**Background.** The effects of resistance training on a muscle's neural, architectural, and mechanical properties are well established. However, whether resistance training can positively change the coordination of multiple motor elements in the control of a well-defined lower limb motor performance objective remains unclear. Such knowledge is critical given that resistance training is an essential and ubiquitous component in gait rehabilitation. This study aimed to investigate if strength gains of the ankle and knee extensors after resistance training increases kinematic motor abundance in hopping.

**Methods.** The data presented in this manuscript represents the pooled group results of a sub-study from a larger project investigating the effects of resistance training on load carriage running energetics. 30 healthy adults performed self-paced unilateral hopping, and strength testing before and after six weeks of lower limb resistance training. Motion capture was used to derive the elemental variables of planar segment angles of the foot, shank, thigh, and pelvis, and the performance variable of leg length. Uncontrolled manifold analysis (UCM) was used to provide an index of motor abundance (IMA) in the synergistic coordination of segment angles in the stabilization of leg length. Bayesian Functional Data Analysis was used for statistical inference, with a non-zero crossing of the 95% Credible Interval (CrI) used as a test of significance.

**Results.** Greater ankle strength significantly increased IMA, whilst greater knee strength decreased IMA, in the periods surrounding the first and last 25% of hop stance. For example, at 25% hop stance, a 1 Nm/kg increase in ankle extensor strength increased IMA by 0.48 (95% CrI 0.16 to 0.58), and a similar increase in knee extensor strength decreased IMA by -0.55 (95% CrI -0.74 to -0.35). Around mid-stance, only knee extensor gains predicted an increase in IMA.

**Discussion.** Resistance training not only improves strength, but also the structure of coordination in the control of a well-defined motor objective. The role of resistance training on motor abundance in gait should be investigated in patient cohorts, other gait patterns, and its translation into functional improvements.

# **ABSTRACT.**

## **Background.**

The effects of resistance training on a muscle’s neural, architectural, and mechanical properties are well established. However, whether resistance training can positively change the coordination of multiple motor elements in the control of a well-defined lower limb motor performance objective remains unclear. Such knowledge is critical given that resistance training is an essential and ubiquitous component in gait rehabilitation. This study aimed to investigate if strength gains of the ankle and knee extensors after resistance training increases kinematic motor abundance in hopping.

## **Methods.**

The data presented in this manuscript represents the pooled group results of a sub-study from a larger project investigating the effects of resistance training on load carriage running energetics. 30 healthy adults performed self-paced unilateral hopping, and strength testing before and after six weeks of lower limb resistance training. Motion capture was used to derive the elemental variables of planar segment angles of the foot, shank, thigh, and pelvis, and the performance variable of leg length. Uncontrolled manifold analysis (UCM) was used to provide an index of motor abundance (IMA) in the synergistic coordination of segment angles in the stabilization of leg length. Bayesian Functional Data Analysis was used for statistical inference, with a non-zero crossing of the 95% Credible Interval (CrI) used as a test of significance.

## **Results.**

Greater ankle strength significantly increased IMA, whilst greater knee strength decreased IMA, in the periods surrounding the first and last 25% of hop stance. For example, at 25% hop stance,

a 1 Nm/kg increase in ankle extensor strength increased IMA by 0.48 (95% CrI 0.16 to 0.58), and a similar increase in knee extensor strength decreased IMA by -0.55 (95% CrI -0.74 to -0.35). Around mid-stance, only knee extensor gains predicted an increase in IMA.

# **Discussion.**

Resistance training not only improves strength, but also the structure of coordination in the control of a well-defined motor objective. The role of resistance training on motor abundance in gait should be investigated in patient cohorts, other gait patterns, and its translation into functional improvements.

# INTRODUCTION

Regular participation in walking and running has important health benefits (Lee et al. 2014), and is commonly undertaken along irregular surfaces. Normally, humans have no problems maintaining dynamic postural control and energy efficiency during gait despite these surface irregularities, ensuring a smooth center of mass (COM) trajectory. Excessive COM trajectory disturbance in gait can be energetically costly and potentially destabilizing to postural control (Andrada et al. 2013; Geyer et al. 2006).

