Protein structure is not static; residues undergo conformational rearrangements and, in doing so, create, stabilize or break non-covalent interactions. Molecular Dynamics (MD) is a technique used to simulate these movements with atomic resolution. However, given the data-intensive nature of the technique, gathering relevant information from MD simulations is a complex and time consuming process requiring several computational tools to perform these analyses. Among different approaches, the study of Residue Interaction Networks (RINs) has proven to facilitate the study of protein structures. In a RIN, nodes represent amino-acid residues and the connections between them depict non-covalent interactions.

Here, we describe RIP-MD, a Visual Molecular Dynamics (VMD) plugin to facilitate the study of RINs using trajectories obtained from MD simulations of proteins. Our software generates RINs from MD trajectory files. The noncovalent interactions defined by RIP-MD include H-bonds, Salt bridges, VdWs, cation- π , π - π , Arginine-Arginine and Coulomb interactions. In addition, RIP-MD also computes interactions based on distances between C α s and disulfide bridges. The results of the analysis are shown in an user friendly interface. Moreover, the user can take advantage of the VMD visualization capacities, whereby through some effortless steps, it is possible to select and visualize interactions described for a single, several or all residues in a MD trajectory. Network and descriptive table files are also generated, allowing their further study in other specialized platforms. Our method was written in python in a parallelized fashion. This characteristic allows the analysis of large systems impossible to handle otherwise. RIP-MD is available at <http://www.dlab.cl/ripmd>.

1 Abstract

Protein structure is not static; residues undergo conformational rearrangements and, in doing so, create, stabilize or break non-covalent interactions. Molecular Dynamics (MD) is a technique used to simulate these movements with atomic resolution. However, given the data-intensive nature of the technique, gathering relevant information from MD simulations is a complex and time consuming process requiring several computational tools to perform these analyses. Among different approaches, the study of Residue Interaction Networks (RINs) has proven to facilitate the study of protein structures. In a RIN, nodes represent amino-acid residues and the connections between them depict non-covalent interactions.

Here, we describe RIP-MD, a Visual Molecular Dynamics (VMD) plugin to facilitate the study of RINs using trajectories obtained from MD simulations of proteins. Our software generates RINs from MD trajectory files. The non-covalent interactions defined by RIP-MD include H-bonds, Salt bridges, VdWs, cation- π , π - π , Arginine-Arginine and Coulomb interactions. In addition, RIP-MD also computes interactions based on distances between C_{α} s and disulfide bridges. The results of the analysis are shown in an user friendly interface. Moreover, the user can take advantage of the VMD visualization capacities, whereby through some effortless steps, it is possible to select and visualize interactions described for a single, several or all residues in a MD trajectory. Network and descriptive table files are also generated, allowing their further study in other specialized platforms. Our method was written in python in a parallelized fashion. This characteristic allows the analysis of large systems impossible to handle otherwise. RIP-MD is available at <http://www.dlab.cl/ripmd>.

39 2 Introduction

40 The function of proteins is determined by both their 3D structure and their
 41 behavior. Therefore, the traditional dogma *sequence→structure→function* is
 42 currently restated as *sequence→structure→dynamics→function*. Not surpris-
 43 ingly, Molecular Dynamic (MD) methods have become essential tools to explore
 44 protein dynamics with atomic resolution [38]. Notwithstanding, one of the ma-
 45 jor caveats of MD is the huge amount of data produced by each simulation,
 46 hindering both data handling and analysis. Thus, the generation of proper
 47 tools to conduct structural and dynamic analyses, is an area of active research
 48 and development [20, 19]. Among other methods, the production of Residue In-
 49 teraction Networks (RINs) gained popularity due to their simple and intuitive
 50 approach. RINs are a graph representation of protein structures in which nodes
 51 represent Amino Acids (AAs) and the existence of an interaction between two
 52 AAs is represented by edges. Some interesting usage of RINs in MD include
 53 the identification of key AAs involved in several processes such as allostery
 54 [34, 28, 25], enzymatic activity [22], protein folding [39] and in protein-protein
 55 interactions [7]. RINs have also been adopted for the prediction of the effect of
 56 single point mutations in protein stability [15]; the analysis of protein stability
 57 [5]; the superimposition and comparison of protein structures [18, 28]; assess-
 58 ing the quality of predicted protein structures [37]; and the study of light dark
 59 transitions in photoreceptors [25].

