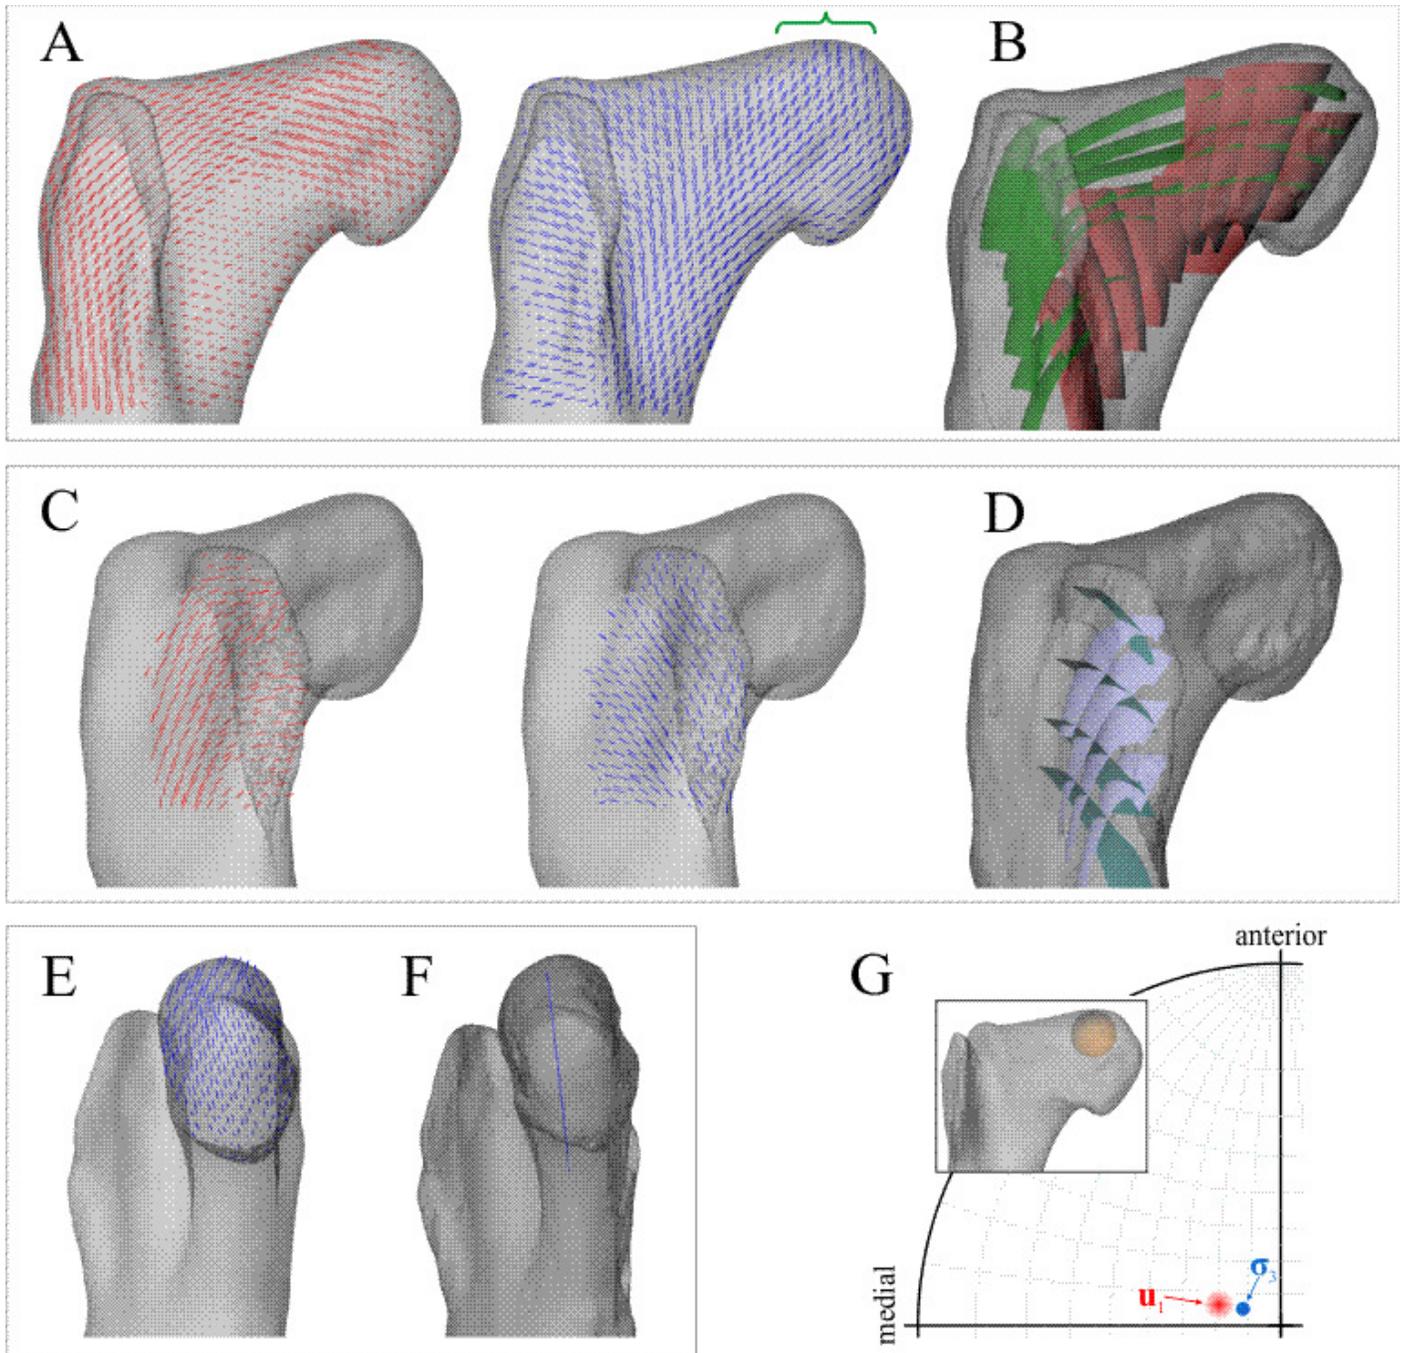

Figure 7

Principal stress trajectories for the distal femur and fourth trochanter in the solution posture of *Daspletosaurus*, compared with observed cancellous bone fabric.

(A) Vector field of σ_1 (red) and σ_3 (blue) in a 3-D slice, parallel to the coronal plane and through the anterior aspect of the distal metaphysis, in anterior view. (B) Observed cancellous bone architecture in the distal metaphysis of *Allosaurus* and tyrannosaurids (cf. Part I), in the same view as A. (C) Vector field of σ_1 in the fourth trochanter, in medial view. (D) Observed cancellous bone architecture in the fourth trochanter of *Allosaurus* and tyrannosaurids (cf. Part I), in the same view as C. (E) Vector field of σ_3 in the lateral condyle, shown as a 3-D slice parallel to the sagittal plane and through the middle of the condyle. (F) Observed cancellous bone architecture in the lateral condyle of *Allosaurus* and tyrannosaurids (cf. Part I), in the same view as E. (G) Vector field of σ_3 in the medial condyle, shown as a 3-D slice parallel to the sagittal plane and through the middle of the condyle. (H) Observed cancellous bone architecture in the medial condyle of *Allosaurus* and tyrannosaurids (cf. Part I), in the same view as G. (I) Comparison of the mean direction of σ_3 in the medial condyle (blue) and the estimated mean direction of u_1 for *Allosaurus* and tyrannosaurids (red), plotted on an equal-angle stereoplot with southern hemisphere projection. Inset shows location of region for which the mean direction of σ_3 was calculated.

