Axonal stimulation with electric currents is an effective method for controlling neural activity. An electric field parallel to the axon is widely accepted as the predominant component in the activation of an axon. However, recent studies indicate that the transverse component to the axolemma is also effective in depolarizing the axon. To quantitatively investigate the amount of axolemma polarization induced by a transverse electric field, we computed the transmembrane potential (V_m) for a conductive body that represents an unmyelinated axon (or the bare axon between the myelin sheath in a myelinated axon). We also computed the transmembrane potential of the sheath-covered axonal segment in a myelinated axon. We then systematically analyzed the biophysical factors that affect axonal polarization under transverse electric stimulation for both the bare and sheath-covered axons. Geometrical patterns of polarization of both axon types were dependent on field properties (magnitude and field orientation to the axon). Polarization of both axons was also dependent on their axolemma radii and electrical conductivities. The myelin provided a significant “shielding effect” against the transverse electric fields, preventing excessive axolemma depolarization. Demyelination could allow for prominent axolemma depolarization in the transverse electric field, via a significant increase in myelin conductivity. This shifts the voltage drop of the myelin sheath to the axolemma. Pathological changes at a cellular level should be considered when electric fields are used for the treatment of demyelination diseases. The calculated term for membrane polarization (V_m) could be used to modify the current cable equation that describes axon excitation by an external electric field to account for the activating effects of both parallel and transverse fields surrounding the target axon.

Shielding effects of myelin sheath on axolemma depolarization under transverse electric field stimulation

ABSTRACT

Axonal stimulation with electric currents is an effective method for controlling neural activity. An electric field parallel to the axon is widely accepted as the predominant component in the activation of an axon. However, recent studies indicate that the transverse component to the axolemma is also effective in depolarizing the axon. To quantitatively investigate the amount of axolemma polarization induced by a transverse electric field, we computed the transmembrane potential (V_m) for a conductive body that represents an unmyelinated axon (or the bare axon between the myelin sheath in a myelinated axon). We also computed the transmembrane potential of the sheath-covered axonal segment in a myelinated axon. We then systematically analyzed the biophysical factors that affect axonal polarization under transverse electric stimulation for both the bare and sheath-covered axons. Geometrical patterns of polarization of both axon types were dependent on field properties (magnitude and field orientation to the axon). Polarization of both axons was also dependent on their axolemma radii and electrical conductivities. The myelin provided a significant “shielding effect” against the transverse electric fields, preventing excessive axolemma depolarization. Demyelination could allow for prominent axolemma depolarization in the transverse electric field, via a significant increase in myelin conductivity. This shifts the voltage

drop of the myelin sheath to the axolemma. Pathological changes at a cellular level should be considered when electric fields are used for the treatment of demyelination diseases. The calculated term for membrane polarization (V_m) could be used to modify the current cable equation that describes axon excitation by an external electric field to account for the activating effects of both parallel and transverse fields surrounding the target axon.

INTRODUCTION

Electrical stimulation of nerve cells was first reported by Luigi Galvani in 1780 (Galvani 1791), who accidentally found that muscles from a dead frog would twitch when touched with a charged metal scalpel, a discovery that sparked the appreciation of electricity in relation to animation — or life. Today, electric stimulation of neurons in the peripheral or central nervous systems have been widely utilized for controlling neural network activity (Selimbeyoglu & Parvizi 2010), synaptic transmission (Nowak & Bullier 1998), and pain (Coderre et al. 1993). Electric currents can also be generated via magneto-electric induction with magnetic coils for non-invasive control of neural activity (Maccabee et al. 1991; Maccabee et al. 1993; Ye et al. 2011; Ye et al. 2010; Ye & Steiger 2015).