Perturbation to the COM trajectory can be minimized over irregular surfaces by adjusting the length of a simplified virtual leg (henceforth termed as leg), spanning the COM to the center of pressure (COP) (Andrada et al. 2013; Geyer et al. 2006). Leg length is regulated by four major segments (foot, shank, thigh, and pelvis), along which flexion-extension occurs. The excess of segments required to control a single leg, means that the body has an abundance of solutions to flexibly combine segment angles to achieve the same leg length (Auyang et al. 2009). Greater motor abundance in leg length regulation affords the body greater adaptability to rapidly react to irregular surfaces to minimize COM trajectory perturbation. In the context of quantifying motor abundance in leg length regulation, the Uncontrolled Manifold (UCM) analysis has been used to investigate the motor control of unilateral hopping (Auyang et al. 2009). UCM provides a ratio of two variances: one where the variance in angles (motor elements) does not change leg length (performance variable), to a variance in angles which changes leg length (Auyang et al. 2009).

The manifestation of normal abundance in motor task may depend on the task's physical demand relative to an individual's physiological strength capacity (Greve et al. 2013; Olafsdottir et al. 2008; Park et al. 2015; Shim et al. 2008; Yen & Chang 2010). Greater motor abundance may emerge when the task's relative physical demand increases (Greve et al. 2013). For example,

older adults with lower maximal strength have non-significantly greater motor abundance in sit-to-stand compared to younger adults with greater maximal strength (Greve et al. 2013). When an external load is added to walking, there was a significant increase in the motor abundance of joint angle co-variation in the control of the COM trajectory in the frontal plane, and a non-significant increase in abundance in the control of the COM trajectory in the sagittal plane (Qu 2012). It is reasonable to expect that if one muscle is operating near its physiological limit, additional muscles would be recruited to achieve successful performance.

In contrast, prospective resistance training studies of the upper limb (Olafsdottir et al. 2008; Park et al. 2015; Shim et al. 2008) demonstrated that greater wrist and finger strength was associated with greater abundance in finger force coordination tasks. Resistance training may augment motor abundance by increasing reciprocal inhibition (Geertsens et al. 2008), of co-varying muscle groups via heteronomous spinal pathways; increasing the role of bi-articular muscles in inter-segmental kinematic co-variation (Cleather et al. 2015); and increasing the number of muscle modes available for co-variation (Hashiguchi et al. 2016).

Although prospective study designs (Olafsdottir et al. 2008; Park et al. 2015; Shim et al. 2008) already provide a higher level of evidence base than a cross-sectional design (Greve et al. 2013; Qu 2012), the relationship between physiological strength and motor abundance, may still have been confounded by other factors. First, different mathematical formulation of the variance ratios of motor abundance between studies may have contributed to the conflicting evidence (see differences between (Olafsdottir et al. 2008) and (Greve et al. 2013)). Second, differences may lie in the hierarchical level of analysis as it pertains to the neural control of motor abundance. Greve et al. (2013) investigated the covariation of joint-level kinematics to whole-body performance variables, such as ground reaction force. The analysis by Greve et al. (2013) thus

did not consider an intermediary level of hierarchical control – that is in the stabilization of limb-level performance variables (Toney & Chang 2016). In contrast, Olafsdottir et al. (2008) investigated the covariation of limb-level (finger) force in the stabilization of the total force generated by four fingers. To this end, a prospective study design which quantifies lower limb motor abundance within a hierarchical control framework, would increase the evidence base behind using resistance training to improve motor abundance.

Resistance training is an essential component in gait rehabilitation (Papa et al. 2017). Whether a gain in physiological strength capacity benefits or harms motor abundance is an essential question to answer, as it directly implicates the role of resistance training in gait rehabilitation. The aim of this study was to investigate if lower limb strength gains after resistance training influenced lower limb motor abundance. Hopping represents an excellent model of forward gait patterns to fulfill the present study's aim. First, lower limb spring-mass dynamics in hopping is present in walking and running (Geyer et al. 2006). Second, leg length is a regulated performance variable in hopping using UCM analysis (Auyang et al. 2009). Given that leg length mechanics contributes to COM trajectory (Moritz & Farley 2003), greater motor abundance in leg length stabilization in hopping may translate into more available motor solutions to minimize COM trajectory perturbation when walking or running over irregular surfaces. Third, normal inter-segmental kinematic and kinetic coordination in hopping, quantified using UCM and vector coding, varies depending on the task's relative physical demand (Auyang et al. 2009; Smith et al. 2014; Yen & Chang 2010). Similar to the effects of finger muscle strengthening on finger pressing motor abundance (Olafsdottir et al. 2008), the hypothesis of this study was that greater strength gains after resistance training would increase kinematic motor abundance in leg length regulation during hopping.

