**Background.** Yak (*Bos grunniens*) is the most important domestic animal for people living at high altitudes, especially on the Qinghai-Tibetan Plateau. Yak ordinarily feed by grazing. Yak grazing has a strong impact on pedigree record accuracy because it is difficult to control mating in grazing yak. Polled yak are less dangerous to herdsman than horned yak. For this reason, polled yak breeding is preferred by herdsman. **Methods.** A standardized set of microsatellite loci was assessed and applied to parentage testing and individual identification in yak. Seventy-one microsatellite loci were selected from literature databases. Most of them were used for cattle. Thirty-five microsatellite loci generated excellent results from PCR amplification and were evaluated for parentage testing and individual identification in 236 unrelated polled yaks. Seventeen loci had polymorphic information content (PIC) > 0.5 and were in Hardy-Weinberg equilibrium without linkage disequilibrium. Of these 35 markers, the seventeen loci were used in a core set of multiplexed markers suitable for parentage testing and individual identification in polled yak. **Results.** The multiplex PCRs and loading systems provided very high exclusion probabilities (EP) determined from combined core set genotypes. The followed combined exclusion probabilities were obtained: EP1 (exclusion probability for one candidate parent when one confirmed parental genotype is missing) = 0.99718116; EP2 (exclusion probability for one candidate parent when one confirmed parental genotype is available) = 0.99997381; EPP (exclusion probability for one alleged parental genotype pair is available) = 0.99999998. The combined EI (exclusion probability of finding two identical genotypes) and combined ESI (exclusion probability of finding the identity of two siblings) were > 0.99999999 and 0.99999899, respectively. The results of this analysis indicated that this combination of seventeen microsatellite markers could improve process efficiency, reliability, and utility in paternity testing and individual identification. **Discussion.** Fluorescent detection primers can identify many microsatellite alleles that are applicable

in polled yak population genetics analyses. Fluorescence labeling is useful for multiplex amplification and loading systems, decreases detection time, reduces testing costs, and generates copious amounts of microsatellite genotype data. Polymorphic microsatellite loci are suitable for parentage/relatedness analysis in other yak breeds with locus allele frequencies similar to those of the polled yak.

# ABSTRACT

**Background.** Yak (*Bos grunniens*) is the most important domestic animal for people living at high altitudes, especially on the Qinghai-Tibetan Plateau. Yak ordinarily feed by grazing. Yak grazing has a strong impact on pedigree record accuracy because it is difficult to control mating in grazing yak. Polled yak are less dangerous to herdsman than horned yak. For this reason, polled yak breeding is preferred by herdsman.

**Methods.** A standardized set of microsatellite loci was assessed and applied to parentage testing and individual identification in yak. Seventy-one microsatellite loci were selected from literature databases. Most of them were used for cattle. Thirty-five microsatellite loci generated excellent results from PCR amplification and were evaluated for parentage testing and individual identification in 236 unrelated polled yaks. Seventeen loci had polymorphic information content (PIC) > 0.5 and were in Hardy-Weinberg equilibrium without linkage disequilibrium. Of these 35 markers, the seventeen loci were used in a core set of multiplexed markers suitable for parentage testing and individual identification in polled yak.

**Results.** The multiplex PCRs and loading systems provided very high exclusion probabilities (EP) determined from combined core set genotypes. The followed combined exclusion probabilities were obtained: EP1 (exclusion probability for one candidate parent when one confirmed parental genotype is missing) = 0.99718116; EP2 (exclusion probability for one candidate parent when one confirmed parental genotype is available) = 0.99997381; EPP (exclusion probability for one alleged parental genotype pair is available) = 0.99999998. The combined EI (exclusion probability of finding two identical genotypes) and combined ESI (exclusion probability of finding the identity of two siblings) were > 0.99999999 and 0.99999899, respectively. The results of this analysis indicated that this combination of seventeen microsatellite markers could improve process efficiency, reliability, and utility in paternity testing and individual identification.

**Discussion.** Fluorescent detection primers can identify many microsatellite alleles that are applicable in polled yak population genetics analyses. Fluorescence labeling is useful for

multiplex amplification and loading systems, decreases detection time, reduces testing costs, and generates copious amounts of microsatellite genotype data. Polymorphic microsatellite loci are suitable for parentage/relatedness analysis in other yak breeds with locus allele frequencies similar to those of the polled yak.