An electric field surrounding a straight nerve axon can be separated into two components: one parallel to ($E_{||}$) and the other perpendicular (transversal, E_{\perp}) to the axon. The $E_{||}$ is widely regarded as the predominant factor that activates the axons (Basser et al. 1992; Roth & Basser 1990), which is supported by numerous experimental results (Amassian et al. 1989; Basser & Roth 2000). Consequently, theoretical analyses of electrical activation have predominately been focused on computing $E_{||}$ along a fiber (Esselle & Stuchly 1994; Esselle & Stuchly 1995; Nagarajan & Durand 1995; Ravazzani et al. 1996; Roth & Basser 1990; Roth et al. 1990). The current cable equation, $\lambda^2 \frac{\partial^2 \varphi_m}{\partial x^2} - \tau \frac{\partial \varphi_m}{\partial t} - \varphi_m = -\lambda^2 \frac{\partial V_e}{\partial x^2}$, which describes axonal activation, contains only the axial term ($E_{||}$). Here, $\lambda^2 = \frac{R_m c}{2R_i}$ and $\tau = R_m C_m$ are the space and time constants, respectively. φ_m is the transmembrane potential and V_e is the extracellular electric field applied to the fiber. It is nonzero only if $E_{||}$ is nonzero. The surface resistance and capacitance of the membrane are R_m and C_m , respectively. The intracellular resistivity is R_i and the fiber radius is c . This simplification facilitates the rapid calculation of neural activation. However, it ignores the presence of the cell,

which perturbs the local extracellular electric field. It also ignores the mutual interactions between the neurons and the applied electric field (Ye & Steiger 2015), mainly the electric field that directly penetrates and depolarizes the cell membrane, or E_{\perp} .

Transversal field for membrane polarization

Mounting evidence from experimental and simulation studies support the notion that cell membranes can be polarized by transversal electric fields. An electric field that penetrates the cell membrane was directly observed to cause polarization in hippocampal neurons (Bikson et al. 2001), in neural stem cells (Zhao et al. 2015), and in oocytes (Lee & Grill 2005). When E_{\perp} is extremely strong, it can even cause membrane instability and pore formation (Bingham et al. 2010). Analytical computations of the transverse membrane potential under electric stimulation started as early as the 1950s (Fricke 1953; Schwan 1957) for a simple cellular shape. Recent works have calculated membrane polarization by the transverse field in cells with more complex geometry (Kotnik & Miklavcic 2000a; Kotnik & Miklavcic 2000b), and by the transverse electric field induced by time-varying magnetic field (Ye et al. 2007; Ye et al. 2011).

Because of the observable, polarizing effects of the transverse field on large structures like the cell body, it is reasonable to speculate that a transverse field could also play a significant role in the polarization of axons. Indeed, evidence favoring transversal activation of axons also appear in the literature. It was reported (Pourtaheri et al. 2009) that individual axons can be selectively activated by a transverse field in a nerve bundle. These fields produce strong effects in the stimulation of ulnar nerves (Cros et al. 1990; Olney et al. 1990) and long fibers (Grill & Wei 2009). Using a magnetic coil to induce the electric field, Ruohonen et al. (Ruohonen et al. 1996) discovered that activation of peripheral nerves could occur when the coil was oriented in a way that only generated E_{\perp} , and a later theoretical work (Ye et al. 2011) confirmed the axonal depolarization by this field. Clinically, the fast switching of magnetic fields during MRI scanning generates E_{\perp} in patients, which is considered an important risk factor for unwanted peripheral nerve stimulation (While & Forbes 2004).

At present, the consensus is that E_{\perp} is a modulator to the dominant effects caused by E_{\parallel} , although some researchers have speculated that the stimulation effects from transverse fields may arise due to nerve undulation, which generates longitudinal field components (Lontis et al. 2009; Schnabel & Struijk 1999; Struijk & Durand 1998). In the presence of E_{\parallel} , it was thought that E_{\perp} could introduce subthreshold membrane depolarization which enhances stimulation by providing

an additive effect on $E_{//}$ (Lontis et al. 2009). Alternatively, E_{\perp} may provide rapid axonal polarization in the transverse direction and $E_{//}$ drives the slow development of the mean transmembrane potential (Cranford et al. 2012). $E_{//}$ and E_{\perp} could potentially provide a strategy for differential activation of axons with different properties (Ruohonen et al. 1996).