# **MATERIALS AND METHODS.**

## **Study design, participants**

The data presented in this manuscript represents the pooled group results of a sub-study from a larger project investigating the effects of resistance training on load carriage running energetics (Liew et al. 2017). Thirty healthy active adults were recruited for this study (16 male, 14 female, mean (standard deviation) age of 30.35 (9.11) years, mass of 69.13 (12.65) kg, height of 1.72 (0.76) m). This study was approved by the Curtin University Human Research Ethics Committee (RD-41-14). Informed written consent was sought and gained prior to study enrolment.

## **Intervention**

The two training programs were developed to improve load carriage running energetics (Table S1 in supplementary material). One group performed “conventional” heavy-resistance isoinertial training on the bilateral leg press, unilateral calf raises, and lunge exercises. These exercises have been routinely adopted in conventional load-carriage military training (Knapik et al. 2012). The other group performed “load carriage specific” resistance training targeting the specific biomechanical requirements of load carriage running (Liew et al. 2017). Exercises in this group comprised of externally loaded single-leg hopping to increase leg stiffness, countermovement jumps to increase knee power generation, and hip flexor pull to increase pre-swing running energetics (Liew et al. 2017). Greater leg stiffness, knee power generation, and pre-swing hip energetics were previously shown to be required to sustain constant running velocity during load carriage (Liew et al. 2016; Silder et al. 2015). Despite the differences between the training programs, the present study was only interested in accounting for the between time (pre-post) change in strength (ankle extensor = mean increase 0.34 Nm/kg [95% Confidence Interval (CI)

131 0.25 to 0.42 Nm/kg]; knee extensor = mean increase 0.24 Nm/kg [95% CI 0.11 to 0.37 Nm/kg])  
 132 (Liew et al. 2017), in predicting alterations in hopping motor abundance.

### 133 **Three dimension motion capture on hopping**

134 Participants performed unilateral hopping, on both sides, at a self-selected frequency lasting  
 135 approximately 15s. The only instruction provided was to hop at a “comfortable pace”. In the post  
 136 hoc analysis stage, only hops maintained within 10% of the individual’s mean hop frequency  
 137 was kept for further analysis (termed as successful trials). This 10% frequency window was  
 138 deemed appropriate given that a previous study reported a variation of up to 20 % for adults  
 139 hopping at their preferred frequency (Beerse & Wu 2016). A between side standing rest period of  
 140 one minute was provided. An 18 camera motion capture system (Vicon T-series, Oxford Metrics,  
 141 UK) (250 Hz), with synchronized in-ground force plates (AMTI, Watertown, MA) (2000 Hz)  
 142 were used to collect marker trajectories and force data (Vicon Nexus, v2.3, Oxford Metrics, UK).  
 143 Force data were used to detect initial contact and toe-off, with a 20 N vertical force threshold  
 144 used. The marker placements and biomechanical model were based on a previously work (Liew  
 145 et al. 2016). Marker trajectories were low pass filtered at 12 Hz (zero lag, 4<sup>th</sup> order, Butterworth).  
 146 Global optimization performed in Visual 3D (C-motion, Germantown, MD) was used to derive  
 147 the model’s kinematics.

### 148 **Isokinetic strength measurement**

149 Isokinetic concentric strength testing of the bilateral knee and ankle extensors was performed in  
 150 a dynamometer (HUMAC NORM, Computer Sports Medicine Inc., Stoughton, MA), collecting  
 151 data at 100 Hz and set up according to the manufacturer’s guidelines (Liew et al. 2017). For each  
 152 muscle group tested, participants first performed 10 repetitions of warm-up contractions at 90°/s,

and two sets of six maximal concentric-concentric contractions at 60°/s. Each set was interspersed with one minute of seated rest in-situ. Between muscle group and side rest periods of three minutes were provided.