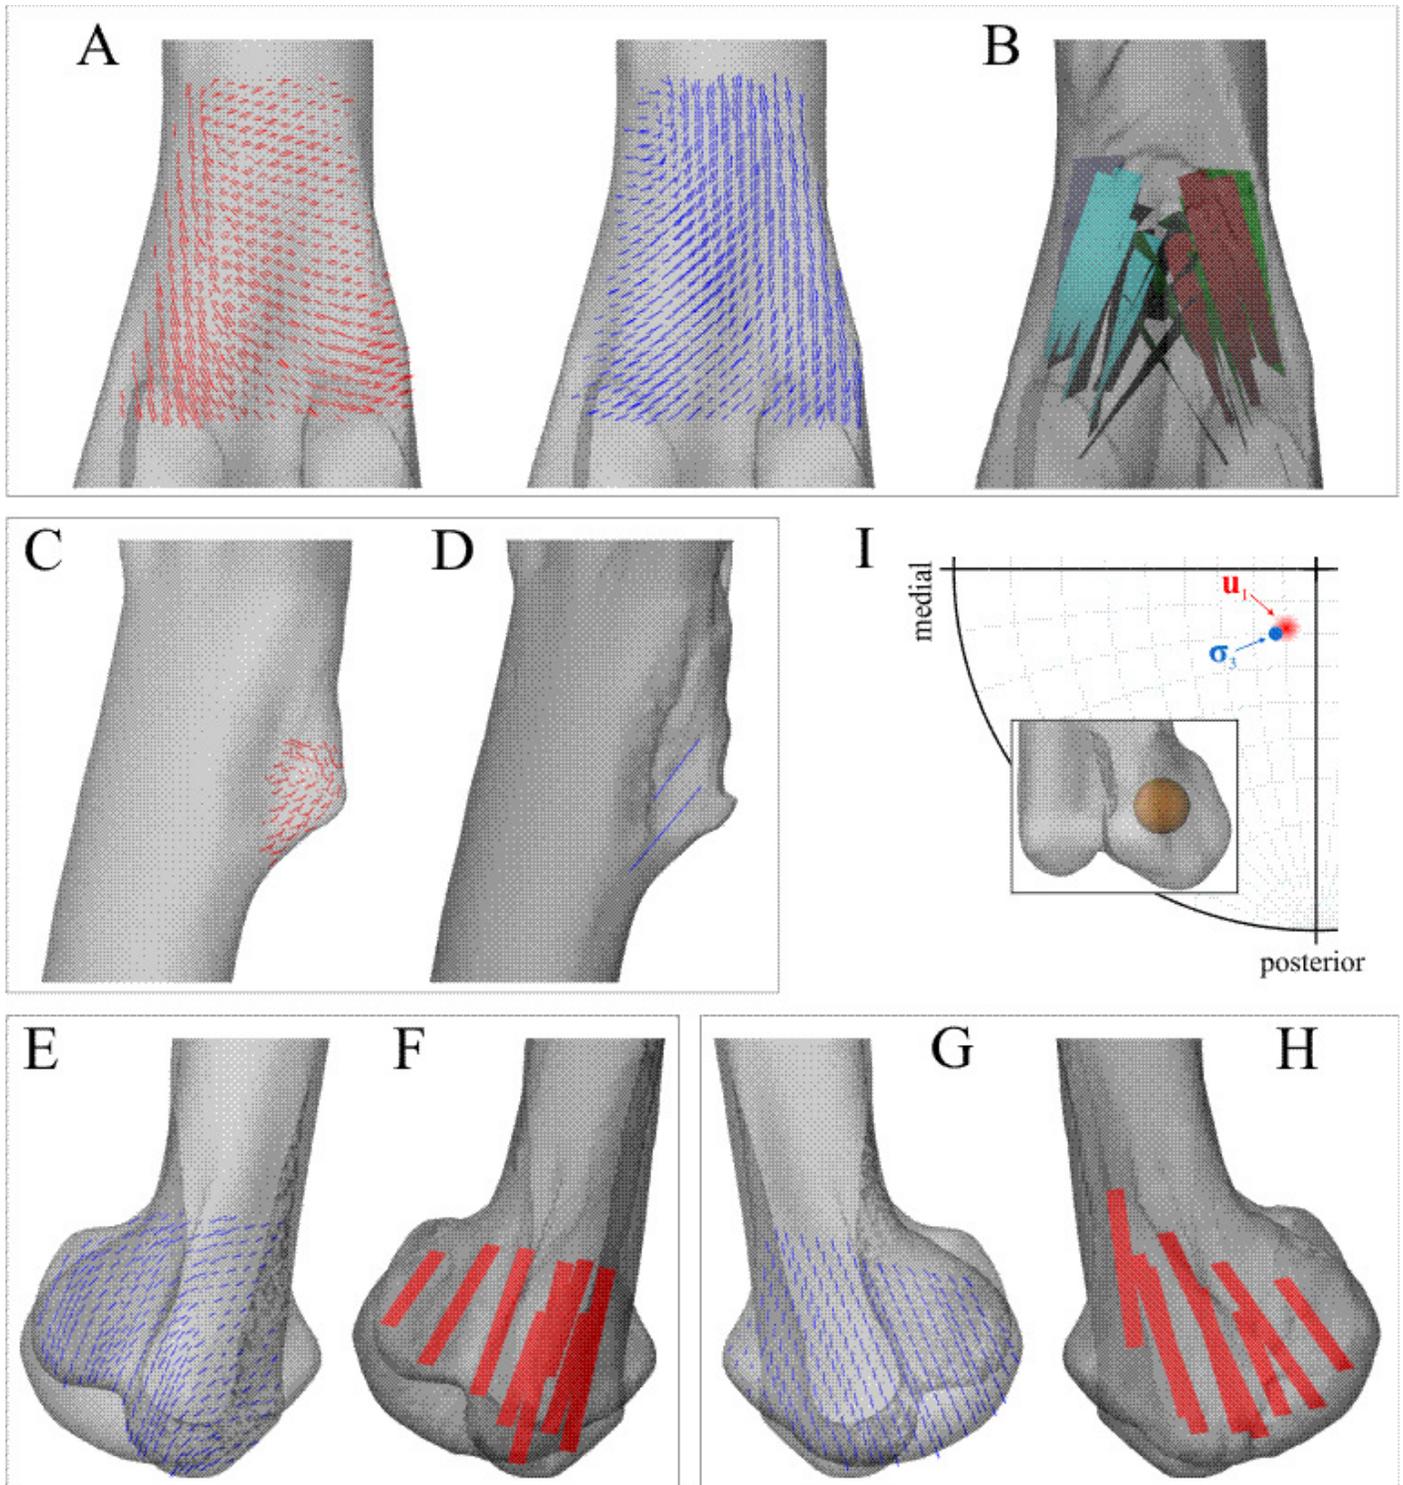

Figure 8

Principal stress trajectories for the tibia and fibula in the solution posture for *Daspletosaurus*, compared with observed cancellous bone fabric.

