Background. Yak (*Bos grunniens*) is the most important domestic animal for people living at high altitudes. Yak ordinarily feeds by grazing, and this behavior impacts the accuracy of the pedigree record because it is difficult to control mating in grazing yak. This study aimed to evaluate the pedigree system and individual identification in polled yak.

Methods. Seventy-one microsatellite loci were selected from the literature, mostly from the studies on cattle. Thirty-five microsatellite loci generated excellent PCR results and were evaluated for the parentage testing and individual identification of 236 unrelated polled yaks. Seventeen of these 35 microsatellite loci had polymorphic information content (PIC) values greater than 0.5, and these loci were in Hardy-Weinberg equilibrium without linkage disequilibrium.

Results. Using multiplex PCR, capillary electrophoresis, and genotyping, very high exclusion probabilities were obtained for the combined core set of 17 loci. The exclusion probability (PE) for one candidate parent when the genotype of the other parent is not known was 0.99718116. PE for one candidate parent when the genotype of the other parent is known was 0.99997381. PE for a known candidate parent pair was 0.99999998. The combined PEI (exclusion probability for identity of two unrelated individuals) and PESI (exclusion probability for identity of two siblings) were > 0.99999999 and 0.99999899, respectively. These findings indicated that the combination of 17 microsatellite markers could be useful for efficient and reliable parentage testing and individual identification in polled yak.

Discussion. Many microsatellite loci have been investigated for cattle paternity testing. Nevertheless, these loci cannot be directly applied to yak identification because the two bovid species have different genomic sequences and organization. Seventeen loci were selected from 71 microsatellite loci based on efficient amplification, unambiguous genotyping, and high PIC values for polled yaks, and were suitable for parentage analysis in polled yak populations.

ABSTRACT

Background. Yak (*Bos grunniens*) is the most important domestic animal for people living at high altitudes. Yak ordinarily feeds by grazing, and this behavior impacts the accuracy of the pedigree record because it is difficult to control mating in grazing yak. This study aimed to evaluate the pedigree system and individual identification in polled yak.

Methods. Seventy-one microsatellite loci were selected from the literature, mostly from the studies on cattle. Thirty-five microsatellite loci generated excellent PCR results and were evaluated for the parentage testing and individual identification of 236 unrelated polled yaks. Seventeen of these 35 microsatellite loci had polymorphic information content (PIC) values greater than 0.5, and these loci were in Hardy-Weinberg equilibrium without linkage disequilibrium.

Results. Using multiplex PCR, capillary electrophoresis, and genotyping, very high exclusion probabilities were obtained for the combined core set of 17 loci. The exclusion probability (PE) for one candidate parent when the genotype of the other parent is not known was 0.99718116. PE for one candidate parent when the genotype of the other parent is known was 0.99997381. PE for a known candidate parent pair was 0.99999998. The combined PEI (exclusion probability for identity of two unrelated individuals) and PESI (exclusion probability for identity of two siblings) were > 0.99999999 and 0.99999899, respectively. These findings indicated that the combination of 17 microsatellite markers could be useful for efficient and reliable parentage testing and individual identification in polled yak.

Discussion. Many microsatellite loci have been investigated for cattle paternity testing. Nevertheless, these loci cannot be directly applied to yak identification because the two bovid species have different genomic sequences and organization. Seventeen loci were selected from 71 microsatellite loci based on efficient amplification, unambiguous genotyping, and high PIC values for polled yaks, and were suitable for parentage analysis in polled yak populations.