# INTRODUCTION

Yak (*Bos grunniens*), a member of the Bovidae, has successfully adapted to the severe cold and low oxygen levels characteristic of high altitude regions (~2,500-5,500 m) such as the Himalayas in south-central Asia, the Qinghai-Tibetan Plateau, Mongolia, and Russia (Wu 2016). These regions are known for their high elevations, pristine natural environments, and frequent seasonal variations (Haynes & Yang 2013; Ishizaki et al. 2005; Mizuno et al. 2015). The ability of yak to survive in such rugged natural environments is the result of numerous behavioral, physiological, and genetic adaptations (Barsila et al. 2014; Ding et al. 2015; Hu et al. 2012; Huang et al. 2012; Qiu et al. 2012; Wang et al. 2017b). For instance, yak have steady daily fasting heat production levels at constant ambient air temperatures even with increasing altitude (Ding et al. 2014; Han et al. 2003). Yak can thrive in an extreme environment such as the Tibetan Plateau where few other animals can survive. Yak have made significant contributions to human life in the Tibetan Plateau by providing meat, milk, fur, leather, transportation, and more (Hu et al. 2016; Lee et al. 2017; Medhammar et al. 2012; Wang et al. 2018).

The ~13 million domestic yak in China constitute ~90% of the global yak population. There are fourteen yak breeds in China, of which one is artificial (Wu 2016). Polled yak strain have been bred for many years at the foot of the Ashidan Mountain. Polling is very useful in herd management because it reduces the risk of horn-inflicted injury or death among the herdsman.

Polled yak breeding is very valuable in pasturing areas. Accurate genealogical records help estimate genetic parameters and improve breeding programs. They ensure efficient and effective breeding progress and avoid excessive inbreeding. When yak graze, however, mating is very difficult to control. Semen samples could be mislabeled in error during preparation, and mating records might be confused as a result of clerical errors made during artificial insemination. Therefore, accurate yak pedigree records compiled by paternity testing and individual identification are essential in polled yak breeding.

Molecular markers like microsatellite DNA indicate the degree of genetic relatedness between animals and facilitate paternity verification and individual recognition (Estoup et al. 2002; Zhang et al. 2006). Microsatellites, namely short tandem repeats (STR) or simple sequence repeats (SSR), are tracts of repetitive DNA in which certain motifs ranging in length from 1-10 nucleotides are repeated 5-50× (Carneiro Vieira et al. 2016). Microsatellite DNA can be used to develop pedigreed animal populations and evaluate animal breeding to support genetic improvement by selective breeding (Weising et al. 1998). The application of microsatellites as molecular markers for animal identification and parentage verification is highly accurate and effective in both routine applications and forensic casework (Budowle et al. 2005; Iyengar & Hadi 2014; Linacre et al. 2011).

Recently, DNA analysis of microsatellite markers has been used to verify parentage in breed registries and identify individual animals linked to a particular database or owner. Microsatellite panels have been well characterized for cattle (Zhao et al. 2017), horses (Kang et al. 2016), sheep (Rosa et al. 2013), dogs (Jeong et al. 2015) and parrots (Coetzer et al. 2017). Many highly polymorphic microsatellites have been identified, characterized, and mapped for bovine breeds. Marker panels have also been developed (Carolino et al. 2009). Microsatellite marker panels have been used to identify and assign individuals to families and populations (Stevanovic et al. 2010). The application of microsatellites in the identification of yak relationships has seldom been reported. Moreover, there are no reports on paternity testing for yak breeds. Consequently, there is a strong requirement for yak identity control and parentage verification.

A highly informative set of DNA markers whose alleles can be easily scored is critical if it is to be used effectively in paternity testing and individual identification. The objective of the present study was to develop and evaluate multiplex microsatellite systems designed for the purposes of polled yak parentage control and kinship analyses. Many of these microsatellite loci are already commonly used to characterize genetic parameters for cattle. This study aimed to validate a set of highly polymorphic microsatellites for use in parentage testing and individual identification in polled yak. The results of this study can be used to develop powerful, efficient genetic tools for breeders to verify parentage verification and match individual yaks when their identities are ambiguous or missing.