(A) Vector field of σ_3 in the medial tibial condyle, shown as a 3-D slice through the middle of the condyle and parallel to the sagittal plane, in medial view. (B) Observed cancellous bone architecture in the medial tibial condyle of *Allosaurus* and tyrannosaurids (cf. Part I), in the same view as A. (C) Vector field of σ_3 in the medial and lateral tibial condyles, shown as 3-D slices through the middle of the condyles and parallel to the coronal plane, in posterior view. (D) Observed cancellous bone architecture in the medial and lateral tibial condyles of *Allosaurus* and tyrannosaurids (cf. Part I), in the same view as C. (E) Vector field of σ_3 in the lateral tibial condyle, shown as a 3-D slice through the middle of the condyle and parallel to the sagittal plane, in lateral view. (F) Observed cancellous bone architecture in the lateral tibial condyle of *Allosaurus* and tyrannosaurids (cf. Part I), in the same view as E. (G) Vector field of σ_1 in the cnemial crest, shown as a 3-D slice parallel to the coronal plane, in anterior view. (H) Observed cancellous bone architecture in cnemial crest of *Allosaurus* and tyrannosaurids (cf. Part I), sectioned in the plane of the crest, shown in the same view as G; blue section lines illustrate primary architectural direction. (I) Vector field of σ_1 in the cnemial crest, shown as a 3-D slice parallel to the sagittal plane, in medial view. (J) Observed cancellous bone architecture in cnemial crest of *Allosaurus* and tyrannosaurids (cf. Part I), sectioned in the plane of the crest, shown in the same view as I. (K) Vector field of σ_3 in the medial aspect of the fibular head, in medial view. (L) Observed cancellous bone architecture in the fibular head of *Allosaurus* and tyrannosaurids (cf. Part I), in the same view as K.