Modify cable equation to include the contribution of transverse field

In cases with significant transverse stimuli, where the membrane-field interaction is sufficient and polarization is primarily due to the transverse field, the cable model assumptions are known to be invalid (Krassowska & Neu 1994). Many modeling studies have argued for the inclusion of the transverse field for the accurate simulation of neural activation, as well as the development of mathematical tools to serve this purpose (Gimsa & Wachner 2001; Kotnik & Miklavcic 2000a; Kotnik & Miklavcic 2006; Krassowska & Neu 1994; Ye et al. 2011; Ye & Steiger 2015).

Several papers have reported their first endeavors for modifying the cable equation. Yu et al. (Yu et al. 2005) modified the activation function to include the transversal field in magnetic stimulation. Ravazzani et al. magnetically stimulated the median nerve and recorded the evoked muscle responses, and discovered that including the transversal field in the cable equation provided a much improved correlation between the muscle EMG and the activating function (Ravazzani et al. 1996). A recent endeavor, which modified the current cable equation to include the transversal term (Wang et al. 2018), showed that the transversal field could affect threshold of demyelinated axons, but not in myelinated axons. Another work by the same group included the transverse term in the cable equation that describes magnetic field stimulation (Wang 2018). In both these studies, the membrane was represented by a resistor in parallel with a membrane capacitance. For computational simplicity, all the above-mentioned works ignored the physical presence of the lipid bilayer membrane, a “shell” like structure that has non-zero thickness. Consequently, the field perturbation caused by the membrane, which is essential for the re-distribution of the transverse field proximal to the axon (Farkas et al. 1984) (Jerry et al. 1996) (Lee & Grill 2005) (Mossop et al. 2007), as well as the buildup of transmembrane potential (Kotnik & Miklavcic 2000a; Kotnik & Miklavcic 2000b) through cell-field interaction (Ye & Steiger 2015), were ignored. Furthermore, in the myelinated axon model, the possibility that the presence of the myelin sheath might shield the internal structure such as the axon membrane (Kotnik & Miklavcic 2006; Ye & Curcuro 2016) was not considered.

In the present paper, we model a bare axon as a conductive cylindrical shell, and provide an analytical expression of membrane polarization (V_m) for an unmyelinated axon (or the node of Ranvier in myelinated axon), under transverse electric field stimulation. We also provide V_m for a myelin-covered axon, which was modeled as a co-centric, two shell structure. We investigate biophysical factors that may affect the V_m , including field intensity and orientation, axonal biophysics and the impact of pathological demyelination. We discuss the possibility of placing V_m into a modified cable equation, so that the contributions of both the longitudinal and transverse components of an electrical field could be simultaneously evaluated during electric stimulation of axons.

METHOD

Cylindrical axon model in a transverse electric field

We modeled a bare axon and its myelin sheath using homogeneous cylindrical volume conductors (Esselle & Stuchly 1994; Schnabel & Struijk 2001). Figure 1A illustrates the location and orientation of a myelin-covered axon in a cylindrical coordinate system (r, θ, z) . The axon was exposed to a transverse, direct current (DC) electric field (E_θ). It included a total of five isotropic and homogenous regions: the medium (#0), the myelin sheath (#1), the periaxonal space (#2), the axolemma (#3), and the axonal cytoplasm (#4). The dielectric permittivities and conductivities in the five regions were $\varepsilon_0, \varepsilon_1, \varepsilon_2, \varepsilon_3, \varepsilon_4$ and $\sigma_0, \sigma_1, \sigma_2, \sigma_3, \sigma_4$, respectively. The myelin had an outer radius (a), inner radius (b) and the thickness ($b-a$). The axon had an outer radius (c) and inner radius (d). Thickness of the axolemma was therefore $c-d$. Figure 1B illustrates a bare axon, which was composed of only the periaxonal space (#2), the axolemma (#3) and the axonal cytoplasm regions.