INTRODUCTION

Yak (*Bos grunniens*), a member of Bovidae family, has successfully been adapted to the severe
cold and low oxygen levels, characteristics of high altitude regions (~2,500–5,500 m), such as
the Himalayas in South-Central Asia, the Qinghai-Tibetan Plateau, Mongolia, and Russia (Wu
2016). These regions are known for their high elevations, pristine natural environments, and
extreme seasonal variations (Mizuno et al. 2015). The ability of yak to survive in such rugged
natural environment is due to its varied behavioral, physiological, and genetic adaptations
(Barsila et al. 2014; Hu et al. 2012; Qiu et al. 2012). For instance, remarkable reduction of heat
production at night when not grazing and increased energy consumption when grazing under
free-range conditions enables yaks to save more energy and resist the extremely harsh conditions
than other cattle under similar environmental conditions (Ding et al. 2014). Yak can thrive under
extreme environmental conditions, such as the Tibetan Plateau where few other animals can
survive. In this region, yak have significantly contributed to human life by providing meat, milk,
fur, leather, and transportation compared to other animals (Medhammar et al. 2012; Wang et al.
2018).

There are about 13 million domestic yak in China, accounting for approximately 90% of the
global yak population. Although there are 18 yak breeds in China, only one breed (Datong) has
been included in a breeding program (Wu 2016). However, polled yak has been bred for many
years at the foot of Ashidan Mountain, as polling reduces the risk of horn-inflicted injury or
death among the herdsmen. Accurate genealogical records can help estimate genetic parameters
and improve breeding programs, ensuring efficient and effective breeding progression to avoid
excessive inbreeding. However, it is difficult to control mating among yaks while grazing.
Furthermore, semen samples could be erroneously mislabeled during preparation, and mating
records might be misinterpreted because of clerical errors made during artificial insemination.
Therefore, accurate yak pedigree records that are compiled by parentage testing and individual
identification are essential to the yak breeding process.

Molecular markers can indicate the degree of genetic relatedness between animals, facilitating

69 parentage verification and individual identification (Estoup et al. 2002). Microsatellites refer to

70 short tandem repeats (STRs) or simple sequence repeats (SSRs), and are considered as tracts of

71 DNA motifs ranging from one to 10 nucleotides in length with repeats of 5–50 times (Carneiro

72 Vieira et al. 2016). Microsatellites can be used to develop pedigree animal populations and

73 evaluate animal breeding, supporting genetic improvement by selective breeding (Weising et al.

74 1998). The application of microsatellites as molecular markers for animal identification and

75 parentage verification produced highly accurate and effective results in both breeding and

76 forensics (Linacre et al. 2011).

77   Microsatellite marker analysis has been used to verify the parentage in breeding registries and

78 identify individual animals that are linked to a particular database or owner. Microsatellite panels

79 of cattle (Zhao et al. 2017), horse (Kang et al. 2016), sheep (Rosa et al. 2013), dog (Jeong et al.

80 2015), and parrot (Coetzer et al. 2017) have been well characterized. Parentage control in the

81 beef cattle breeds, Charolais, Limousin, and Preta, in Portugal was assessed using 10

82 microsatellite markers, and the results revealed a combined exclusion probability (PE) above

83 0.9995, indicating their ability to exclude a random parent pair (Carolino et al. 2009). The

84 application of 11 microsatellite loci in paternity testing in Yugoslav Pied cattle breed in Serbia

85 revealed a combined PE of 0.999 (Stevanovic et al. 2010). Sixteen specific microsatellite

86 markers were used to develop a genetic system of meat traceability for several beef cattle breeds,

87 including Japanese Black, Anduo yak, Limousin, Jiaxian Red, Nanyang Yellow, and Luxi

88 Yellow (Zhao et al. 2017). Previous studies reported that microsatellite genotyping was used for

89 population genetics analysis and parentage testing in yak. However, these loci and their primers

90 were originally developed for cattle, and then used directly in yak (Li et al. 2013; Nguyen et al.

91 2005). Therefore, there is a need for explorative and application-based studies on microsatellite

92 markers or panels of microsatellite markers that are suitable for accurate individual identification

93 and parentage testing in yak.