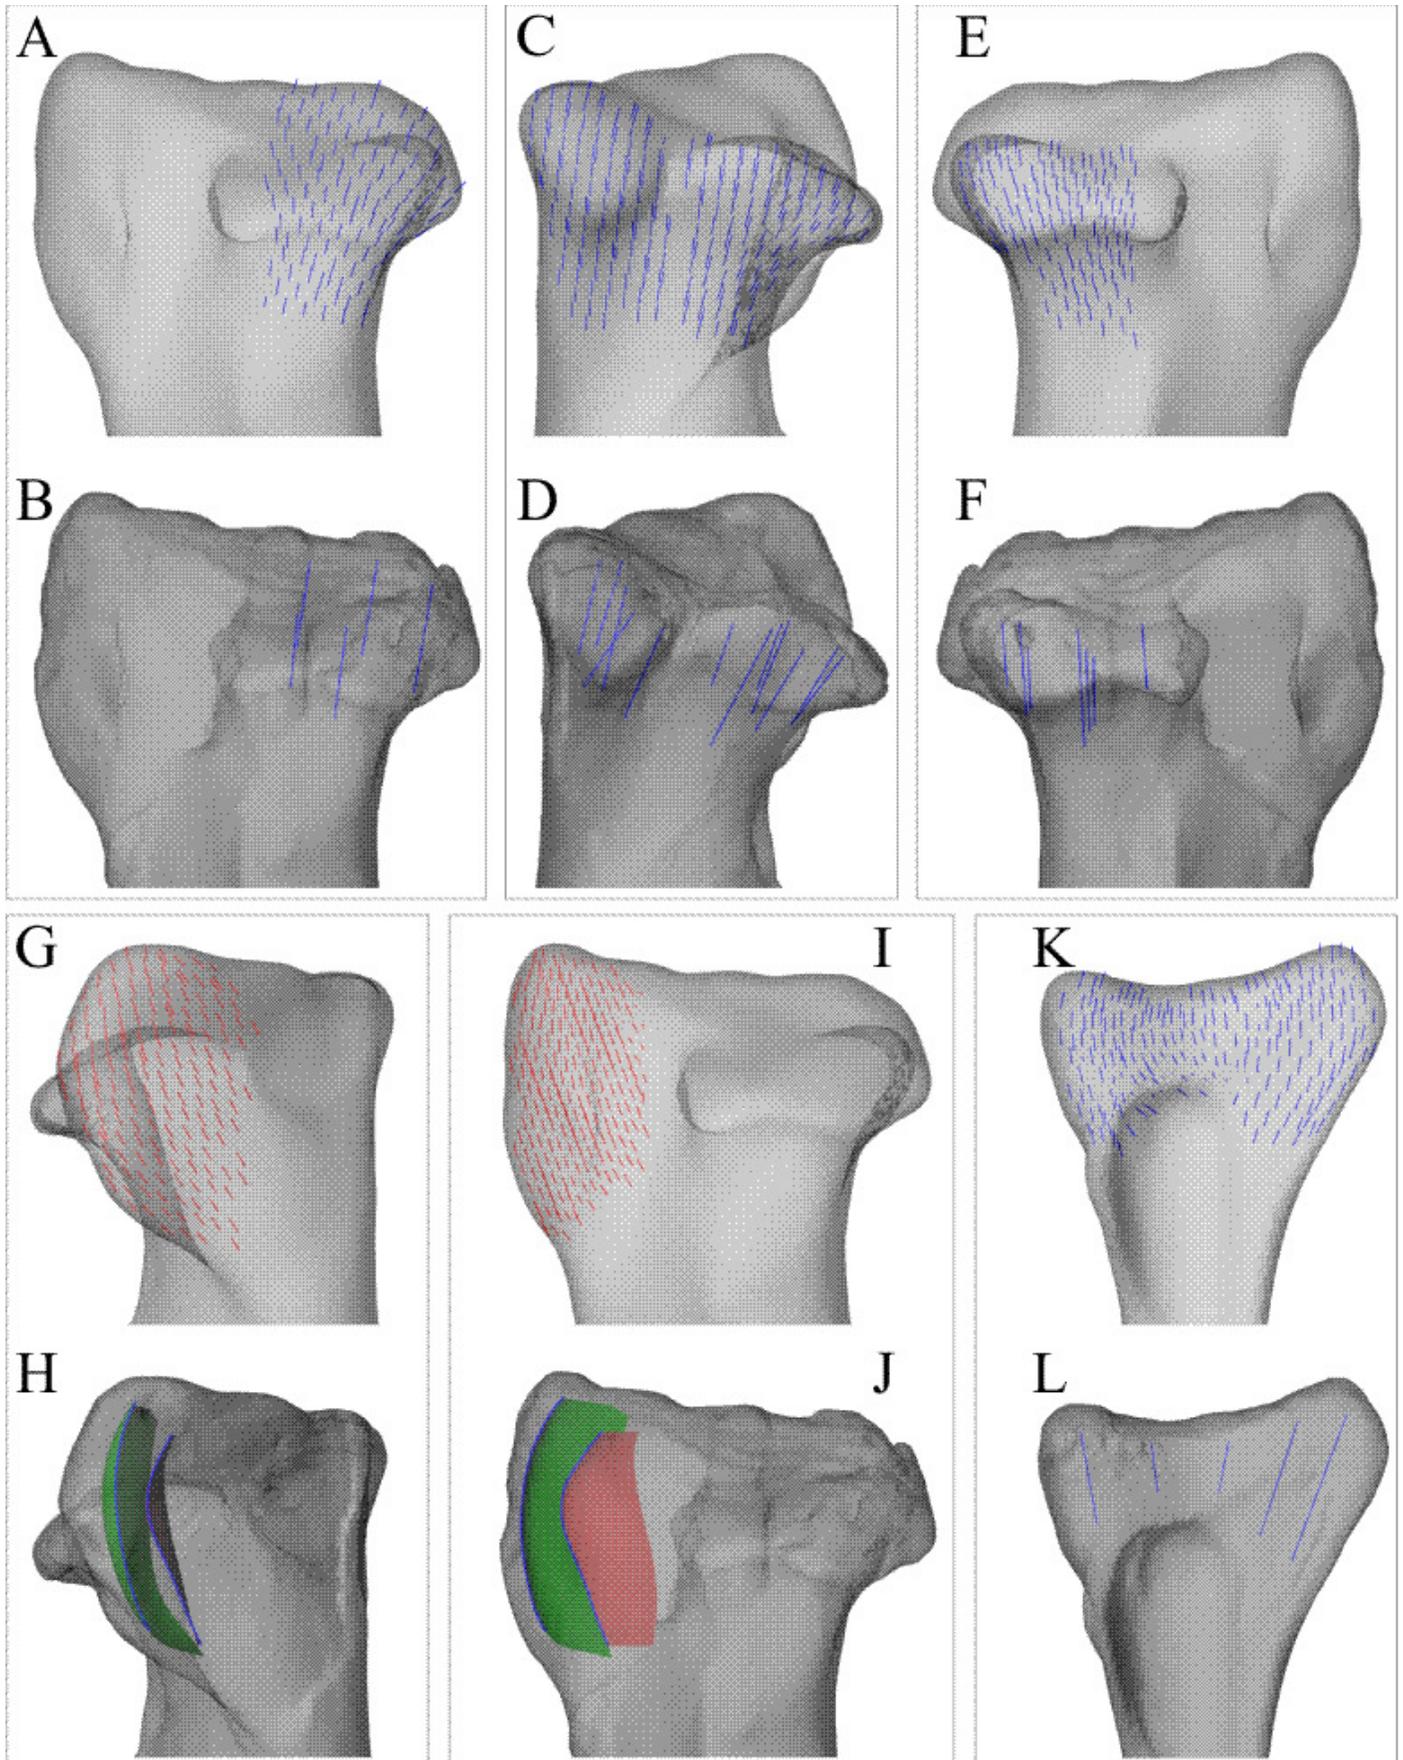

Figure 9

Principal stress trajectories for the proximal femur in the solution posture of '*Troodon*', compared with observed cancellous bone fabric.

(A, B) Vector field of σ_3 in the femoral head, shown as 3-D slices parallel to the coronal plane (A, in anterior view) and sagittal plane (B, in medial view). (C, D) Observed vector field of u_1 in the femoral head, in the same views as A and B, respectively (cf. Part I). (E) Comparison of the mean direction of σ_3 in the femoral head (blue) and the mean direction of u_1 (red), plotted on an equal-angle stereoplot with northern hemisphere projection. Inset shows location of region for which the mean direction of σ_3 was calculated. (F, G) Vector field of σ_3 under the greater trochanter, shown as 3-D slices parallel to the coronal plane (F, in posterior view) and sagittal plane (G, in lateral view). (H, I) Observed vector field of u_1 under the greater trochanter, shown in the same views as F and G, respectively (cf. Part I). (J) Vector field of σ_1 in the lesser trochanter, shown in oblique anterolateral view. (K) Observed vector field of u_1 in the lesser trochanter, shown in the same view as J for both specimens studied (cf. Part I).