## MATERIALS AND METHODS

### Marker selection and primer design

Microsatellites were selected from cattle breeding literature. The markers had to meet the following criteria: (a) high PIC and heterozygosity; (b) a large number of alleles; (c) no known null alleles; (d) homogeneous repeat motifs (Schnabel et al. 2000). A total of 71 bovine microsatellite markers were selected, of which 65 were derived from cattle references and 6 exclusively for yak (Li 2004). All 71 microsatellites and their flanking sequences were found on the cattle genome. Their corresponding sequences on the yak genome were sought. Primers for most of the loci used in earlier studies were adapted to the yak genome because of mutations or low scores. The following 14 loci did not need adjustment: BM1824, BM2113, BMS2533, ETH121, ETH225, ILSTS008, INRA124, RM099, INRA126, UMN0103, UMN0307, UMN0920, UMN2303, UMN3007, and UMN3008. The primers used in this study are listed in Table S1.

### Sample collection

The polled yaks were selected from the herds on Ashidan Mountain in Qinghai province. To

avoid consanguinity, only samples without genetic relationship were selected in pedigree. Blood was drawn from the jugular veins of 236 unrelated individuals, including 38 sires and 198 dams. All yaks were handled in strict accordance with good animal practice according to *the Animal Ethics Procedures and Guidelines of the People's Republic of China*, and the study was approved by *the Animal Administration and Ethics Committee of Lanzhou Institute of Husbandry and Pharmaceutical Sciences of Chinese Academy of Agricultural Sciences* (Permit No. SYXK-2016-0039). The blood was mixed with preservation buffer (1.5 mg mL<sup>-1</sup> EDTA and 137 mmol L<sup>-1</sup> NaCl) at a 5:1 ratio. The blood was stored at -80 °C in an ultra-cold freezer prior to DNA extraction.

# **DNA extraction and quantification**

Genomic DNA was extracted from white blood cells digested with proteinase-K. The samples were centrifuged at 5,000 g for 2 min. The clear aqueous layer was then transferred to a new test tube and 0.5 mL of 10 mg mL<sup>-1</sup> RNase A was added to it. The sample was then extracted with phenol:chloroform:isoamyl alcohol (25:24:1) followed by chloroform. The DNA was precipitated with ethanol then resuspended in 50 mL TE buffer (10 mM Tris-HCl and 1 mM EDTA, pH 8.0). The extracted DNA was quantified using a NanoDrop 2000 fluorometer (Thermo Fisher Scientific, Waltham, MA, USA). OD<sub>260:280</sub> = 1.7-1.9 and OD<sub>260:230</sub> = 2.0-2.2 (data not shown).

# **Preliminary primer screening**

Unlabeled primer pairs (Table S1) were ordered for each microsatellite marker and sample fragments were amplified. The PCRs were conducted in 20-μL aliquots consisting of 20-50 ng genomic DNA, 10 mM Tris-HCl (pH 9.0), 50 mM KCl, 1.5 mM MgCl<sub>2</sub>, 2.0 mM of each dNTP, 5 ng BSA, and 1.0 U *Taq*<sup>TM</sup> Hot Start Version polymerase (TaKaRa Bio Inc., Kusatsu, Shiga, Japan). Primer concentrations ranged from 1.0-5.5 μM. The thermal cycle parameters were 5 min

at 95 °C followed by 35 cycles of 30 s at 95 °C, 30 s at 55-58 °C (Table S1), and 20 s at 72 °C, then a final extension step of 5 min at 72 °C in a Verity PCR Veriti 96-Well Thermal Cycler (Applied Biosystems Corp., Foster City, CA, USA). After amplification, the PCR products were visualized on 2% agarose gel (Gene Tech Co. Ltd., Chai Wan, Hong Kong). A 5-μL sample was mixed with 1 μL loading dye (TaKaRa Bio Inc., Kusatsu, Shiga, Japan). Electrophoresis was run for 35 min at 85 V and the samples were visualized with an GelDoc™ XR+ gel imaging system (Bio-Rad Corp., Hercules, CA, USA).

The amplification fragments with high specificity, high amplification efficiency, and loci that were either non-syntenic or separated by >10 cM (to avoid genetic linkage) (Table S2) were manually cut out of the agarose gel and send to the biological companies for sequencing. The samples were forwarded to Invitrogen (Carlsbad, CA, USA) and Thermo Fisher Scientific (Waltham, MA, USA) without prior purification. Fragment analysis was conducted on an ABI 3730xl automated sequencer (Applied Biosystems Corp., Foster City, CA, USA). Only forward primers were used to sequence the targets. Repeat marker sequences were revealed with Sanger sequencing (Invitrogen, Carlsbad, CA, USA, and Thermo Fisher Scientific, Waltham, MA, USA).