Governing equation and boundary conditions

Using the cylindrical coordinates (r, θ, z) , the electric field distribution was calculated by

$$\mathbf{E} = -\nabla V = -\left(\frac{\partial V}{\partial r}, \frac{1}{r} \frac{\partial V}{\partial \theta}, \frac{\partial V}{\partial z}\right) \quad (1)$$

For the DC electric field stimulation, an electric potential was obtained by solving Laplace's equation

$$\nabla^2 V = 0 \quad (2)$$

147 The potential, V , is the electric scalar potential due to the charge accumulation between the interface
148 of the two different media (Stratton 1941). In a cylindrical coordinate system (r, θ, z) , it is written as

$$149 \quad \frac{1}{r} \frac{\partial}{\partial r} \left(r \frac{\partial V}{\partial r} \right) + \frac{1}{r^2} \frac{\partial^2 V}{\partial \theta^2} = 0 \quad (3)$$

150 Several boundary conditions were evaluated in solving the equation (Appendix): (A). The
151 electric potential was continuous across the boundary of the two different media. (B). The normal
152 current density was continuous across the two different media. “Complex conductivity”, defined as
153 $S = \sigma + j\omega\epsilon$, was calculated to account for the dielectric permittivity of the material (Kotnik &
154 Miklavcic 2000b; Kotnik et al. 1998; Polk & Song 1990). Here, σ was the conductivity of the tissue,
155 ϵ was the permittivity, ω was the angular frequency of the field (zero for DC electric field) and
156 $j = \sqrt{-1}$ was the imaginary unit. On the extracellular media/myelin interface (#0#1, $r=a$),

$$157 \quad S_0 E_{0r} - S_1 E_{1r} = 0 \quad (4)$$

158 On the myelin /periaxonal interface (#1#2, $r=b$),

$$159 \quad S_1 E_{1r} - S_2 E_{2r} = 0 \quad (5)$$

160 On the periaxonal/axon interface (#2#3, $r=c$),

$$161 \quad S_2 E_{2r} - S_3 E_{3r} = 0 \quad (6)$$

162 On the axon/cytoplasm interface (#3#4, $r=d$),

$$163 \quad S_3 E_{3r} - S_4 E_{4r} = 0 \quad (7)$$

164 where $S_0 = \sigma_0 + j\omega\epsilon_0$, $S_1 = \sigma_1 + j\omega\epsilon_1$, $S_2 = \sigma_2 + j\omega\epsilon_2$, $S_3 = \sigma_3 + j\omega\epsilon_3$, $S_4 = \sigma_4 + j\omega\epsilon_4$. (C).

165 Electric fields an infinite distance away should not be perturbed by presence of the axon. (D). The
166 electric potential inside the cytoplasm ($r=0$) was finite.

167 Model parameters

168 Table 1 lists the default values of the model parameters and their ranges. The choice of the
169 electric parameters were based on reports in the literature (Kotnik et al. 1997; Kotnik & Miklavcic
170 2006). Axon radius was selected from Berthold and Rydmark (Berthold & Rydmark 1995). The
171 diameter of the unmyelinated axons ranges from approximately 0.1 μm to 2 μm (3 μm in humans).

We used 0.6 μm as the standard value and 0.1 – 3 μm as the range. The thickness of the axonal membrane was selected from Nagarajan and Durant (Nagarajan & Durand 1995). The diameter of the myelin was set to double the axon diameter. Lamella are produced by many layers of processes from oligodendrocytes with significant membrane resistivity (Bakiri et al. 2011). The resistance of the myelin was scaled linearly by the number (n) of lamella (Chomiak & Hu 2009). The standard electric intensity was 200 V/m. The maximum intensity is the one that can cause membrane electroporation (Sadik et al. 2011).

Software packages

Equations were derived with Mathematica 10 (Wolfram Research, Inc. Champaign, IL). Numerical simulations were performed with Matlab 8.4.0 (The MathWorks, Inc. Natick, MA).

RESULTS

Analytical expressions of axonal transmembrane potential (V_m) and voltage drop on the myelin sheath (ϕ) under transverse electric stimulation

The solution for Laplace's equation (Eq. 3) was written in the form (Griffiths 1999)

$$V(r, \theta) = A_0 \ln(r) + B_0 + \sum_{n=1}^{\infty} r^n [A_n \sin(n\theta) + B_n \cos(n\theta)] + \sum_{n=-\infty}^{-1} r^n [C_n \sin(n\theta) + D_n \cos(n\theta)] \quad (8)$$