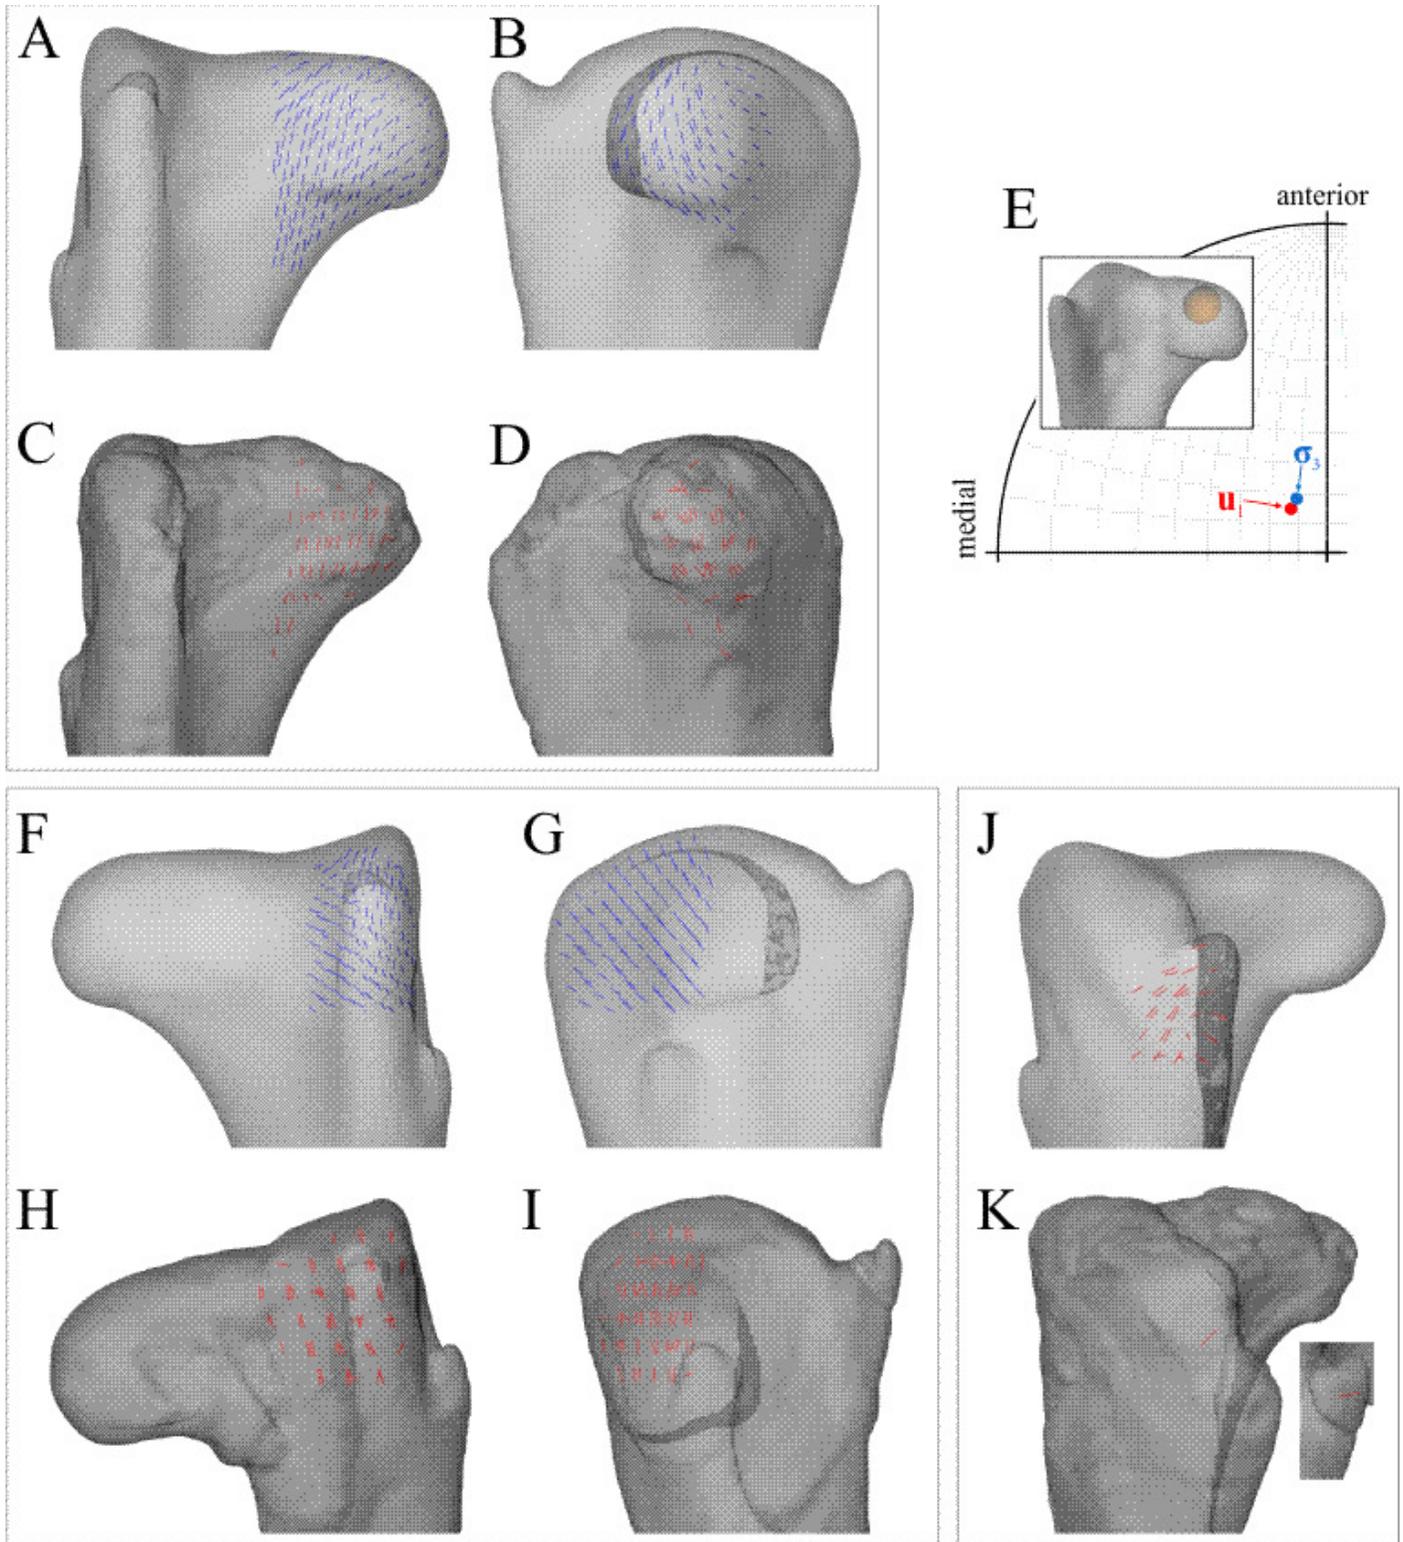

Figure 10

Principal stress trajectories for the distal femoral condyles in the solution posture of 'Troodon', compared with observed cancellous bone fabric.

(A) Vector field of σ_3 in the lateral condyle, shown as a 3-D slice parallel to the sagittal plane. (B) Observed vector field of u_1 in the lateral condyle, shown in the same view as A (cf. Part I). (C) Vector field of σ_3 in the medial condyle, shown as a 3-D slice parallel to the sagittal plane. (D) Observed vector field of u_1 in the medial condyle, shown in the same view as C (cf. Part I). (E) Comparison of the mean direction of σ_3 in the medial condyle (blue) and the mean direction of u_1 (red), plotted on an equal-angle stereoplot with southern hemisphere projection. This shows that in the solution posture the mean direction of σ_3 was of the same general azimuth as the mean direction of u_1 , but was markedly more posteriorly inclined. Inset shows location of region for which the mean direction of σ_3 was calculated.