## Genetic information acquisition

Confirmed primer sequences flanking microsatellite loci were synthesized with a fluorescent label attached to the 5' end of each forward primer. The forward primers set was fluorescently labeled with FAM™, HEX™, or TAMRA™ dyes (Thermo Fisher Scientific, Waltham, MA, USA). Microsatellites were separately amplified by PCR to identify loci with high levels of allelic polymorphism. The amplification systems and conditions were similar to those used with the unlabeled primers described above.

After amplification, 1 μL amplified fragment mix was added to 0.5 μL loading buffer (blue dextran, 50 mg mL<sup>-1</sup>; EDTA, 25 mM) and 4 μL deionized formamide then denatured by incubation for 5 min at 95 °C. Then, 0.5 μL internal size standard (Thermo ABI 4322682;

Thermo Fisher Scientific, Waltham, MA, USA) was added to each sample. Fluorescently labeled PCR products were identified by capillary electrophoresis (ABI3730xl Genetic Analyzer, Applied Biosystems Corp., Foster City, CA, USA). The fluorescently labeled DNA fragments were analyzed with GENESCAN v. 3.7 (Applied Biosystems Corp., Foster City, CA, USA) then with GENOTYPER v. 3.7 NT (Applied Biosystems Corp., Foster City, CA, USA) and automatically sorted according to the internal size standard. The numbers of the microsatellite repeat motifs were calculated on the basis of the fragment lengths of the PCR product (Table S3).

### Genetic information analysis

Genotypic data were initially processed in Microsoft Office Excel 2007, manually checked for errors, and transformed into other input files for various analyses. Performance characteristics [observed heterozygosity (HO); expected heterozygosity (HE); polymorphism information content (PIC); estimated null allele frequency (F(null)); Hardy-Weinberg equilibrium (HWE); and genotypic disequilibrium] were measured with GENEPOP v. 4.6 (Raymond & Rousset 1995; Rousset 2008) and CERVUS v. 3.0.7 (Kalinowski et al. 2007; Kalinowski et al. 2010; Slate et al. 2000).

### Multiplex PCR conditions

Genotyping 236 yak for 35 loci (Table 1) produced a core set of 17 loci with high PICs (Table 2). Four multiplex PCRs were assembled, each of which contained four or five microsatellite markers. A list of the primer sequences used in the multiplex appears in Table 2. The multiplex PCR amplification was performed in 15-μL volumes per sample. Each of these consisted of ~25 ng genomic DNA, 10 mM Tris-HCl (pH 8.3), 35 mM KCl, 1.8 mM MgCl<sub>2</sub>, 5.0 mM of each dNTPs, and 2.5 U *Taq*<sup>TM</sup> Hot Start Version polymerase (TaKaRa Bio Inc., Kusatsu, Shiga, Japan). The primer concentrations are shown in Table 2. For PCR amplification, a thermal cycler (Veriti 96-Well, Applied Biosystems Corp., Foster City, CA, USA) was run at 95 °C for 5 min

followed by 25 cycles of 95 °C for 30 s, 55-58 °C for 30 s and 72 °C for 30 s, then 10 cycles of 95 °C for 30 s, 53 °C for 30 s, and 72 °C for 30 s, finishing with a final extension at 72 °C for 5 min. Genetic typing of these microsatellite loci was performed in a manner similar to that described above.

## **Paternity test and individual identification**

Different types of exclusion probability were determined with CERVUS v. 3.0.7. These included (a) EP1, the exclusion probability for one candidate parent when one confirmed parental genotype was missing; (b) EP2, the exclusion probability for one candidate parent given the genotype of a known parent of the opposite sex; (c) EPP, the exclusion probability for one candidate parent pair; (d) EI, the exclusion probability for the identity of two unrelated individuals; and (e) ESI, the exclusion probability of finding the identity of two siblings (Kalinowski et al. 2007; Kalinowski et al. 2010; Slate et al. 2000).

Three parental exclusion probabilities were calculated corresponding to different scenarios. EP1 assumes that genotypes are known for the offspring and one putative parent but not the other. EP2 assumes that genotypes are known for the offspring, one confirmed parent, and one putative parent (both parents genotyped). EPP assumes that genotypes are known for the offspring and one parent pair; it is the probability of a misattributed progeny (mismatched with both parents) from two genotyped parents (Jamieson & Taylor 1997).