60 Many types of RINs can be defined depending on how the interactions be-
 61 tween AAs are outlined. The most common definition is the euclidean distance
 62 between atoms belonging to different residues, and thus interactions exists only
 63 if the distance between AAs is shorter than a given threshold. When this dis-
 64 tance is calculated between C_{α} s or C_{β} s, RINs are traditionally known as Contact
 65 Maps (CMs) [34, 6]. RINs based on thresholded distances are simple graphs,
 66 i.e., a pair of nodes can only be connected by a single edge. Nevertheless, there
 67 is another approach to build RINs that considers explicitly all non-covalent in-
 68 teractions pertaining a pair of AAs [29, 41], giving rise to a multigraph in which
 69 nodes can be connected by several edges. In this way, each edge represents
 70 a single non-covalent interaction. Non-covalent interactions depicted by edges
 71 usually include salt bridges (SBs), hydrogen bonds (HBs), π - π , cation- π and
 72 van der Waals (vdW) contacts among others. Multigraph RINs contain more
 73 information than simple graphs built upon distance thresholds, since all inter-
 74 actions are described in the graph. As a drawback, the existence of several
 75 connections between pairs of nodes prevents the use of common algorithms and
 76 metrics that can be applied to characterize and analyze simple graphs (see [4]
 77 for a discussion of the calculation of shortest paths in multigraphs).

78 Most of the current approaches to depict protein structures as a network are
 79 static [42], representing a single protein structure as a RIN disregarding the dy-
 80 namic properties of the AAs and atoms forming it. Lately, several authors have
 81 introduced RIN based methodologies on full MD trajectories, the so called dy-
 82 namic RINs, allowing for the generation of consensus graphs that characterizes
 83 and contains the (averaged) dynamic properties of each residue with respect to
 84 the rest [3, 12, 31, 33]. Nonetheless, all the aforementioned methods are based

on distance thresholds between single atoms lacking the important information provided by the explicit inclusion of non-covalent interactions.

Herein, we present RIP-MD (*Residue Interaction Networks in Protein Molecular Dynamics*), a software to generate both static and dynamics RINs. RIP-MD is available as a web server for RIN derivation using static protein structures (PDB files [2]), or as a Visual Molecular Dynamics (VMD) [21] plugin to obtain dynamic RINs derived from MD trajectories. RIP-MD is meant to be an intuitive and easy-to-follow visualization tool for (pairwise) residue interactions. The latter is particularly relevant for MD in which the generated data is enormous. However, due to the employment of networks, the users can take advantage of the mathematical formalism of network theory (i.e. by using Cytoscape) to further analyze their simulations. RIP-MD reads MD trajectory files in DCD binary format generating snapshots at fixed time intervals from which a dynamic RIN is built on. RIP-MD can be employed to perform several analyses, including cross-correlation studies between the different types of interactions; generation of a consensus RIN where edges exists if they are present in at least a given percentage of the snapshots; and the calculation of different node centralities. In the next sections a detailed description of RIP-MD is elaborated. Furthermore, the utility of RIP-MD is emphasized with two examples of MD trajectories: the analysis of possible interactions that stabilize the structure of a Gap Junction Channel and the structural changes on the Lymphocyte antigen 96 protein.

A web server for the creation of RINs from single PDB files, the stand alone and the VMD plug-in versions of RIP-MD can be accessed and downloaded from dlab.cl/ripmd. In addition, to facilitate the use of RIP-MD under any operative system we also provide it already installed in a VirtualBox[®] machine.

3 Methods

The general workflow of RIP-MD is summarized in Figure 1. RIP-MD starts either with a dynamic (MD trajectory) or static (PDB file) protein structure, and the parameters defining the interactions as input (Figure 1.A). The next step pre-processes the input to ensure it complies with the required format (Figure 1.B). Then, a search for interactions between all atoms is carried out in each snapshot from the MD trajectory or using the static structure from the PDB file (see Figure 1.C). In the last step (Figure 1.D), RIP-MD generates the output files including correlation maps and files defining a RIN, which can be further characterized in network visualization tools such as Cytoscape [35]. Each of these steps is described in detail below.