The expression was further simplified for the five modeled regions (Griffiths 1999; Ye et al. 2011)

$$V_n = \left(\frac{A_n}{r} + C_n r \right) \sin \theta \quad (9)$$

where A_n, C_n were unknown coefficients ($n = 0, 1, 2, 3, 4$). These coefficients were solved in the Appendix (Supplementary file 1), by considering boundary conditions (A)-(D). Substituting A_3, C_3 into (9), we obtained the expression of voltage inside the axolemma

$$V_3 = - \frac{8a^2 b^2 c^2 E_0 S_0 S_1 S_2 \cos \theta}{r} \left[\frac{\text{term1}}{\text{term2} + \text{term3}} \right] \quad (10)$$

Where

$$\text{term1} = d^2 (S_3 - S_4) + r^2 (S_3 + S_4)$$

$$\text{term2} = b^2 (S_0 - S_1) \times$$

$$\{c^2(S_1 + S_2)[d^2(S_2 + S_3)(S_3 - S_4) + c^2(S_2 - S_3)(S_3 + S_4)] + b^2(S_1 - S_2)[d^2(S_2 - S_3)(S_3 - S_4) + c^2(S_2 + S_3)(S_3 + S_4)]\}$$

$$term3 = a^2(S_0 + S_1) \times$$

$$\{c^2(S_1 - S_2)[d^2(S_2 + S_3)(S_3 - S_4) + c^2(S_2 - S_3)(S_3 + S_4)] + b^2(S_1 + S_2)[d^2(S_2 - S_3)(S_3 - S_4) + c^2(S_2 + S_3)(S_3 + S_4)]\}$$

The axonal transmembrane potential (V_m) of the field was obtained by subtracting the membrane potential at the inner surface from that of the outer surface of the axon (Kotnik et al. 1997; Kotnik & Miklavcic 2000a; Ye et al. 2011; Ye et al. 2010), $V_m = V_3(r = d) - V_3(r = c)$. For a myelin-covered axon (Supplementary file 2),

$$V_m = 8a^2b^2c(c - d)E_0S_0\left[\frac{term4}{term2 + term3}\right]\cos\theta \quad (11)$$

Where

$$term4 = S_1S_2[d(-S_3 + S_4) + c(S_3 + S_4)]$$

Voltage drop (ϕ) across the myelin sheath was obtained by subtracting the myelin potential at the inner surface from the outer surface of the myelin (Supplementary file 2)

$$\phi = 2a(a - b)E_0S_0\left[\frac{term5 + term6}{term2 + term3}\right]\cos\theta \quad (12)$$

Where

$$term5 = b\{c^2(S_1 + S_2) \times$$

$$[d^2(S_2 + S_3)(-S_3 + S_4) - c^2(S_2 - S_3)(S_3 + S_4)] - b^2(S_1 - S_2)[d^2(S_2 - S_3)(S_3 - S_4) + c^2(S_2 + S_3)(S_3 + S_4)]\}$$

$$term6 = a\{c^2(S_1 - S_2) \times$$

$$[d^2(S_2 + S_3)(S_3 - S_4) + c^2(S_2 - S_3)(S_3 + S_4)] + b^2(S_1 + S_2)[d^2(S_2 - S_3)(S_3 - S_4) + c^2(S_2 + S_3)(S_3 + S_4)]\}$$

V_m and ϕ were functions of both field properties and tissue properties. The field properties included the orientation of the field and its intensity. The tissue properties include the electric

parameters (conductivity and di-electricity) and the geometrical parameters (i.e., diameters of the axon). The above V_m expression for the myelin-covered axon (Eq. 11) was further simplified for a bare axon by assuming $S_1=S_0$ and $S_2=S_0$ (Supplementary file 3),

$$V_m = \frac{2c(c-d)E_0S_0[d(-S_3+S_4)+c(S_3+S_4)]}{d^2(S_0-S_3)(S_3-S_4)+c^2(S_0+S_3)(S_3+S_4)}\cos\theta \quad (13)$$

Impact of electric field properties on V_m

When a transverse electric field penetrates the axolemma, the geometrical pattern of V_m is determined by the axon's orientation to the electric field. The axolemma should be hyperpolarized wherever an electric current enters the membrane and be depolarized wherever the current extrudes from the membrane (Ye & Steiger 2015). We plotted the transmembrane potential for a 50 μm myelinated axon (Figure 2A) and a straight bare axon (Figure 2B), based on the calculated V_m using standard values (Table 1). As expected, the locations of maximum polarization were at two lines corresponding to when $\theta=180^\circ$ (hyperpolarization, blue) and $\theta=0^\circ$ (depolarization, yellow), respectively. The axons were not polarized at the locations where $\theta=90^\circ$ and $\theta=270^\circ$.