## **RESULTS**

### **Microsatellite loci genetic characteristics**

The numbers of alleles, allele size ranges, HO, HE, PIC, F(null), and HWE for the 35 microsatellite loci for the polled yak are presented in Table 1. A total of 214 alleles were identified in the polled yak population. Significant ( $P < 0.001$ ) heterozygote deficits were

detected at loci BM2943, INRA035, and RM099 because they were monomorphic. For the 32 polymorphic loci left, the number of alleles per locus ranged from 3 (CSSM013 and CSSM033) to 12 (SPS115) and the PIC varied from 0.084 (MM12) to 0.815 (ILSTS028). Four of the 32 polymorphic loci had  $PIC < 0.25$  (low). Eleven of them had moderate PIC values ranging from 0.25 to 0.50. The remaining 17 loci had high PIC ( $>0.50$ ) (Table 1).

The 17 genetic markers with high PIC were reproducible, informative, and robust for parentage testing and identification program. The numbers of alleles ranged from 5 to 12 within this subset of 17 polled yak loci. Heterozygosities ranged from 0.573 (POTCHA) to 0.806 (ILSTS028) with an overall average of 0.662. Deviations between observed and estimated heterozygosity ranged from 0.003 (INRA005) to 0.103 (TGLA126). The 17 markers had an average PIC of 0.636 ranging from 0.529 (INRA005) to 0.815 (ILSTS028). F(null) alleles were estimated to be in the range of -0.0218 for YAK08 to +0.0819 for TGLA126 (Table 1).

### **Hardy-Weinberg and genotypic disequilibrium tests**

Exclusion probabilities were calculated from the allele frequencies based on the underlying assumptions of HWE. The HWE for the 17 microsatellite loci were not significant ( $P > 0.05$ ). The 17 loci with high PIC ( $>0.5$ ) were selected for yak paternity testing. Non-random gamete association to form genotypes also influences the allele frequencies used to calculate genotype frequencies. In natural populations, this effect probably occurs because of population substructuring. Genotypic disequilibrium within the polled yak resulted in 136 comparisons. There were no interlocus disequilibria.

### **Multiplex amplification and loading**

Multiplexes were organized such that four groups of four or five loci with high PIC were co-amplified by PCR. Non-overlapping allele lengths were chosen in such a way that they would have the same fluorescent color label. Typical fluorescence signals of detections for the core 17

microsatellite loci are shown in Figure 1. Using the three available fluorescent colors, we multiplex-loaded and scored two groups of eight or nine loci in each single gel lane.

# **Parentage inference**

The EP1 of the 17 markers ranged from 0.189 (BM720) to 0.503 (ILSTS028) and their average value was 0.285. The average EP2 was higher than that for the EP1. The average for all markers was 0.451 and the range was from 0.328 (INRA005) to 0.673 (ILSTS028). For all 17 markers, the combined EP1 and EP2 were 0.99718116 and 0.99997381, respectively. For the alleged parents, the combined EPP was 0.99999998. The combined EI and ESI were  $> 0.99999999$  and 0.99999899, respectively (Table 2). Therefore, the identity and parentage exclusion probabilities based on the 17 microsatellite loci were highly discriminant.

# **DISCUSSION**

Previous studies implied that 3-4% of the losses in genetic progress were caused by 10% increases in pedigree errors per year in dairy breeding (Israel & Weller 2000). Nevertheless, other studies indicated that these dairy breeding pedigree errors have increased to 22% since the 1980s (Ron et al. 1996; Visscher et al. 2002). In fact, the yak pedigree error rate may be  $> 22\%$  since yak feed primarily by grazing. On the other hand, wrong insemination records caused by clerical- and insemination errors and by stain disappearance may also influence pedigree error rates. Therefore, it is necessary to identify and correct the pedigree through paternity testing and individual identification. These practices are essential for reliable breeding programs aimed at the genetic improvement of yak. Several reports have been published on the use of microsatellite markers for cattle identification (Sharma et al. 2015; Zhao et al. 2017), but the performance characteristics of a yak identification panel have not yet been characterized. Paternity testing in yak breeding would increase profitability by improving selective breeding program efficiency.