3.1 Input and pre-processing steps:

As previously mentioned, RIP-MD takes as input either a dynamic or a static protein structure (Figure 1.A). Structural analyses within RIP-MD are handled by *MDAnalysis* [30, 17], a python library to manipulate MD trajectories. The first action in this step is to delete heteroatoms maintaining only protein atoms. If the user wants to add missing atoms, such as hydrogens, these are added based on internal coordinates with *PDB2PQR* [9, 10]. After all these steps, additional parameters such as (partial) charges, Lennard-Jones parameters and secondary

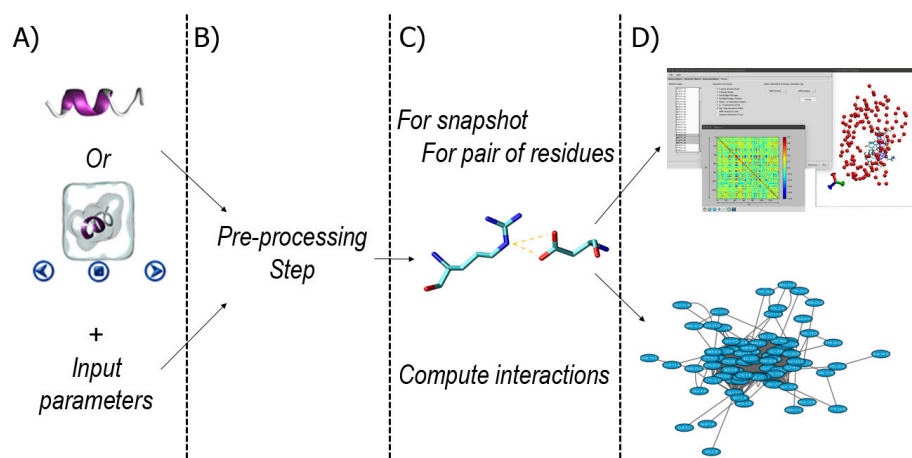

Figure 1: Workflow in *RIP-MD*. Panel A), input of structural information and analyses parameters. Panel B), pre-processing step. Panel C), definition of interactions (C_{α} contacts, H bonds, Salt bridges, Disulfide bonds, cation- π , π - π , Arginine-Arginine, Coulomb and Van der Waals contacts) according to the input parameters. Panel D), generation of RIN and output files.

structure are either defined or calculated. In the case of MD trajectories, partial charges are assigned from the topology file, *i.e.* PSF file, employed to perform the simulation. Charges for static structures and Lennard-Jones parameters are assigned from the parameters files of the CHARMM force field [26]. Secondary structure and solvent accessibility for each AA are defined using *DSSP* [23, 24]. For further details about input files and their format, please refer to the *RIP-MD* user manual.

3.2 Interactions defined in *RIP-MD*:

RIP-MD defines several types of interactions between the AAs in a protein structure: C_{α} contacts, hydrogen bonds, salt bridges, disulfide bonds, cation- π , π - π , Arg-Arg, Coulomb and van der Waals contacts. Parameters defining each interaction, together with their mathematical formulation is explained in detail in Supp. File Text S1 and resumed in Table 1. Importantly, users may employ the provided by-default parameters defining each of these interactions or set them accordingly to his/her needs.

3.3 *RIP-MD* versions and availability:

RIP-MD is available free of charge at <http://www.dlab.cl/ripmd> in three options:

- Standalone program: This version is thought for users who want to take advantage of High Performance Computing (HPC) architectures to perform analysis of very large systems, such very long MD trajectories that are impossible to handle otherwise.

C α contacts	$dist(C\alpha_i, C\alpha_j) \leq d$	$d = 8\text{\AA}$
Hydrogen Bonds	$dist(donor, acceptor) \leq d$ $\theta(C-H, acceptor) \geq a$	$d = 3\text{\AA}$ $a = 120^\circ$
Salt Bridges	contacts between NH/NZ groups of ARG/LYS and OE*/OD* in ASP/GLU $\leq d$	$d \leq 6\text{\AA}$
Disulfide Bonds	S atoms of two cysteins $\leq d$ dihedral $\theta(C-S-S-C) \in [a, b]$	$d \leq 3\text{\AA}$ $a \geq 60^\circ$ & $b \leq 90^\circ$
Cation- π interactions*	distance between aromatic rings $\leq d$	$d \leq 6\text{\AA}$
π - π interactions*	$dist(aromatic\ ring, cation) \leq d$ $\theta(normal\ vector\ ring, ring\ center - cation) = a$	$d = 7\text{\AA}$ $a \in [0^\circ, 60^\circ]$ or $a \in [120^\circ, 180^\circ]$
Arg-Arg	$dist(guanidine_1, guanidine_2) \leq d$	$d \leq 5\text{\AA}$
Coulomb interactions	charged-group based cut-off using a 1-4 potential	
van der Waals	12-6 Lennard-Jones potential	

Table 1: Summary of all interactions defined in RIP-MD. A detailed description can be found in Supp. File Text S1. * His residues are considered as a cation if they present a protonated nitrogen atom, and as π -system only if they are not protonated. Other π -systems considered are the aromatic rings of Phe, Tyr and Trp.