When the axon was wrapped by a thick myelin sheath, the geometrical pattern of the axolemma depolarization (Figure 2A) remained identical to an unmyelinated axon (Figure 2B). However, since a large voltage gradient (ϕ) was generated on the myelin sheath rather than on the axolemma, V_m was quantitatively negligible for the myelinated axon. With the standard values in Table 1, the maximum ϕ was 0.6 mV for the myelin sheath, and the maximum V_m was only $0.53 \times 10^{-2} \mu\text{V}$ for the axolemma. In contrast, when the axon was not myelinated, the maximum V_m was 0.24 mV.

For both the myelin-covered and bare axons, V_m was proportional to the intensity of the electric field (Figures 2C and 2D). 2 kV/cm was sufficient in inducing electroporation (Sadik et al. 2011). This intensity induced a V_m of 5.3 μV for the myelin-covered axon. For a bare axon, it induced a V_m of 239.9 mV, which is sufficient to break down the structure of the membrane (Gehl 2003; Kinosita & Tsong 1977). These results suggest that the myelin sheath could provide a “shielding effect” on the axolemma against field-induced excessive polarization and structure disruption.

Impact of axonal properties on V_m

We investigated the dependency of V_m on the axonal properties, including the geometrical features (axon radius and membrane thickness) of the axon, and its conductivity. For the parametric analysis, we plotted the maximum polarization ($\theta = 0^\circ$ on the axon surface, Figures 1 and 2) when one parameter was varied through its defined value range, while the others were maintained at their standard values.

An axon with a larger radius was associated with a greater V_m for both the myelin-covered axon and bare axon (Figure 3A) under a transverse field stimulation. Axon thickness, however, did not significantly affect V_m (Figure 3B). V_m was insensitive to the axonal conductance changes within its physiological range (10^{-8} - 10^{-6} S/m), in agreement with the literature that studied spherical cell polarization in an electric field (Kotnik et al. 1997; Kotnik & Miklavcic 2006). However, when axolemma conductivity was significantly increased ($>10^{-3}$ S/m) due to membrane disruption and leakage, such as during electroporation (Mossop et al. 2007; Mossop et al. 2004), axolemma depolarization decreased significantly for both the myelin-covered and bare axons (Figure 3C).

Impact of demyelination on axonal V_m

Myelin, like a neuronal cell membrane, is constructed of a lipid bilayer that contains a hydrophobic center and hydrophilic surface. Myelin wraps around an axon numerous times, each layer acting like multiple resistors in series. Demyelination occurs in many neurological diseases such as spinal cord injury (Ye et al. 2012), cerebral palsy (Ruff et al. 2013) and multiple sclerosis (Lazzarini 2004). Demyelination is defined by the significant loss of myelin thickness (Mainero et al. 2015; Manogaran et al. 2016) and increased conductivity of the myelin.

We first studied how the loss of myelin layers could affect V_m in a transverse electric field. We systematically decreased the myelin thickness from $4.0\ \mu\text{m}$ to $0.1\ \mu\text{m}$. The conductivity of the myelin increased linearly with the reduction of the myelin thickness. This caused a reduction in the potential drop across the myelin sheath, but it did not significantly affect axonal depolarization (Figure 4). The transverse electric field was ineffective in inducing axonal depolarization, assuming the remaining myelin sheath could maintain low conductivity ($\sim 10^{-7}$ S/m).