94   Hence, in the present study, we aimed to establish a paternity test and individual identification

95 system for the polled yak. Therefore, the study was expected to (1) calculate the genetic

96   parameters of polled yak microsatellite loci, which have been commonly reported by population

97   genetics studies of cattle and yak; (2) evaluate the application values of the loci with high

98   polymorphic information content (PIC) for parentage testing and individual identification; and

99   (3) explore a multi-loci combination test system for parentage testing and individual

100   identification.

101

MATERIALS AND METHODS

102

Marker selection and primer design

103

104   The microsatellites used in the present study were selected from the previous reports on cattle

105   breeding based on the following criteria: (a) high PIC; (b) large number of alleles; (c) relatively

106   infrequent null alleles; and (d) homogeneous or approximately homogeneous repeat motifs

107   (Schnabel et al. 2000). Among the 71 bovine microsatellite markers selected, 65 were derived

108   from cattle, and 6 were exclusive to yak (Supplemental Table S1). All 71 microsatellites and

109   their flanking sequences were found in the cattle genome, and were searched for in the yak

110   genome. The primers for most loci used in previous studies were not suitable for the yak genome

111   because of low scores. However, the primers used to amplify BM1824, BM2113, BMS2533,

112   ETH121, ETH225, ILSTS008, INRA124, RM099, INRA126, UMN0103, UMN0307,

113   UMN0920, UMN2303, UMN3007, and UMN3008 loci presented relatively high scores, so these

114   loci were not redesigned for yak. The primers used in the present study are listed in Table S1.

115

Sample collection

116

117   Polled yaks bred via selective breeding were selected from herds in Ashidan Mountain region in

118   Qinghai Province, China. To avoid consanguinity, samples were taken from animals with no

119   genetic relationship. All yaks were handled in strict accordance with good animal practices by

120   following the *Animal Ethics Procedures and Guidelines of the People's Republic of China*. The

121 present study was approved by the *Animal Administration and Ethics Committee of Lanzhou*

122 *Institute of Husbandry and Pharmaceutical Sciences of Chinese Academy of Agricultural*

123 *Sciences* (Permit No. SYXK-2016-0039). Blood was drawn from the jugular veins of 236

124 unrelated individuals, including 38 sires and 198 dams, and samples were mixed with

125 preservation buffer (containing 1.5 mg mL^{-1} EDTA and 137 mmol L^{-1} NaCl) at a ratio of 5:1. The

126 blood samples were stored at -80 ℃ in an ultra-cold freezer until DNA extraction.

127

128 **DNA extraction and quantification**

129 Genomic DNA was extracted from white blood cells, separated from whole blood, and digested

130 with proteinase K. After digestion, the samples were centrifuged at $5000 \times g$ for 2 min, and the

131 resulting supernatant (clear aqueous layer) was transferred to a new test tube. After the addition

132 of 0.5 mL of 10 mg mL^{-1} RNase A, DNA was individually extracted with a

133 phenol:chloroform:isoamyl alcohol mixture (25:24:1) followed by chloroform, precipitated with

134 ethanol, and resuspended in 50 mL TE buffer (10 mM Tris-HCl and 1 mM EDTA, pH 8.0). The

135 extracted DNA was then quantified using a NanoDrop 2000 fluorometer (Thermo Fisher

136 Scientific, Waltham, MA, USA).

137

138 **Preliminary primer screening**

139 Unlabeled primer pairs (Table S1) for each microsatellite marker were used for amplification of

140 DNA fragments. PCR was performed with a reaction mixture at a total volume of 20 μL,

141 comprising of 20–50 ng genomic DNA, 10 mM Tris-HCl (pH 9.0), 50 mM KCl, 1.5 mM MgCl$_2$,

142 2.0 mM each dNTP, 5 ng of bovine serum albumin, and 1.0 U of *Taq*™ Hot Start Version

143 polymerase (TaKaRa Bio Inc., Kusatsu, Shiga, Japan). Primer concentrations ranged from 1.0 to

144 5.5 μM. The thermal cycle parameters were as follows: 5 min at 95 ℃; 35 cycles of 30 s at 95

145 ℃, 30 s at 55–58 ℃ (Table S1), and 20 s at 72 ℃; and a final extension step for 5 min at 72 ℃.