# **Uncontrolled manifold analysis**

A modified sagittal plane forward kinematic model mapping segment angles to leg length used in a previous study was adopted in the present study (Auyang et al. 2009) (see Figure S1 in supplemental for the kinematic model). Leg length was presently defined by the vector between the centre of pressure (COP) to the proximal end of the pelvic segment, instead of the toe and anterior superior iliac spine markers, respectively (Auyang et al. 2009). The foot, shank, thigh, and pelvic segments were defined by the line vectors between 1) COP to ankle joint centre, 2) ankle to knee joint centre, 3) knee to hip joint centre, and 4) hip joint to proximal end of pelvis. All segment angles and leg lengths were time-normalized to 100 data points in the stance period for UCM analysis.

The UCM analysis was carried out using a previously published method (Auyang et al. 2009), for each of the 100 stance data points.

$$NGEV = \frac{trace(orth(J^t).C.orth(J^t))}{d}...(1)$$

$$GEV = \frac{trace(null(J)^t.C.orth(J))}{n-d}...(2)$$

$$IMA = \frac{GEV - NGEV}{GEV + NGEV}...(3)$$

where non-goal equivalent variance (NGEV) represents the variance of all segment angle combinations which deviates leg length; goal equivalent variance (GEV) represents the variance

of all segment angle combinations which does not deviate leg length; index of motor abundance (IMA) where an  $IMA > 0$  represents variation in segment angles which were minimizing leg length variation (i.e. motor abundance), and an  $IMA < 0$  represents variation in segment angles which were maximising leg length variation (Auyang et al. 2009),  $J$  is the Jacobian matrix mapping infinitesimally small changes in segment angles to changes in leg length;  $C$  is the covariance matrix in the deviation of the segment angles from the mean reference segment angles at each datum;  $d$  is the degree of freedom in the performance variable ( $d = 1$  in this study); and  $n$  is the degree of freedom in the elemental variables ( $n = 4$ ).

## Statistical analysis

Descriptive scalar variables of post-pre change in hopping frequency and stance duration, and baseline (pre-training) waveform variables of leg length, foot, shank, thigh, and pelvic segment angles, IMA, GEV, and NGEV were reported. The dependent variable was the between time change in waveform IMA. The predictor variables were the between time change (post-pre) in ankle and knee strength, and the regression coefficients were adjusted for two covariates: 1) change (post-pre) in hopping frequency, and 2) side (right vs left) were included in the statistical model. Bayesian regression functional analysis was performed in R software (Goldsmith & Kitago 2016). Recent investigations in sports science have advocated the avoidance of frequentist null-hypothesis significance testing, and instead to focus on estimating the probabilities associated with observing an effect size. Fixed effect parameters for ankle and knee strength, frequency, and side, and non-parametric smooth functions (modelled with 12 B-splines) were estimated using a Gibbs sampler with a burn-in of 1000 and drawing 11000 inference samples. The residual covariance structure was estimated using Bayesian functional principle

components. A significant effect was defined by a non-zero crossing of the Bayesian 95% credible interval (CrI).

# RESULTS

Five participants were excluded due to the low number of successful hopping trials (< 20 trials) that has been recommended for UCM analysis (Latash et al. 2010) (Figure 1). Baseline differences between the included and excluded participants in baseline characteristics were small: mean difference in age of 5 years, height of 3.5 cm, weight of 1.9 kg, ankle strength of 0.14 Nm/kg, and knee strength of 0.2 Nm/kg. The difference in the mean ankle and knee beta coefficients between a complete case analysis (n = 30) over the present analysis (n=25) were small, at 0.04 and 0.08, respectively. Baseline hopping kinematics, IMA, GEV, NGEV are reported in Figure 2 and 3. The mean (standard deviation) change in hopping frequency was a 0.13 (0.3) Hz increase and change in stance duration was a 0.01 (0.04) s decrease post-testing, relative to a baseline of 2.26 (0.25) Hz and 0.30 (0.03) s, respectively.