We then investigated how an increase of myelin conductivity could affect V_m in a transverse electric field. When myelin conductivity was as low as 5×10^{-5} S/m, reduction in myelin

thickness did not lead to dramatic changes in V_m (Figure 5A). Instead, it led to a voltage drop across the myelin sheath (ϕ). When myelin conductivity was increased to 5×10^{-3} S/m, V_m could exceed ϕ for an extremely thin myelin sheath (Figure 5B). For a very leaky myelin (myelin conductivity is 5×10^{-1} S/m), the axon could be significantly depolarized at any myelin thickness (Figure 5C), and V_m could be greater than ϕ for a thin myelin sheath (Figure 5C, left inset). However, ϕ still dominated for axons with thick myelin sheaths (Figure 5C, right inset). In conclusion, demyelination could cause a re-distribution of the potentials between the axolemma and myelin under transverse electric stimulation. Increases in myelin conductivity during demyelination could cause the voltage distribution to shift from the myelin sheath to the axon. Axonal depolarization became prominent when significant reduction of myelin conductivity occurred during demyelination.

DISCUSSION

This work provides a novel analytical expression that describes the membrane polarization of axons (myelinated and bare) under transverse field stimulation. It analyzes the biophysical factors that affect axonal polarization under physiological conditions, and under pathological conditions such as demyelination. Finally, it provides the needed term to modify the current cable equation, so that the equation can account for the effects of more realistic field, which include both the transverse and parallel directions.

Impact of field orientation on V_m in transverse current stimulation

The model shows that the longitudinal axon was polarized with a distinct geometrical pattern by the transverse electric field, which was dependent on the orientation of the axon in the field. Previously, regional polarization has been observed in a variety of modeling and experimental studies for cells under electric (Durand 2003; Lee & Grill 2005; Lu et al. 2008; Teruel & Meyer 1997) and magnetic field stimulation (Schnabel & Struijk 1999; Schnabel & Struijk 2001; Ye et al. 2007). Functionally, orientation of the electric field to the axon is important for the excitation of axons, such as those from the retina ganglion cells (Grumet et al. 2000). Since only a small patch of membrane is depolarized in the transverse field, it is reasonable to speculate that voltage gated ion channels may have a diverse response to the field, depending on their location on the membrane patch. This could cause the threshold for activation to be higher than that observed from axons in longitudinal fields that induce the same peak depolarization (Schnabel &

Struijk 2001). The higher threshold may explain the relative poor efficiency of axonal activation by transverse field stimulation (McNeal 1976; Ranck 1975).

Impact of axon's biophysical properties on V_m

We found that V_m was dependent on the intrinsic tissue properties of an axon. We observed that V_m was greater in larger diameter axons than in smaller ones (Figure 3A). This observation is in agreement with the notion that larger diameter axons are associated with lower excitation thresholds (Basser & Roth 1991; Carunaru & Durand 1997; Garnsworthy et al. 1988; Reilly 1989). Selective activation of different size fibers has significant clinical implications, such as pain relief (Meyerson & Linderorth 2000), which can be achieved by novel design of the electric field (Konings 2007). In deep brain stimulation (DBS), the effects of the electric currents within different brain regions were dependent on the fiber sizes (Sotiropoulos & Steinmetz 2007). In addition, an increase in axolemma conductivity decreases the axon's sensitivity (buildup of V_m) to the transverse field (Figure 3C), suggesting a shunting effect to the transverse current. In conclusion, the effectiveness of transverse stimulation relies on the physiological features of the target axon.

Axonal diameter could change under certain pathological situations. For example, axon swelling occurs during focal demyelination (Kolaric et al. 2013), as a consequence of aglycemia (Allen et al. 2006), anoxia (Waxman et al. 1992) or ischemia (Garthwaite et al. 1999). It is speculated that these pathological changes could potentially render the enlarged axons more sensitive to the transverse electric field.