The method of choice for livestock identification and parentage verification has been based on

microsatellites (Jan & Fumagalli 2016; Jeong et al. 2015; Wang et al. 2017a). For swine (*Sus scrofa*) and cattle (*Bos taurus*), single nucleotide polymorphisms (SNPs) have been applied in identification and parentage verification (Eggen 2012; Rohrer et al. 2007). A recent study debated whether SNPs rather than microsatellites should be used for parentage verification (Kaiser et al. 2017). Nevertheless, the interpretation of complex parentage cases may require >700 SNP markers. The simplified international exchange of microsatellite profiles involves only 32 genotypes as opposed to the 1,400 genotypes for SNPs (Strucken et al. 2016). For these reasons, microsatellites are preferred over SNPs for parentage testing.

The cattle identification and parentage verification panel recommended by the ISAG (International Society for Animal Genetics) consists mainly of dimeric microsatellite repeat motifs. Similarly, all of the microsatellite markers applied in the present study were dimeric. The various repeat patterns have both advantages and disadvantages. Dinucleotide microsatellites may have mutations or stutter bands which can introduce allele interpretation errors (Walsh et al. 1996). For trimeric-, tetrameric-, and pentameric repeat motifs, stutter slippage efficiency during PCR is even lower (Gill et al. 2005), and ensures clear peak discrimination. On the other hand, an appropriate mutation rate is beneficial for multigenerational parentage verification. For trimeric-, tetrameric-, pentameric-, and hexameric microsatellites, gaps during sequence variant visualization within repeat units result in larger bin sizes (Gill et al. 2000). When sequence variants span too widely, however, it becomes increasingly difficult to confine the microsatellite marker within the same fluorochrome to a single multiplex PCR system. Multimeric repeats can also be compound. The microsatellite markers used in the present study were all dimeric with homogeneous repeat motifs, so the genotyping was unambiguous.

Microsatellite loci must have few null alleles, Hardy-Weinberg balance, and no linkage disequilibria if they are to be effectively used in exclusion probability determinations for paternity testing and individual verification. Null alleles are loci that fail to amplify to detectable levels by PCR because of primer binding site mutations and other errors (Dakin & Avise 2004; Kline et al. 2011). Null alleles are estimated by comparing the observed and expected numbers

of homozygotes for a locus (Dąbrowski et al. 2015; Dakin & Avise 2004). There may be an increased risk of null alleles for certain markers. This fact must be considered when genotyping individual yak for paternity testing. For example, when there is a mismatch of an allele for which both parent and offspring are homozygous, the allele should be sequenced to screen for null alleles. The risks of null allele occurrence were highest for HEL10 ( $F(\text{Null}) = 0.703$ ) and MGTG4B ( $F(\text{Null}) = 0.163$ ) in this study. Therefore, these loci were excluded from the core set used in parental identification.

The formulae for estimating exclusion probabilities assume random mating and non-random association among alleles and loci. The allele frequencies used in the calculation of genotype frequencies and exclusion probabilities must be consistent with Hardy-Weinberg assumptions. The 17 loci selected as core microsatellite markers were all in Hardy-Weinberg equilibrium. We tested for linkage disequilibrium because linked loci are relatively ineffective at determining paternity or individual exclusion and the yak locus locations on chromosomes are unknown. Genotypic disequilibrium tests showed no consistent deviations in populations not expected *a priori* to have them. None of the 17 loci was in disequilibrium, which means that they could be used in polled yak exclusion probability (PE) determinations.

The microsatellites used in cattle parentage testing could not be applied to yak identification directly because it was uncertain as to whether the primers used for cattle would produce the desired results for yak. In addition, allelic frequencies differ between cattle and yak. In the present study, the primers were designed according to yak gene sequences then tested by PCR amplification and electrophoresis. There is a strong correlation between PIC and exclusion probability. Even among various cattle breeds, the PIC of the same microsatellites have different values (Mao et al. 2008; Vohra et al. 2017), and the same applied to yak breeds (Zhang et al. 2008). For this reason, when determining the exclusion probabilities of parentage testing and individual identification for a new breed, the allele frequencies and PIC should be calculated *de novo*. In the current study, the polled yak population was repeatedly tested on the proposed microsatellite markers. Since some markers have similar allele frequencies and PIC among yak

breeds, they are expected to generate accurate results for other yak populations.