146 Amplifications were performed on a Veriti 96-Well Thermal Cycler (Applied Biosystems Corp.,

147   Foster City, CA, USA). The amplicons were visualized on 2% agarose gels (Gene Tech Co. Ltd.,

148   Chai Wan, Hong Kong, PRC). Five microliters of PCR product were mixed with 1 μL of loading

149   dye (TaKaRa Bio Inc.) and electrophoresed for 35 min at 85 V. The samples were then

150   visualized using the GelDoc™ XR+ gel imaging system (Bio-Rad Corp., Hercules, CA, USA).

151   The amplicons with high specificity and high amplification efficiency, whose loci were either

152   non-syntenic or separated by > 10 cM (to avoid strong genetic linkage) (Table S2), were

153   manually cut out of agarose gels and forwarded to Invitrogen (Carlsbad, CA, USA) and Thermo

154   Fisher Scientific without prior purification for Sanger sequencing on an ABI3730xl automated

155   sequencer (Applied Biosystems Corp.) to identify repeat markers. Only the forward primers were

156   used to sequence the target markers.

157

158   **Genetic information acquisition**

159   The confirmed primer sequences flanking the microsatellite loci were synthesized with a

160   fluorescent label (FAM™, HEX™, or TAMRA™; Thermo Fisher Scientific) attached to the 5'

161   end of each forward primer. The microsatellites were separately amplified by PCR to identify the

162   highly polymorphic loci. The amplification systems and conditions were similar to those

163   described above for unlabeled primers.

164   After amplification, 1 μL of amplified fragment mix was added to 0.5 μL of loading buffer

165   (blue dextran, 50 mg mL^{-1}; EDTA, 25 mM) and 4 μL of deionized formamide, and it was then

166   denatured by incubation for 5 min at 95 ℃. An internal size standard (0.5 μL of Thermo ABI

167   4322682; Thermo Fisher Scientific) was added to each sample, and the fluorescently labeled

168   PCR products were then separated by capillary electrophoresis (ABI3730xl Genetic Analyzer;

169   Applied Biosystems Corp.). The fluorescently labeled DNA fragments were first analyzed with

170   GENESCAN v. 3.7 (Applied Biosystems Corp.) followed by GENOTYPER v. 3.7 NT (Applied

171   Biosystems Corp.). The fragments were then automatically sorted according to the internal size

172   standard. The numbers of microsatellite repeat motifs were calculated based on the amplicon

173   lengths (Table S3).

174

Genetic information analysis

176   The genotypic data were initially processed in Microsoft Office Excel 2007, manually checked

177   for errors, and then transformed into input files that were required for subsequent analyses. The

178   performance characteristics [observed heterozygosity (HO), expected heterozygosity (HE), PIC,

179   estimated null allele frequency (F(null)), Hardy-Weinberg equilibrium (HWE), and linkage

180   disequilibrium] were measured with GENEPOP v. 4.6 (Raymond & Rousset 1995; Rousset

181   2008) and CERVUS v. 3.0.7 (Kalinowski et al. 2010; Slate et al. 2000).

182

Multiplex PCR conditions

184   Genotyping of 236 yaks for 35 loci (Table 1) produced a core set of 17 loci with high PIC values

185   (Table 2). Four multiplex PCR reactions were assembled, each containing four or five

186   microsatellite markers. The primer sequences and concentrations used in the multiplex PCR

187   reactions are shown in Table 2. The multiplex PCR reactions were performed with reaction

188   mixtures at a total volume of 15 μL, containing 25 ng of genomic DNA, 10 mM Tris-HCl (pH

189   8.3), 35 mM KCl, 1.8 mM $MgCl_2$, 5.0 mM each dNTPs, and 2.5 U of Taq^{TM} Hot Start Version

190   polymerase (TaKaRa Bio Inc.). Amplifications were performed in a Veriti 96-Well thermal

191   cycler (Applied Biosystems Corp.) under the following conditions: 95 ºC for 5 min; 25 cycles of

192   95 ºC for 30 s, 55–58 ºC for 30 s, and 72 ºC for 30 s; 10 cycles of 95 ºC for 30 s, 53 ºC for 30

193   s, and 72 ºC for 30 s; and final extension at 72 ºC for 5 min. Genotyping of these microsatellite

194   loci was performed as described above.