- *Visual Molecular Dynamics* (VMD)[21] plugin: This version benefits from the graphical interface provided by VMD. This plugin performs a system call to execute the standalone RIP-MD program.
- Webserver: This form of RIP-MD is for those users who want to analyze a single PDB structure without installing the software locally. In this web-server, users first upload their selected structure and then, after few steps, the results can be easily downloaded.

It is important to note that results generated by the web-server and by the stand-alone version of the program are compatible with the *VMD* plugin, making possible to load and display these results into the *VMD* graphical user interface. The installation guide for both the stand-alone and plug-in versions, together with the user manual, is available at the RIP-MD webpage. In addition, users can also download from the webpage a virtual machine with RIP-MD already available which only requires the installation of all proprietary software that can not be distributed by us.

Other scripts employed to generate the figures shown in this article are also available at <http://www.dlab.cl/ripmd> or directly at https://github.com/networkbiolab/supp_script_ripmd.

3.4 Output files.

RIP-MD provides two types of output: interaction graphs and Pearson correlation plots.

3.4.1 Residue Interaction Networks (RINs):

Once the interactions are computed, RIP-MD generates network files that can be visualized in specialized platforms such as Cytoscape [35]. In these networks, each node represents an AA and each edge represents an interaction between AAs. Several network files are generated; one for each type of interaction type and a global network containing all interactions. Network files also describe additional information about several properties of the AAs including secondary

180 structure and solvent accessible surface. These network files also contain edge
181 attributes and the geometrical descriptors defining each interaction. To account
182 for the dynamic behavior of node descriptors and interactions, RIP-MD calcu-
183 lates the percentage of frames in which they are present over the simulation.

184 3.4.2 Pearson correlation plots.

185 RIP-MD employs Pearson correlation to identify, for any given type of interac-
186 tion, the existence of relationships between the dynamic behavior of two AAs.
187 To do so, each AA is represented by a numerical vector in which each element
188 contains the number of interactions of a given type in each frame. Once all
189 vectors are obtained, the existence of a relationship between the rupture or
190 formation of interactions over time is determined by calculating the Pearson
191 correlation between these vectors. These results are provided in the form of
192 correlation plots, square matrices of size N representing the total number of
193 AAs, where each element is colored according to the correlation value.

194 3.5 Comparison with other methods

195 A comparison with two other approaches, Carma [16] and MD-TASK [6], used
196 on our first example (the MD2 pocket closure, see next section) is explained
197 in detail in Supp. File Text S1. These methods were chosen due to their
198 availability, they are easy to install and they consider both inter and intra
199 chain interactions, even though both methods only generate a single type of
200 interactions between residues (C_α and C_β contacts for Carma and MD-TASK
201 respectively). Interested readers can also find in Supp. File Text S1 a brief
202 description of other methods or libraries that can be used to generate RINs for
203 MD simulations, even if, as Carma and MD-TASK, they use MDs instead of
204 non-covalent interactions in their RIN definitions.

205 4 Application of RIP-MD to analyze MD simu- 206 lations of proteins:

207 In the following section we explore two applications of RIP-MD to analyze MD
208 simulations of proteins: conformational changes occurring in a soluble protein
209 and the inter-monomeric interactions of a Gap-Junction Channel (Figure 2).
210 Both analysis were carried out employing the by-default parameters of RIP-
211 MD. The first example (Figures 3 and 4) is meant to show how RIP-MD can
212 visually discriminate among the different stages of a conformational change and
213 how correlated interactions guide the process and are lost when the "closed"
214 state is reached, which might be a common trend in process guided by non-
215 polar interactions. Our new analysis demonstrates new chemical information
216 that was not reported in [14], the original studies in which for the first time the
217 closing process was reported. The second example is meant to emphasize how
218 interactions in x-ray protein crystals are not necessarily the same. Moreover,
219 the visualization power of RIP-MD is highlighted as a very complex system (12
220 monomers) is very easily visualized by our method.