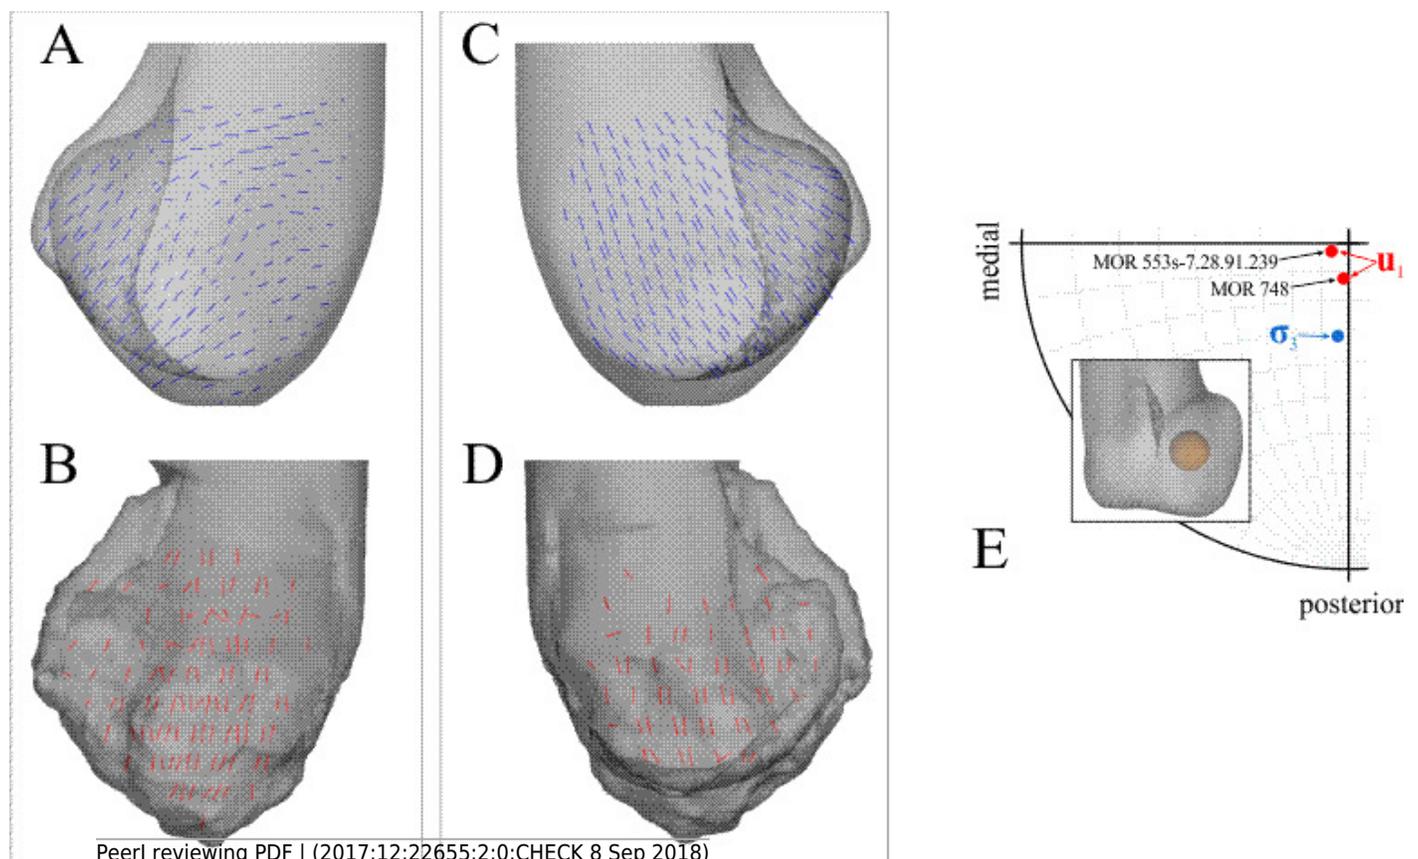

Figure 11

Principal stress trajectories for the tibia and fibula in the solution posture for 'Troodon', compared with observed cancellous bone fabric.

(A) Vector field of σ_3 in the medial tibial condyle, shown as a 3-D slice through the middle of the condyle and parallel to the sagittal plane, in medial view. (B) Observed vector field of u_1 in the medial tibial condyle, in the same view as A (cf. Part I). (C) Vector field of σ_3 in the medial and lateral tibial condyles, shown as 3-D slices through the middle of the condyles and parallel to the coronal plane, in posterior view. (D) Observed vector field of u_1 in the medial and lateral tibial condyles, in the same view as C (cf. Part I). (E) Vector field of σ_3 in the lateral tibial condyle, shown as a 3-D slice through the middle of the condyle and parallel to the sagittal plane, in lateral view. (F) Observed vector field of u_1 in the lateral tibial condyle, in the same view as E (cf. Part I). (G) Vector field of σ_1 in the cnemial crest, shown as a 3-D slice parallel to the coronal plane, in anterior view. (H) Observed vector field of u_1 in the cnemial crest, in the same view as G (cf. Part I). (I) Vector field of σ_1 in the cnemial crest, shown as a 3-D slice parallel to the sagittal plane, in medial view. (J) Observed vector field of u_1 in the cnemial crest, in the same view as I (cf. Part I). (K) Vector field of σ_1 in the lateral fibular head, in lateral view. (L) Vector field of σ_3 in the medial fibular head, in medial view (reversed). (M) Observed vector field of u_1 in the fibular head, in the same view as K (cf. Part I).