195

Parentage testing and individual identification

197   Exclusion probability values for parentage testing were obtained using a likelihood-based

198   method based on genotypic information. Five types of PEs were calculated for the set of loci in

199   CERVUS v. 3.0.7. PE1 was defined as the average probability of excluding an unrelated

200   candidate parent of an arbitrary offspring when the genotype of the other parent is unknown. PE2

201   was defined as the average probability of excluding an unrelated candidate parent of an arbitrary

202   offspring when the genotype of the other parent is known. PEP was defined as the average

203   probability of excluding a pair of unrelated candidate parents of an arbitrary offspring. PEI was

204   defined as the average probability of differentiating two randomly-selected individuals. PESI

205   was defined as the average probability of differentiating two randomly-selected full siblings

206   (Kalinowski et al. 2010; Slate et al. 2000).

207

208   **RESULTS**

209   **Microsatellite loci characteristics**

210   After preliminary screening, a total of 35 microsatellite loci with the highest primer specificity

211   among the 71 microsatellite loci were selected for further analysis. The number of alleles, allele

212   size range, HO, HE, PIC, F(null), and HWE of the 35 microsatellite loci of polled yaks are

213   presented in Table 1. Three monomorphic loci, namely BM2943, INRA035, and RM099, were

214   identified. The remaining 32 loci were polymorphic. The number of alleles per locus ranged

215   from three (CSSM013 and CSSM033) to 12 (SPS115), and PIC values ranged from 0.084

216   (MM12) to 0.815 (ILSTS028). Four of these 32 polymorphic loci had low PIC values (i.e., <

217   0.25), 11 had moderate PIC values (0.25–0.50), and 17 loci had high PIC values (> 0.50) (Table

218   1).

219   The 17 genetic markers with high PIC values were reproducible, informative, and locus-

220   specific for parentage testing and individual identification. The number of alleles ranged from

221   five (BM720, INRA005, TGLA227) to 12 (SPS115). Heterozygosity values ranged from 0.573

222   (POTCHA) to 0.806 (ILSTS028), with an average of 0.662. Deviations between HO and HE

223   ranged from 0.003 (INRA005) to 0.103 (TGLA126). The 17 loci had an average PIC values of

224   0.636, ranging from 0.529 (INRA005) to 0.815 (ILSTS028). The null allele frequency ranged

225   from 0.0015 (TGLA227) to 0.0819 (TGLA126) (Table 1).

226

Hardy-Weinberg and linkage disequilibrium tests

228   The results of HWE tests of the 17 microsatellite loci indicated no significant differences (P >

229   0.05) (Table 1). Therefore, the 17 loci with high PIC values (> 0.5) were selected for yak

230   paternity testing. Linkage disequilibrium within polled yaks resulted in 136 comparisons, and no

231   interlocus disequilibrium was detected between loci on the same chromosome (Table S6).

232

Multiplex amplification and loading

234   Multiplex PCR reactions were organized to co-amplify four groups of 4–5 loci with high PIC

235   values. Non-overlapping allele lengths that presented the same fluorescent color label were

236   selected. Typical fluorescence signals of the core 17 microsatellite loci are shown in Figure 1.

237   Using the three available fluorescent colors, we multiplex-loaded and scored two groups of eight

238   or nine loci in each run.