Figure 2: Protein structures used as case of study: First and last snapshots of the MD2 trajectory simulation (top) and Molecular structure of the human CX26 hemichannel and Gap Junction Channel (bottom). Panel (A), first snapshot of the MD showing the hydrophobic pocket in an open conformation. Panel (B), last snapshot of the MD where MD2 exhibit a closed conformation. Panel (C), secondary structure representation of a GJC formed by the extracellular docking of two HCs (blue and green). The position of the plasmatic membrane appears rendered in orange. The extracellular space is denoted with an “i”, while the intracellular space is denoted with an “e”. Panel (D), Secondary structure representation of a HC from the intracellular view. Each CX26 monomer is represented using different colors.

Figure 3: Time series of the collective variable D_0 (Eq.1). The graphic shows three distinct phases of the pocket closure, as marked by the vertical dashed lines. From 0 to 1,250 ps, the pocket is in an open conformation. From 1,250 to 12,500 ps, the closing process begins and is followed by a small opening of the pocket. From 12,500 ps until the end of the simulation, the pocket remains in a closed state.

4.1 MD2: an example of a conformational change.

MD2 is a soluble protein part of the innate immune response in humans. Upon binding of lipopolysaccharides belonging to Gram- bacteria, MD2 triggers an immune response via the interaction with Toll-Like receptors 4 [11, 32]. As shown by MD simulations [8, 14], MD2 possesses a hydrophobic cavity that rapidly closes upon ligand removal (Figure 2). The later is a clear example of a conformational change switching the RIN, suitable to be visualized with RIP-MD. To do so, we analyzed MD simulations of apo-MD2 obtained from [14]. Briefly, a 20 ns MD of a solvated MD2 was divided into three windows (Figure 3) which characterize the closing process. The closing event along the MD simulation was projected onto the collective variable described in Equation 1.

$$D_0 = \frac{1}{N} \sum_{n=1}^N \sqrt{(COM_{\beta_n} - COM_{MD2})^2} \quad (1)$$

where n stands for each of the 10 β strands of MD2, and COM_{β_n} and COM_{MD2} are the centers of mass of strand n and MD2 respectively. As reported in [14], D_0 unambiguously differentiates the three well defined stages of the closing process. We used RIP-MD to obtain RINs for both HBs and vdW interactions between AAs, employing default parameters (see Table 1 and Sup. Mat.). For each window, Pearson correlations were calculated for the number of HBs and vdW interactions for any given pair of AAs.

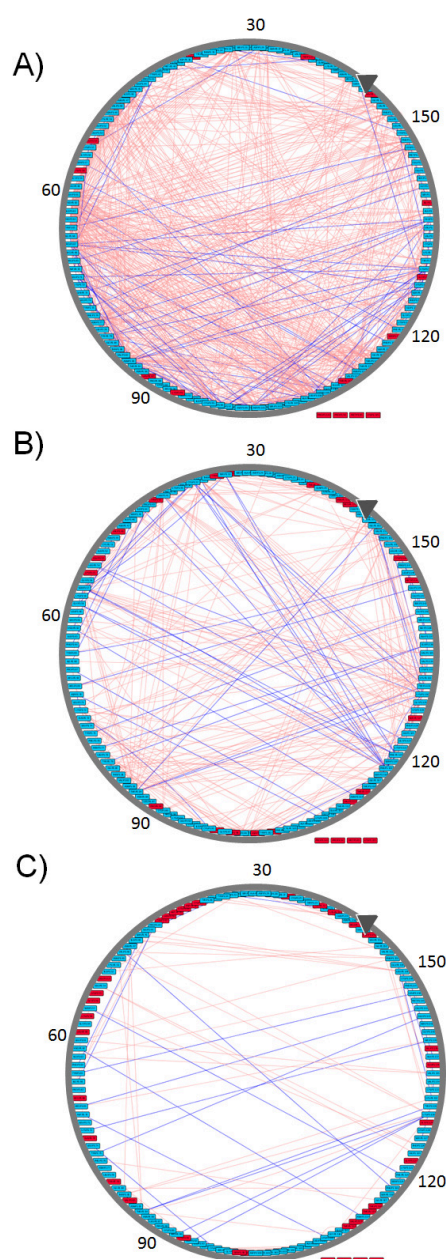

Figure 4: Graphic representation of changes occurring in the *RIN* of MD2 during the three windows of its closing process. All edges represent Pearson absolute correlation values where $|r| \geq 0.5$ in the open (A), closing (B) and closed conformation (C). Pink edges connect those AA interacting through vdW contacts while blue edges connect those AAs forming HBonds. Red nodes indicate residues with no $|r| \geq 0.5$, nodes outside the circle, Pro50, Met85, Lys125 and Pro142, do not form any interaction $|r| \geq 0.5$ in any of the three conformational states. Images were created after loading the resulting networks in Cytoscape with circular layout sorted according to AA numbering, first AA is indicated by the gray arrow.