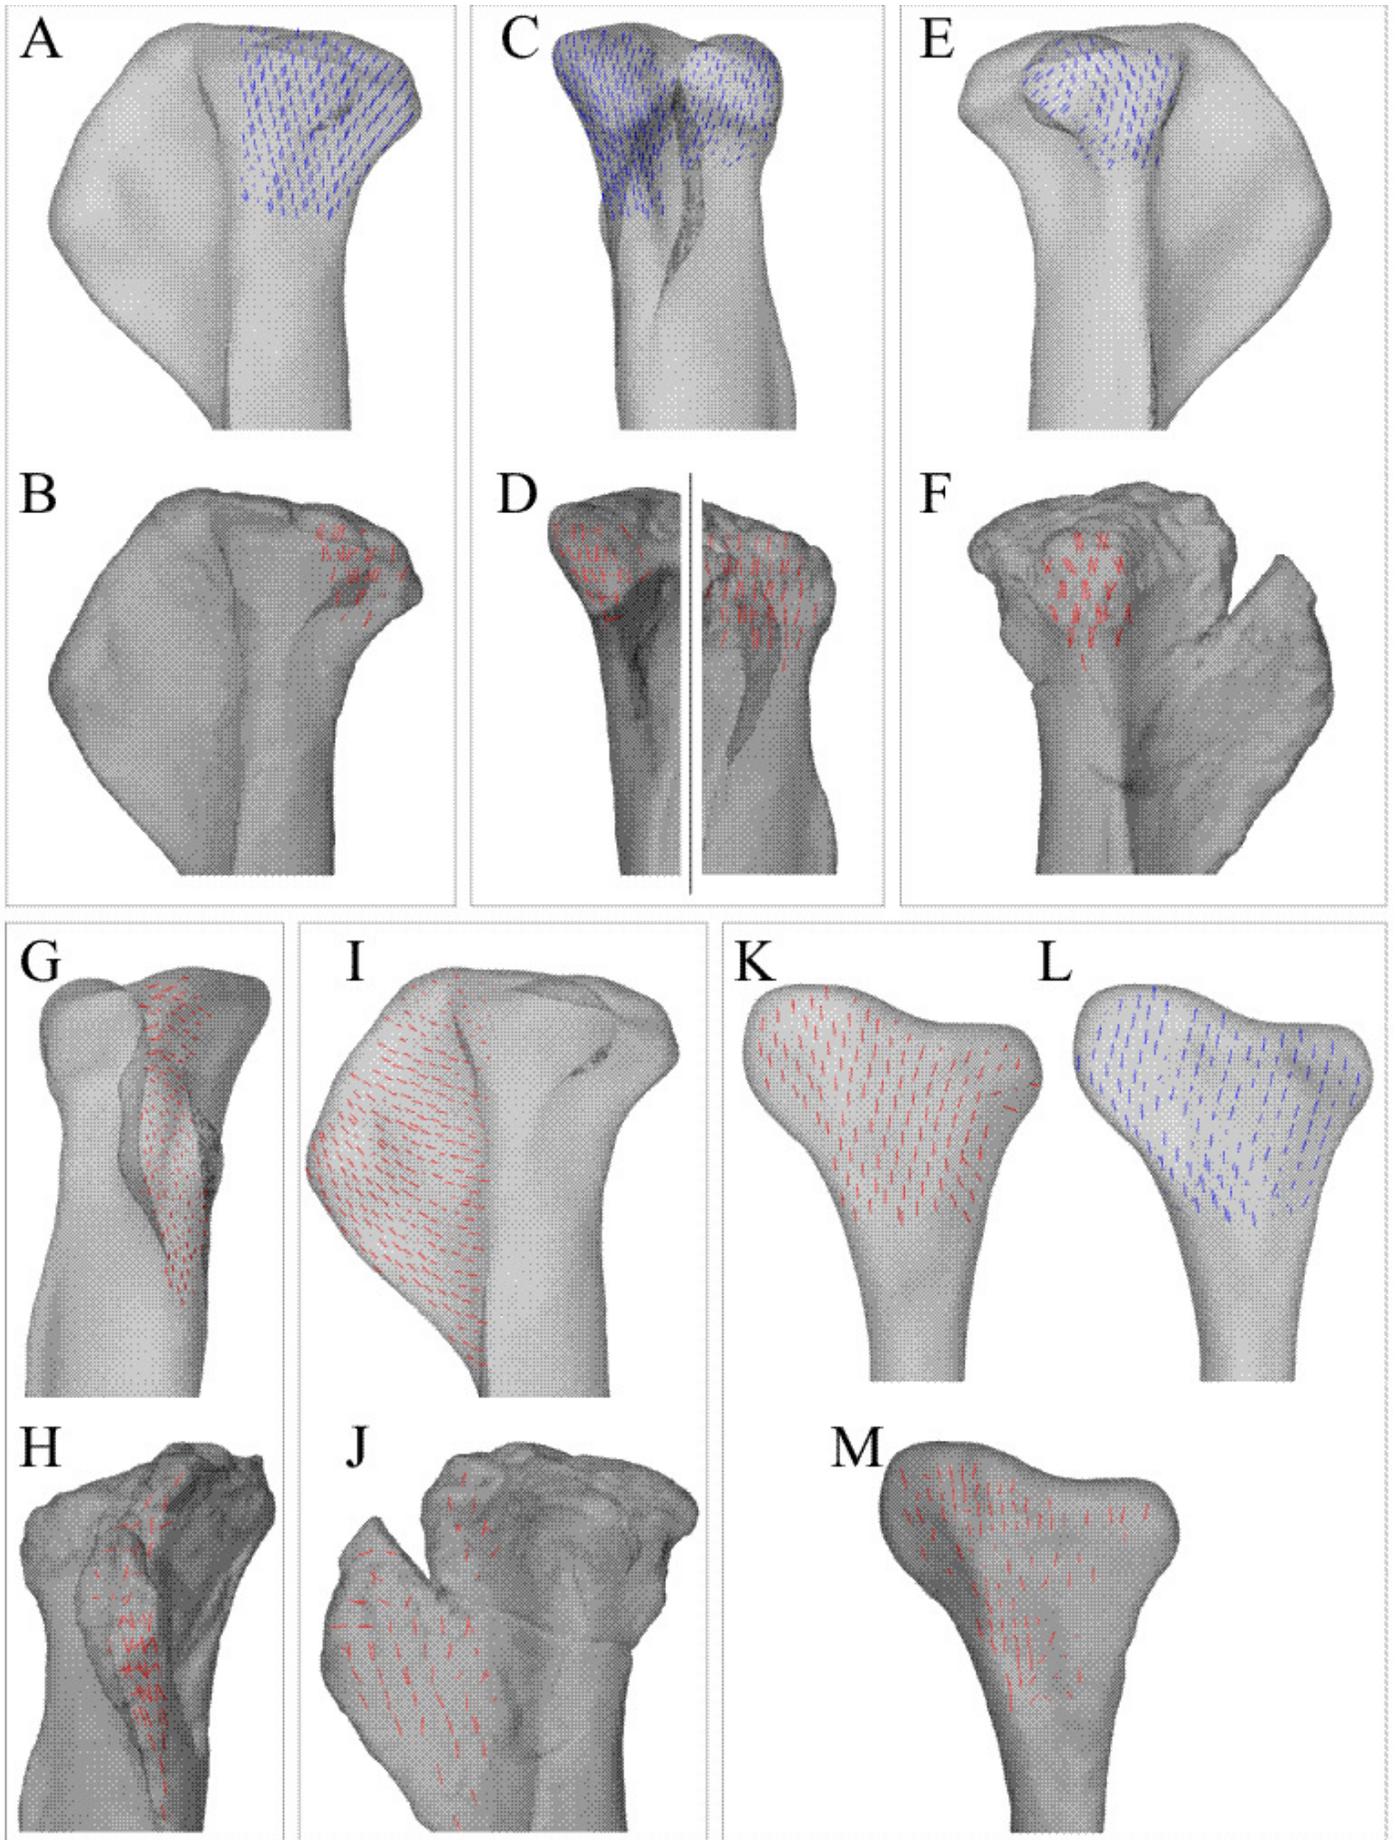

Figure 12

Principal stress trajectories for the proximal femur of *Daspletosaurus* in the two variations in hip articulation tested.

(A) Vector field of σ_3 in the first variation tested, shown as a 3-D slice parallel to the coronal plane and through the middle of the femoral head. (B) Vector field of σ_3 in the first variation tested, shown as a 3-D slice parallel to the sagittal plane and through the apex of the femoral head. (C) Vector field of σ_3 in the second variation tested, shown as a 3-D slice parallel to the coronal plane and through the middle of the femoral head. (D) Vector field of σ_3 in the second variation tested, shown as a 3-D slice parallel to the sagittal plane and through the apex of the femoral head. A and C are in anterior view, B and D are in medial view. Note in particular how the trajectory of σ_3 projects towards the more cylindrical part of the femoral head, lateral to the apex (green braces); compare to Fig. 6A,B,E,F. Also note in C how σ_3 has a strong medial component near the apex of the head.

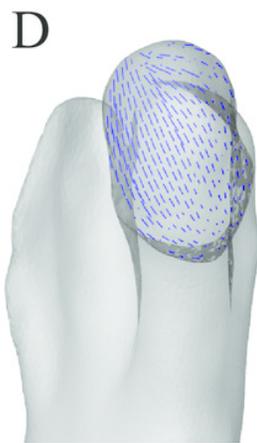

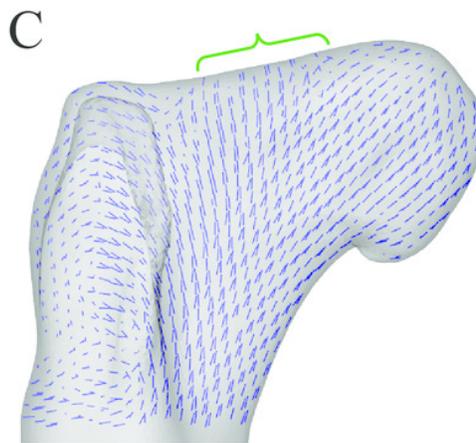

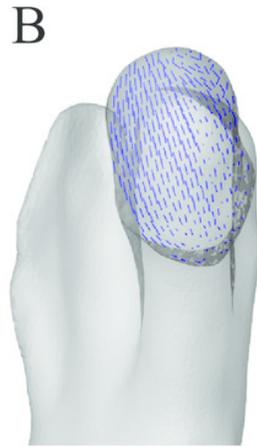

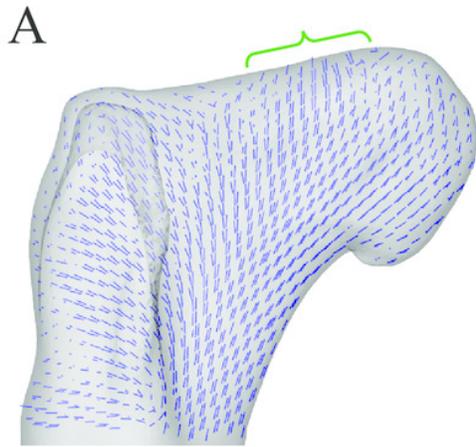

Figure 13

Comparison of parameters related to posture, extracted from the solution postures of the three species modelled: *Daspletosaurus* ('D'), '*Troodon*' ('T') and the chicken ('C').