In the present study, microsatellite loci with high PIC ( $> 0.5$ ) were selected for the identification panels. Nevertheless, the PIC of these loci were still slightly lower than those used for cattle research (Stevanovic et al. 2010; Vohra et al. 2017). Therefore, a greater number of microsatellite markers were selected for the present study. The set of 17 microsatellites sufficed for PE determinations. The combined probabilities of excluding a wrongly assigned sire were 99.718116%, 99.997381%, and 99.999998% for EP1, EP2, and EPP, respectively. These results were similar to those reported for multiplexing systems in Angeln dairy cattle. They had 16 microsatellite markers and nearly 99.9% PE1 (Sanders et al. 2006).

We used several mapped cattle microsatellites to develop sets of yak loci apt for multiplex PCR amplification and multiplex loading into a single gel lane. PCR-based methods, highly variable microsatellite loci, and fluorescent-based genotyping establish a new standard for parentage testing. Furthermore, multiplexing reduces microsatellite typing costs and time. Nevertheless, selecting the markers comprising a universal panel depends on a balance among the required panel accuracy, amplicon length, and ability to undergo a successful multiplex reaction. Multiplex PCR amplifications are technically more difficult than their single-locus counterparts. Multiplex amplifications are also less likely to transfer across species than single-locus amplifications. There is also a relatively higher risk of introducing genotyping errors with multiplex amplifications due to allelic drop-out or false allele production (Taberlet & Luikart 1999). Many multiplex PCR and loading optimization methods have been investigated for cattle paternity testing. Nevertheless, these methods cannot be directly applied to yak identification. Therefore, we developed four multiplex amplifications, each of which contained four or five loci and two multiplex loads each containing eight or nine loci. They were run in two gel lanes. The main advantage of this system is that the allele length ranges do not overlap within the same fluorochrome. Multiplex primer sets to amplify 17 microsatellite markers and fluorescent dye technology combined form a rapid and powerful yak parentage testing method.

We propose that a combination of 17 genetic markers could yield a polled yak panel with

enhanced processing efficiency, reliability, and utility. This system exploits the advancements made in fragment analysis technology. These markers combined with likelihood-based parentage testing will help improve breeding programs and accurately determine polled yak pedigrees. If some of the polled yaks identified by this system were not descendants of the expected breeding male yak, they would be eliminated from a breeding group by breeders to ensure genetic purity and improvement. On the other hand, when semen samples of high-grade male yak are mixed with those of other males, the detection system in this study could identify the semen using the blood sample of the high-grade male yak. Multiplex systems can also be used for the rapid assessment of breed population history, structure, and diversity, and for reconstructing relationships among breeds. These multiplexes may also work in other yak breeds with gene frequencies similar to that of the population tested in the present study.

## CONCLUSIONS

The set of 17 microsatellite markers can be amplified in four multiplex PCR reaction systems and genotyped in two multiplex loading systems. The high variability displayed by these microsatellite loci demonstrates that highly precise genotyping panels could potentially be used in individual genotyping, parentage verification, and individual identification. The microsatellites authenticated in this study could also serve in studies of yak population structure, history, and diversity. They are important resources for the genetic improvement of domestic yak.

## ACKNOWLEDGEMENTS

We thank Hongli Jiang from Beijing UBioLab Genetics Technology Co., Ltd. for technical advice on genotype judging and multiplex systems development. We also thank the staff of Editage who helped improve the written English in this manuscript. We thank the anonymous reviewers for their informative comments on the manuscript.

# Figure 1

Typical fluorescence signal s of detections for the core 17 microsatellite loci.

The "Panels" stand for the multiplex PCR groups. The colors of fluorochrome 6-FAM, HEX, and TAMARA are showed by blue, green, and black respectively. The numbers above the sharp peaks represent length scales based on the internal size standard (bp). The numbers below the sharp peaks represent fragment lengths of PCR amplifications (bp).

Note:

C, concentration of primers; Ta, annealing temperature; PMP, panel numbers for multiplex PCR; PML, panel numbers for multiplex loading; Fluoro, fluorescent dye; RM, repeat motif of microsatellites; EP1, exclusion probability for one confirmed parent genotype missing; EP2, exclusion probability for one confirmed parent genotype available ; EPP, exclusion probability for one alleged parent pair genotype available ; EI, exclusion probability for finding two identical genotypes; ESI, exclusion probability for finding sib; CL, locations of microsatellite loci on cattle chromosomes.