	Window	≥ 0.5	≥ 0.6	≥ 0.7	≥ 0.8	≥ 0.9
HBs	open	1 (98)	1 (53)	1 (24)	1 (10)	1 (4)
	closing	0.64 (63)	0.55 (29)	0.54 (13)	0.7 (7)	0.25 (1)
	closed	0.38 (37)	0.40 (21)	0.54 (13)	0.90 (9)	1.25 (5)
vdW	open	1 (656)	1 (295)	1 (120)	1 (20)	* (0)
	closing	0.39 (257)	0.35 (103)	0.19 (23)	0.10 (2)	* (1)
	closed	0.12 (78)	0.08 (23)	0.07 (8)	0 (0)	* (0)

Table 2: Rate of correlated pairs over the closing process of MD2 according to their absolute Pearson correlation values over the three simulation windows: open, closing and closed conformations. Numbers indicate the rate between the number of correlated pairs of amino acids found in the first window (open state) and the number of correlated pairs in each of the other two windows with respect to the open state for Hydrogen Bonds and van der Waals interactions. In parenthesis the number of pairs of interacting AAs for each absolute Pearson correlation values. “*” indicates the absence of an interaction in the first window so it can not be computed for the other windows.

RINs obtained during the closing process of MD2 (Figure 3) for both HBs and vdW interactions between AAs, reflecting absolute Pearson correlations values $|r| \geq 0.5$ are shown in Figure 4. There is a higher amount of correlated pairs for both HBs and vdW interactions at the initial stage, as the closing process continues the number of correlated pairs decay (see Figure 3). The latter reveals an initial concerted action that triggers the closing event, but is lost after closure, a clear indication of the unspecific nature of non-polar interactions which are dominant within the hydrophobic cavity of MD2. To further quantify these changes, Table 2 presents the number of correlated pairs at each window normalized by the amount of correlated pairs of the first window. Overall, a monotonic decrease upon window increment, notwithstanding any correlation threshold, is observed. Slight deviations from the latter regarding HBs occur at Pearson values equal or above 0.7 (third and fourth columns of Table 2). This increase is due to the formation of stable H-bonds upon MD2 closure (see Table 2). On the other hand, the number of vdW interactions in Table 2 is higher than that of H-bonds, as the latter are specific interactions depending on both the relative distance and orientations of the participant residues. Finally, while most of the pairs of residues are uncorrelated, the β strands tend to be coordinated with respect to the formation and break of both types of interactions, showing how all secondary structure elements are kept in the closure of MD2.

Interestingly, this behavior is not expected for other conformational changes such as folding, in which the formation of polar interactions will lead to the appearance of highly correlated pairs, *e.g.* the formation of an alpha-helix. In this way, RIP-MD served to quantify and visualize the counter-intuitive idea that a large conformational change can indeed lead to lower correlations, a consequence of the nature of the interactions that dominate a given structural process; in this case, non-polar VdWs interactions among residues within the MD2 cavity.

4.2 Gap Junction Channel: An example for “inter-monomeric” and “inter-molecular” interactions in a large system.

GJCs are intercellular hydrophilic channels connecting the cytoplasm of two adjacent cells [40]. GJCs allow the exchange of water, ions and small molecules of up to 1 kDa [36, 1]. GJCs are formed by the extracellular docking of two HCs, (Figure 2.A), where each HC is formed by six CXs monomers (Figure 2.B). In this example, we studied a 20ns all-atom MD simulation of a complete GJC formed by the human CX26 [13]. This molecular system contains twelve identical CX monomers in total, each one comprising 226 AAs. Due to the high computational cost of studying vdW and Coulombic interactions in such a large system, these were disregarded in this example. In addition, due to the covalent nature of disulfide bridges these were not considered in the following analyses. RIP-MD was run with default parameters, keeping only those appearing in at least 75% of the simulation time.