(A) Schematic illustration of the solution postures obtained for the three species, along with the location of the whole-body centre of mass (black and white disc). (B) Whole-body centre of mass location anterior to the hips, normalized to total leg length. (C) Degree of crouch for each species, both as measured from the solution posture, as well as empirically predicted from the data reported by Bishop et al. (2018). (D) Angles of the hip and knee joints. The hip extension angle is expressed relative to the horizontal, whereas the knee flexion angle is expressed relative to the femur. (E) Long-axis rotation and adduction-abduction of the hip joint. Positive values indicate external rotation and abduction (respectively), whereas negative values indicate internal rotation and adduction (respectively).

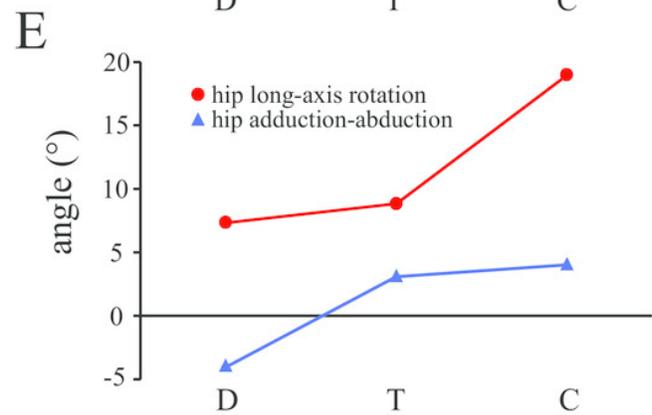

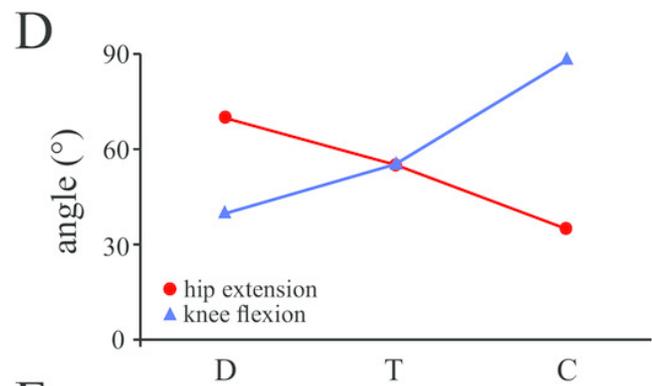

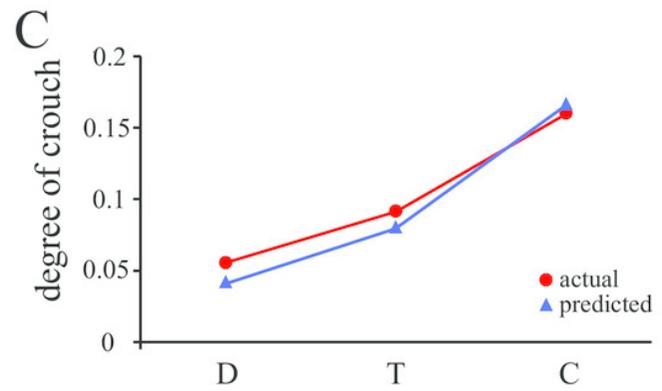

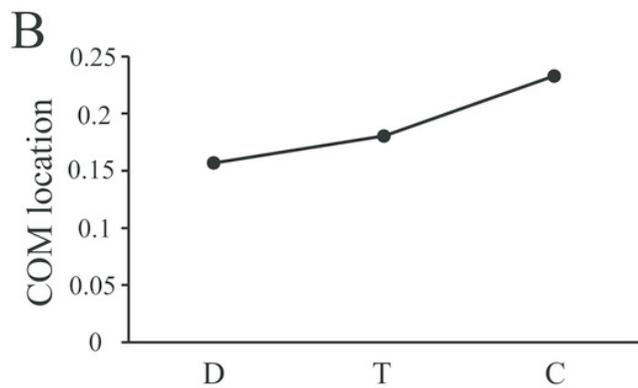

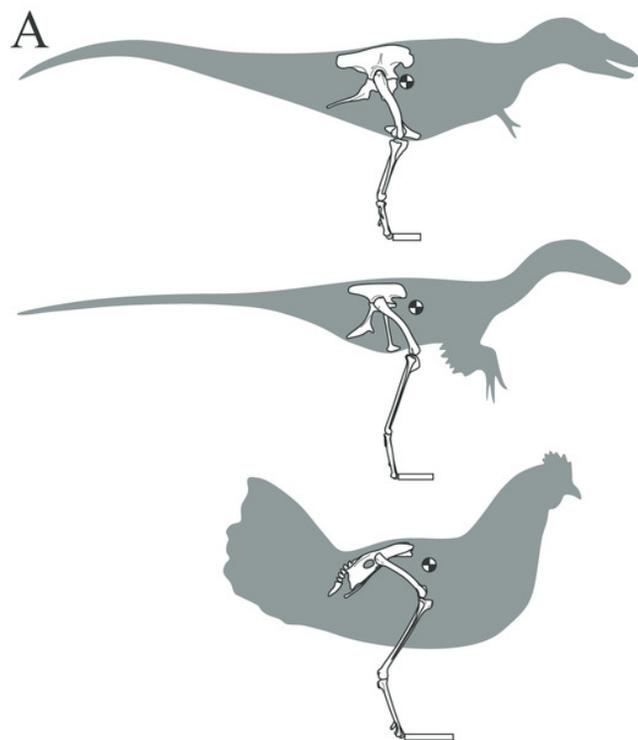

Figure 14

Comparison of parameters related to bone loading mechanics and muscular support, extracted from the solution postures of the three species modelled: *Daspletosaurus* ('D'), '*Troodon*' ('T') and the chicken ('C').

(A) Orientation of the neutral surface of bending and the orientation of principal stresses (σ_1 and σ_3) relative to the femur long-axis, both measured at mid-shaft. Insets show the neutral surface with respect to the mid-shaft cross-section, as well as anatomical directions ('A', anterior; 'P', posterior; 'M', medial; 'L', lateral). (B) Ratio of maximum shear to bending stress in the femoral mid-shaft. (C) Normalized moments of hip abductor and medial rotator muscles. The hip abductor for all species is the iliofemoralis externus (activation set to zero in the chicken; see Part II). In *Daspletosaurus* and '*Troodon*', the medial rotators are the ilioprochantericus caudalis and puboischiofemorales internus 1 et 2; in the chicken, they are the ilioprochanterici caudalis et medius. (D) Oblique anterolateral view of the hip of *Daspletosaurus*, showing the abductor and medial rotator muscles (colours as in C).