239

Parentage inference

241   The exclusion probabilities were calculated from the allele frequencies based on the underlying

242   assumptions of HWE. The PE1 values of the 17 core loci ranged from 0.189 (BM720) to 0.503

243   (ILSTS028), with an average of 0.285. The average PE2 values of the 17 markers was 0.451, and

244   values ranged from 0.328 (INRA005) to 0.673 (ILSTS028). Regarding the 17 core loci, the

245   combined PE1 and PE2 values were 0.99718116 and 0.99997381, respectively. For the putative

246   parents, the combined PEP value was 0.99999998. Combined PEI and PESI values were >

247   0.99999999 and 0.99999899, respectively (Table 2). Therefore, the PE values indicated that the

248   discriminatory power of the 17 loci was high.

249

DISCUSSION

250

251   Previous studies indicated that 4.3% of annual losses with regard to genetic gain during dairy

252   breeding were caused by pedigree errors (10%), compared to simulation analysis of accurate

253   paternity determination data(Israel & Weller 2000). In fact, the pedigree error rate in yaks was

254   high due to incorrect paternity as yaks feed primarily by grazing, thwarting parentage attribution.

255   Additionally, clerical and insemination errors and fading ink on artificial insemination records

256   and labels might contribute to sample mixing, thereby, leading to pedigree errors. Therefore, it is

257   necessary to identify and correct the pedigree through parentage testing and individual

258   identification. These practices that aim at genetic improvement of yak are essential for

259   generating reliable breeding programs. Several reports have been published on the use of

260   microsatellite markers for cattle identification (Sharma et al. 2015; Zhao et al. 2017), but the

261   performance characteristics of yak identification panels have not yet been established. Parentage

262   testing for yak breeding increases the profitability by improving the efficiency of selective

263   breeding programs.

264   The most commonly used methods of livestock identification and parentage verification rely

265   on microsatellites (Jan & Fumagalli 2016; Jeong et al. 2015; Wang et al. 2017). However, single

266   nucleotide polymorphisms (SNPs) have been applied in the identification and parentage

267   verification of swine (*Sus scrofa*) and cattle (*Bos taurus*) (Eggen 2012; Rohrer et al. 2007). A

268   recent study debated on the use of SNPs instead of microsatellites for parentage verification

269   (Kaiser et al. 2017). However, at least 200 SNPs should be used for parentage testing to reduce

270   false-negative results, and at least 700 SNPs are required to completely eliminate false positives

271   (Strucken et al. 2016). In addition, parentage analysis based on SNPs has few predictable

272   statistical problems that must be considered carefully and evaluated appropriately before

273   substituting the classical STRs approach (Amorim & Pereira 2005). For these reasons,

274   microsatellites are preferred over SNPs for parentage testing.

275   Most of the microsatellite markers used for cattle identification and parentage verification are

276   dimeric repeat motifs (Carolino et al. 2009; Stevanovic et al. 2010; van de Goor et al. 2009; Zhao

277 et al. 2017). Similarly, all microsatellite markers used in the present study were dimeric. Repeat

278 patterns have advantages as well as disadvantages. Dimeric microsatellites might have mutations

279 or stutter bands that present allele interpretation errors (Walsh et al. 1996). On the contrary,

280 during PCR conduction, trimeric, tetrameric, and pentameric repeat motifs demonstrated lower

281 stutter slippage efficiency than dimeric microsatellites (Gill et al. 2005), and they ensured clear

282 peak discrimination. On the other hand, an appropriate mutation rate might be beneficial for the

283 verification of multigenerational parentage. This is because mutations might occur between an

284 ancestor and a descendant's assumed father/mother, but not between an assumed father/mother

285 and offspring, thus allowing the identification of true father/mother. For trimeric, tetrameric,

286 pentameric, and hexameric microsatellites, gaps occurring during the sequence variant

287 visualization within the repeat units can result in larger bin sizes than those of dimeric

288 microsatellites (Gill et al. 2000). However, if the span of the sequence variants is too wide, it

289 becomes increasingly difficult to confine the microsatellite markers within a fluorochrome to a

290 single multiplex PCR system. Furthermore, multimeric repeats can also be compound. All of the

291 microsatellite markers used in the present study were dimeric containing homogeneous repeat

292 motifs, therefore, some markers can be labeled as one fluorochrome in a single multiplex PCR

293 with unambiguous genotyping.