Table 3 exhibits the interactions found by RIP-MD over the human CX26 GJC simulation. All interaction types are found to be highly stable over the simulation with an overall persistence of 95%-100%, indicating that this molecular structure remains structurally stable at least over the 20ns of the MD simulation. Since C_{α} contacts describe spatial relationships between AAs with a plenty of available methods to study their interaction [34], only the other types of interactions calculated by RIP-MD are further analyzed.

	[75%,80%)	[80%,85%)	[85%,90%)	[90%,95%)	[95%,100%]	Total
C_{α} s	133	169	173	239	10311	11025
HBs	112	135	131	205	1557	2140
SBs	20	10	25	39	448	542
π - π	9	11	15	21	84	140
Arg-Arg	0	0	0	1	0	1
All	274	325	344	505	12400	13848

Table 3: Interactions present in different time intervals over the 20 ns GJC MD simulation

Table 4 shows those interactions occurring at least during the 75% of the MD simulation for all the following cases: interactions between AAs of the same chain for each of the two HCs (Intra-chain), between chains of the same HC (Inter-chain) and between AAs of different HCs (Inter-HCs). It should be noted that HBs and SBs are interactions appearing mainly between different chains, while π - π and Arg-Arg interactions are both intramonomeric interactions. Interestingly, only HBs appear at the interface of the two docked CXs (Fig 5). The role of these non-bonded interactions in the maintenance of the GJC quaternary structure were also described in the original paper reporting the CX26 crystal structure [27].

The information shown in the bottom section of Table 4 was then compared with the original static structure of the GJC after energy minimization (model based on PDB ID 2ZW3, see [1] for details). The top section of Table 4 resumes the number of interactions present in this structure. The first thing to notice when comparing the dynamic and static versions of the network is the lower number of interactions in the dynamic network. This reduction can be due

to their low stability at physiological temperatures, the replacement of intra-hbonds with hbonds established with solvent molecules or a poor description of a given interaction by the force-field, *e.g.* $\pi - \pi$ interactions. Notoriously, the number inter-CXs HB interactions increases from 9 in the static structure to 26 in the dynamic network, highlighting the relevance of HBs to maintain the GJC complex. It is also very relevant that most of the inter-CXs HBs observed in the non-dynamic RIN are absent in the dynamic version, with only 2 HBs appearing in the entire simulation (Table 5). Regarding the other types of interactions, most of the intra and inter-chain HBs, SBs, Cation- π and $\pi - \pi$ interactions appear in the dynamic and non-dynamic RINs.

		HC1		HC2		Inter-HC
		Intra-chain	Inter-chain	Intra-chain	Inter-chain	
Static	HBs	1312	101	1301	106	9
	SBs	168	106	174	104	0
	Cation- π	3	0	6	0	0
	$\pi - \pi$	70	11	65	10	0
	Arg-Arg	0	4	0	5	0
	Total	1553	222	1546	225	9
Dynamic	HBs	991	66	990	67	26
	SBs	183	101	170	88	0
	$\pi - \pi$	66	6	64	4	0
	Arg-Arg	0	0	0	1	0
	Total	1240	173	1224	160	26

Table 4: Number and type of interactions present in the human CX26 GJC. Interactions are divided into intra-chain, inter-chain in the same HC and inter-HC monomers. The top section displays the interactions in the dynamic network (interactions present in at least 75% of the simulation), and the bottom in the network derived from the static structure.

		HBs	SBs	Cation- π	$\pi - \pi$	Arg-Arg
Static	Intra-chain	948	89	9	43	0
	Inter-chain	136	44	0	14	9
	Inter-HC	7	0	0	0	0
MD	Intra-chain	316	100	0	38	0
	Inter-chain	62	23	0	3	1
	Inter-HC	24	0	0	0	0
Both	Intra-chain	1665	253	0	92	0
	Inter-chain	71	166	0	7	0
	Inter-HC	2	0	0	0	0

Table 5: Number of interactions of each type appearing only in the static, in the MD simulation and in both RINs of the human CX26 GJC. Interactions are separated by type and into intra-chain, inter-chain and inter-HCs.