For simplicity of reporting, only effects at a discrete hop phase within a statistically significant temporal period are reported here. At 25% hop stance, a 1 Nm/kg increase in ankle extensor strength increased IMA by 0.48 (95% CrI 0.16 to 0.58), and a 1 Nm/kg increase in knee extensor strength decreased IMA by -0.55 (95% CrI -0.74 to -0.35) (Figure 4). At 55% stance, a 1 Nm/kg increase in knee extensor strength increased IMA by 0.25 (95% CrI 0.001 to 0.49) (Figure 4). At 75% hop stance, a 1 Nm/kg increase in ankle extensor strength reduced IMA by -0.34 (95% CrI -0.58 to -0.13), and a 1 Nm/kg increase in knee extensor strength increased IMA by 0.30 (95% CrI 0.07 to 0.54) (Figure 4). At 95% hop stance, a 1 Nm/kg increase in ankle extensor strength

216 increased IMA by 0.24 (95% CrI 0.03 to 0.45), and a 1 Nm/kg increase in knee extensor strength  
217 decreased IMA by -0.81 (95% CrI -1.05 to -0.58) (Figure 4).

## 218 **DISCUSSION**

219 Leg length regulation is a strategy of coping with irregular surfaces to minimize disturbance to  
220 the COM trajectory during gait (Andrada et al. 2013; Geyer et al. 2006). Normally, leg length  
221 regulation is achieved by harnessing segmental kinematic motor abundance (Auyang et al. 2009).  
222 Even though resistance training has been typically prescribed to treat gait impairments, there is  
223 uncertainty as to the relationship between physiological strength capacity and normal motor  
224 abundance. This poses a dilemma as to whether resistance training benefits or harms gait motor  
225 control rehabilitation. In this study, we prospectively investigated if lower limb strength gains  
226 after resistance training, predicted a change in IMA during a simple model of spring-mass gait -  
227 unilateral hopping. In partial agreement with our hypothesis, greater strength gains predicted an  
228 increase in IMA, but this effect was dependent on the muscles being strengthened. In addition,  
229 the effects of ankle strength gained on IMA was opposite to that of knee strength gains.

230 The increase in kinematic motor abundance with a gain in ankle extensor strength prior to mid-  
231 stance and toe-off of hopping, was consistent with the findings of previous resistance training  
232 studies of the upper limb (Olafsdottir et al. 2008; Park et al. 2015; Shim et al. 2008). The  
233 mechanisms linking strength gains to motor abundance improvements was not investigated in the  
234 present study, but may speculatively involve mechanical and neural factors. The bi-articular  
235 gastrocnemius is mechanically capable of plantar flexing the foot while flexing the knee  
236 (Cleather et al. 2015). Greater gastrocnemius strength could augment inter-segmental kinematic  
237 co-variation, increasing motor abundance during hopping. Resistance training has also been

shown to increase reciprocal inhibition of antagonistic muscles within a joint muscle pair (Geertsens et al. 2008). However, no studies to the authors' knowledge have directly investigated the influence of resistance training on heteronomous reflex pathways, which would enable inter-muscular co-variation and facilitate hopping kinematic motor abundance.

It was previously suggested that greater motor abundance will emerge in tasks with greater relative physical demand (Greve et al. 2017; Greve et al. 2013), which contradicts the present findings. It may be that the relationship between physical demand and motor abundance is non-linear with potentially plateauing effects. Both physiological weakening and strengthening may augment motor abundance depending in part on the task's absolute demand on the participants, and the capacity to use available motor elements. Wang et al. (Wang et al. 2017) reported that older adults have preserved muscle motor abundance but were more delayed at their recruitment during rapid balance recovery, than younger adults. The tasks used by Greve and Colleagues were either much slower (Greve et al. 2013), or required a combination of low muscular force and fast movement speed (Greve et al. 2017). It is plausible that the speed-force demands in previous studies were low (Greve et al. 2017; Greve et al. 2013), such that muscle groups had sufficient time to stabilize the performance variable(s). In addition, if a muscle is operating at its physiological limit, it can no longer compensate for the reduction in activation of other muscles. In this instance, co-variation may still occur but only between muscles with adequate physiological strength reserve. The relationship between task demand and motor abundance may be better understood by investigating abundance at the level of muscle activations, including UCM analysis in a reduced subset of motor elements (Toney & Chang 2016).