294   In order to use them in paternity testing and individual identification, microsatellite loci must

295 have rare null alleles, and be at HWE, and the gametic association (linkage disequilibrium)

296 should be absent. Null alleles are not amplified to detectable levels via PCR because of

297 mutations at primer binding sites (Kline et al. 2011). The frequency of null alleles is mainly

298 estimated by Mendelian incompatibilities (Strucken et al. 2016) and by comparing the observed

299 and expected number of homozygotes at a locus (Dąbrowski et al. 2015). This fact must be

300 considered when performing genotyping for parentage testing and when there is an apparent

301 opposite homozygosity between parent and offspring. In the present study, the estimated null

302 allele frequencies remained the highest for HEL10 (F(Null) = 0.703) and MGTG4B (F(Null) =

303 0.163). Therefore, these loci were excluded from the core set used for parental identification.

304   The formulae used to estimate the exclusion probabilities assume random mating, random

305   association between alleles of different loci, and allele frequencies consistent with HWE. The 17

306   loci that were selected as core microsatellite markers were at HWE (Table 1), indicating that they

307   can be used to calculate PE values.

308   The microsatellites used in cattle parentage testing could not be directly applied to yak

309   identification due to uncertainty of whether the primers used for cattle would produce the desired

310   results in yak. In the present study, the microsatellite primers were designed based on the yak

311   gene sequences, and were then tested by PCR and electrophoresis. In addition, the allelic

312   frequencies differed between the cattle and yak. Even among cattle breeds, the microsatellite PIC

313   values differed (Mao et al. 2008), and the same might be applied to yak breeds (Zhang et al.

314   2008). Thus, while determining the PE values of parentage testing and individual identification

315   for a new breed, allele frequencies and PIC values should be calculated *de novo*.

316   The microsatellite loci with PIC value > 0.5 were selected for the identification panel.

317   Nevertheless, the PIC values of these loci were still moderately lower than those used for cattle

318   testing (Stevanovic et al. 2010; Vohra et al. 2017). Therefore, a high number of microsatellite

319   markers were screened in the present study, and a set of 17 microsatellite markers proved to be

320   sufficient for determining PE values. The combined exclusion probabilities of wrongly assigned

321   sires were 99.718116%, 99.997381%, and 99.999998% for PE1, PE2, and PEP, respectively.

322   Similar results were reported in Angeln dairy cattle, with 16 microsatellites and approximately

323   99.9% PE1 (Sanders et al. 2006). The PEP value calculated for the set of 17 microsatellites for

324   parentage testing in the present study was 99.997381%, which was marginally higher than that

325   obtained for Swiss yaks (99.5%) using 13 STR markers (Nguyen et al. 2005). Therefore, the set

326   of microsatellite loci used in the present study significantly contributed to parental identification

327   in the polled yak population.

328   We used several mapped cattle microsatellites to develop the sets of yak loci that were suitable

329   for multiplex PCR amplification, and multiplex loading was conducted in a single run to reduce

330   human errors, typing cost, and time. Nevertheless, selecting markers for a universal panel

331   depends on the balance among the required panel accuracy, amplicon length, and ability to

332   undergo a successful multiplex reaction. Multiplex PCR amplifications are technically more

333   difficult than their single-locus counterparts, but they are less likely to transfer across species

334   than single-locus amplifications. Several multiplex PCR and loading optimization methods have

335   been investigated for parentage testing of cattle. Nevertheless, these methods cannot be directly

336   applied to yak identification. Therefore, we developed four multiplex amplifications (each

337   containing four or five loci) and two multiplex loads (each containing eight or nine loci) running

338   in two gel lanes. The main advantage of this system is that the allele length ranges do not

339   overlap within the same fluorochrome.