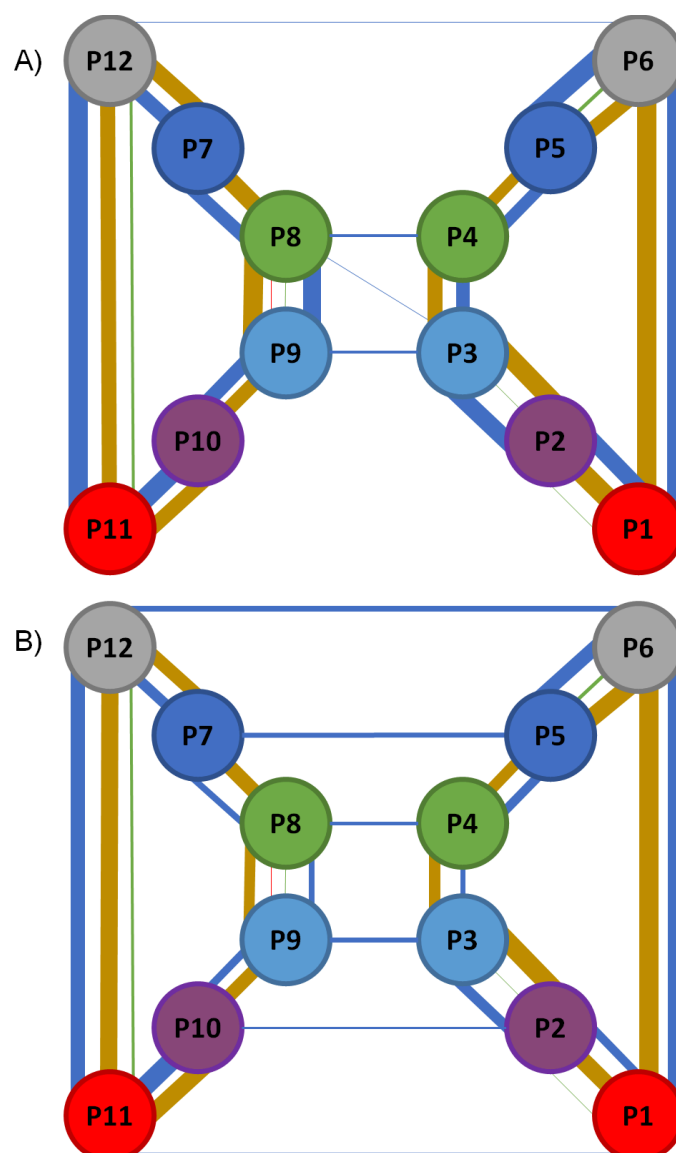

Figure 5: Representation of the RIN formed for the static and the dynamic structure of GJC. Panel A) show the network for the static structure and Panel B) for the MD simulation. Each circle represents a CX subunit using a color code for subunit in each of them: red for chain A (segments P1 and P11); purple for chain (segments P2 and P10); light blue for chain C (segments P3 and P9); green for chain D (segments P4 and P8); blue for chain E (segments P5 and P7); and gray for chain F (segments P6 and P12). Interactions thickness represent the quantity of interactions, colored with the following color code: red for Arg-Arg interactions; blue for HBs; gold for SBs; and green for π - π interactions. No self-interactions are represented.

5 Conclusion

MD simulation is a routinely employed technique to study the dynamic behavior of a system *i.e.* a protein. Therefore, tools that can extract relevant information in a simple and user-friendly way are urgently needed. Here we describe RIP-MD, a method that using graph theory approaches generates RINs for different types of electrostatic interactions in protein MD simulations. We are currently working on an improved version of RIP-MD to consider waters, ions and other non-AAs molecules to generate RINs. Using RIP-MD we were able to study MD simulations of two systems: MD2 and a GJC. Regarding MD2, we focused on the study of the protein movement as reflected by Pearson correlation plots of HBs and van der Waals contacts. This analysis showed notable differences between the different stages of the conformational change of the protein, revealing an initial concerted action at the beginning of the closing process, with an overall reduction of correlations for the closed state. In the case study of GJC, a comparison of the initial structure and a short MD simulation revealed that inter-chain interfaces are stabilized mainly by HBs and SBs, and that Arg-Arg and Cation- π interactions tend to disappear over the trajectory.

RIP-MD is freely available for the academic community, and it is distributed in three forms: a webserver, where users can analyze a single *PDB*; an standalone version that can take advantage of Multi-Core systems to generate these RINs; and a VMD plugin that executes the standalone version of the software and at the same time benefits from the graphical viewer of VMD. All these distributions, together with manuals and help files can be accessed from <http://dlab.cl/ripmd>.