The period surrounding mid-stance in hopping is critical of leg length regulation for peak muscular force minimization (Auyang et al. 2009), which minimizes the energy expenditure and

joint contact loads during hopping. It was surprising that knee extensor strength, but not ankle extensor strength gain, had augmenting effects on kinematic motor abundance between 50% to 75% stance. The foot segment angle around mid-stance was nearly invariant (Figure 1) (Joao et al. 2014). If the foot functions as a punctum fixum around mid-stance (Joao et al. 2014), the gastrocnemius is only able to flex and extend the thigh segment, without compensatory foot kinematics to stabilize overall leg length. The invariant foot-segment angle may instead shift the joint-level mediator of leg length stabilization to the knee. In contrast, greater knee extensor strength reduced abundance for leg length control in the periods surrounding initial contact and toe-off. It may be that the influence of knee extensor strength gain on kinematic abundance was shifted to the control of leg orientation (angle between the leg and ground) (Auyang et al. 2009). Leg orientation at initial contact may determine the overall position relative to the COM in stance, and at toe-off as it influence flight-phase ground clearance.

The reduction in kinematic motor abundance predicted by an increase in knee extensor strength prior to mid-stance and toe-off differed from a study investigating walking in individuals with and without knee osteoarthritis (OA) (Tawy et al. 2018). Several reasons could account for the disagreement. Tawy et al. (Tawy et al. 2018) did not directly quantify the relationship between knee extensor strength and motor abundance. The occurrence of knee OA is associated with a range of neuromuscular deficits (Mills et al. 2013), and the importance of knee extensor strength to motor abundance cannot be ascertained from a between-groups comparison. Second, Tawy et al. (Tawy et al. 2018) used COM trajectory, while the present study used leg length, as the performance variable for UCM analysis. It must be emphasized that using both the COM and leg length as performance variables are equally valid. The organization of motor control may involve a hierarchical structure (Latash 2010), where segment-level variation serve to stabilize limb-level

outcomes, and inter-limb variation stabilizes whole-body outcomes. Thus, the present study focused only on limb-level motor control, while Tawy et al. (Tawy et al. 2018) performed UCM analysis across two layers of hierarchical control.

Several aspects of the present study's methodology need to be discussed in lieu of differences in reported IMA of the present study, with that of a previous work (Auyang et al. 2009). First, the number of hop cycles included per participant ranged from 20 to 57 cycles. In contrast, Auyang et al. (Auyang et al. 2009) used 170 cycles for UCM calculation, which may explain the difference in IMA values between studies. Second, leg length was defined starting from the COP in the present study, but from the toe marker in Auyang et al. (Auyang et al. 2009). COP accuracy may be reduced when the magnitude of the GRF is small, which could explain the differences in IMA between the present study and Auyang et al. (Auyang et al. 2009) during the periods surrounding initial contact and toe-off. However, the effective leg length during human locomotion may be more accurately defined from the point of ground force application, compared to the fixed toe-marker (Coleman et al. 2012). Despite this difference in leg length definition, the overall shape of the IMA reported in this study was similar to Auyang et al. (Auyang et al. 2009).

Previous studies provided evidence for the benefit of resistance training on finger force motor abundance (Olafsdottir et al. 2008; Park et al. 2015; Shim et al. 2008), and the results of the present study extends the evidence for the same benefit to the lower limb. By increasing motor abundance to stabilize leg length in hopping, resistance training may increase the adaptability of forward gait patterns over irregular surfaces. It is likely that different gait patterns require different joint-level and limb-level strengthening to benefit kinematic motor abundance, and this should be investigated in future studies. A limitation of this study was that the analysis predicting

motor abundance from alterations in strength gains were analyzed using a prospective, pre-post design. However, we reduced the confounding factor of repeated measurement, by only including the effects of strength changes into the statistical model. A second limitation of this study was that the influence of strength gains on kinematic abundance was analyzed in healthy individuals. This limitation may in fact be a strength, as we were able to isolate the investigation of IMA changes to strength changes.

## CONCLUSIONS

In addition to the well-known effects on a muscle's neural, architectural, and mechanical properties, resistance training also influences the coordination of multiple motor elements in the control of a well-defined motor performance objective. The benefits of strength gain on motor abundance was dependent on the site of muscle strengthened and the phase of gait. The role of resistance training on motor abundance should be investigated in patient cohorts, other gait patterns, as well as its translation into functional improvements.

## ACKNOWLEDGEMENTS.

The authors of this study would like to thank Nour Faiz Aqil Yaccob, Jason Hu, Nicholas Callaghan, Tess Moynihan, Hannah Watt, and Giorgia Alford for delivering the interventions. The results of this study are presented clearly, honestly, and without fabrication, falsification, or inappropriate data manipulation.