340   Hence, we proposed that a combination of 17 microsatellites can yield a polled yak panel with

341   enhanced processing efficiency, reliability, and utility. Moreover, this system uses the standard

342   genotyping methods of DNA fragment analysis technology. Combined with likelihood-based

343   parentage testing, these 17 markers will help improve breeding programs and accurately

344   determine polled yak pedigrees. If this system is used to identify polled yaks that are not the

345   descendants of the expected breeding male yak, breeders can eliminate them from the breeding

346   group to ensure genetic purity and breed improvement. On the other hand, if the semen samples

347   of high-grade male yaks are mixed with those of other males, the detection system can use DNA

348   from semen and blood of the high-grade male yak for identification. Multiplex systems can also

349   be used to rapidly assess the history, structure, and diversity of the breeding population, and

350   these systems can reconstruct relationships among breeds. Furthermore, these multiplex systems

351   might also be applied to other yak breeds with gene frequencies that are similar to that of the

352   population tested in the present study.

353   Although the core set of microsatellite loci presented here was meaningful for yak parentage

354   testing, this methodology still has the following limitations: (a) Since different yak breeds have

355   different microsatellite genotypes, this core set was only suitable for parentage testing of polled

356   yak; (b) The PIC values of the microsatellite loci are not sufficiently high to reduce the number

357   of loci, thus avoiding low PE values; and (c) The number of panels for multiplex PCR reactions

358   and multiplex loading still remained too high, leading to time-consuming and high cost.

359   Therefore, a large number of microsatellites with high PIC values should be obtained for

360   different yak breeds to develop efficient parentage test systems, with higher PE values and fewer

361   markers. Furthermore, microsatellites should be suitable to each specific yak breed, and markers

362   should be screened using single multiplex PCR reactions or multiplex loading.

363

CONCLUSIONS

365   A set of 17 microsatellite markers, which were assembled into four multiplex PCR reaction

366   systems and genotyped in two multiplex loading systems, were identified and evaluated. The

367   high variability displayed by these microsatellite loci demonstrated that highly precise

368   genotyping panels might be used for individual genotyping, parentage verification, and

369   individual identification. The microsatellites reported in this study could also be used to evaluate

370   yak population structure, history, and diversity, which subsequently aids the genetic

371   improvement of domestic yak.

372

ACKNOWLEDGEMENTS

374   We thank Hongli Jiang from Beijing UBioLab Genetics Technology Co., Ltd. for technical

375   advice on genotype evaluation and multiplex system development. We also thank Editage for

376   improving the language of this manuscript. We thank the Editor and the anonymous Reviewers

377   for their constructive comments on the manuscript.

Note:

C, concentration of primers; Ta, annealing temperature; PMP, panel numbers for multiplex PCR; PML, panel numbers for multiplex loading; Fluoro, fluorescent dye; RM, repeat motif of microsatellites; PE1, the average probability that the set of loci will exclude an unrelated candidate parent from parentage of an arbitrary offspring when the genotype of the other parent is unknown; PE2, the average probability that the set of loci will exclude an unrelated candidate parent from parentage of an arbitrary offspring when the genotype of the other parent is known; PEP, the average probability that the set of loci will exclude a pair of unrelated candidate parents from parentage of an arbitrary offspring; PEI, the average probability that the set of loci will differentiate between two randomly-selected individuals; PESI, the average probability that the set of loci will differentiate between two randomly-selected full siblings; CL, locations of microsatellite loci on cattle chromosoms.

Figure 1

Typical fluorescence signal s of detections for the core 17 microsatellite loci.

A: Panel 1, B: Panel 2, C: Panel 3, D: Panel 4. The "Panels" stand for the multiplex PCR groups. The colors of fluorochrome 6-FAM, HEX, and TAMARA are showed by blue, green, and black respectively. The numbers above the sharp peaks represent length scales based on the internal size standard (bp). The numbers below the sharp peaks represent fragment lengths of PCR amplifications (bp).