Impact of demyelination and other pathological conditions on V_m in transverse electric stimulation

Dynamic changes of myelin occur during demyelination. It is unknown if pathological demyelination could affect the sensitivity of a myelinated axon to a transverse electric field. While myelin-covered axons could only be slightly depolarized by the transverse field, bare axons can have a moderate buildup of V_m (Figure 2), especially when the axon diameter is large (Figure 5A). We used the model to test two possibilities of reduced myelination and their impacts on V_m . Reduction in the myelin thickness, along with a scaled linear increase in myelin conductance, was not sufficient to enhance depolarization (Figure 4). In contrast, V_m was enhanced when the myelin

sheath became electrically leaky (highly conductive) (Figure 5). It is therefore expected that transverse electric fields could apply variable axonal depolarization, depending on the myelin conductivity changes during the process of demyelination. Electrical stimulation protocols for the treatment of demyelination diseases (Dooley & Sharkey 1981; Dooley et al. 1978) could be further optimized by considering remyelination/demyelination factors during treatment, to ensure maximum outcomes.

Dynamic changes of myelin also occur during development (Sturrock 1980), neural regeneration (Huang et al. 2013), and pathological situations such as traumatic brain injury (Robain & Mandel 1974; Tyler 2012). At the cellular level, membrane resistance of the oligodendrocyte could change during development and maturity (Karadottir et al. 2005), and in a medium with low osmolarity (Kimmelberg & Kettenmann 1990). It is speculated that these dynamic changes in the myelin properties could cause the axons to react differently to the electric field. This supports the notion that the dynamic interaction between the electric field and the neuronal tissue, as well as the outcome of the stimulation, are determined by both the electric parameters and the tissue properties (Ye & Steiger 2015).

Modification of the cable equation to include the transverse field

The analytical expression of the V_m term could potentially be used to modify the current cable equation to account for both $E_{||}$ and E_{\perp} . Ruohonen et al. modified the cable equation

(Ruohonen et al. 1996) to be in the form of $\lambda^2 \frac{\partial^2 \varphi_m}{\partial x^2} - \tau \frac{\partial \varphi_m}{\partial t} - \varphi_m - 2c(\alpha E'_{||} - E_{\perp}) = 0$. Here,

$\alpha E'_{||} - E_{\perp}$ is interpreted as the *modified activating function*, where $\alpha = \frac{\lambda^2}{2c} = \frac{R_m}{4R_i}$ (Ruohonen et al.

1996). Comparatively large values of α indicates that $E'_{||}$ is responsible for the majority of excitation, while $\alpha = 0$ indicates that E_{\perp} is more important.

In this modified equation, the term $2cE_{\perp}$ is the membrane potential created by the transverse field. For magnetic stimulation, an analytical expression (Ye et al. 2011) is available to replace this term for the modified cable equation. For direct electric stimulation, the V_m term for the unmyelinated axon (Eq. 13) can be used to replace the $2cE_{\perp}$ term, to include the impact of the transverse electric field. Previously, effects of the transverse field and the axial field have been compared in several works (Lontis et al. 2009; Ruohonen et al. 1996; Yu et al. 2005). The

transverse electric field is required to be several times greater than the longitudinal field to produce comparable results (McNeal 1976; Ranck 1975; Ruohonen et al. 1996). A precondition for the modified activation function to yield accurate results is for the electric field to be approximately uniform and be perpendicular to the axon fiber (Schnabel & Struijk 2001), which is readily satisfied in our model.

Limitations and future directions

This paper was not intended to fully elucidate the mechanisms behind transverse field activation of nerve tissue, since it did not include any ionic channel mechanisms. The model also does not necessarily apply to the stimulation of fiber bundles. Axons within a bundle could interfere with other axon's polarization under a transverse electric field (Pourtaheri et al. 2009). Local electric fields could be perturbed by an axon, which produces a small, secondary effect on the surrounding axons (Lee & Grill 2005; Susil et al. 1998). In a nerve bundle, V_m could also be a function of the anisotropy of the bundle (Nagarajan & Durand 1995), which was not studied in the present model. Finally, the transverse field could be significantly weaker due to the lower values of conductance of surrounding perineurium (Struijk & Schnabel 2001). More complicated modeling work should resort to numerical methods, whose accuracy can be validated by the analytical results from this work.

The model predicts that the node section in a myelinated axon will have the same polarization as the unmyelinated axon. If one considers that the node has a much higher density of Na^+ channel distribution (Freeman et al. 2016), it is predicted that myelinated axons will have a lower threshold of activation under transverse electric field. This model prediction could be tested by stimulating a structure that contains both unmyelinated and myelinated axons, such as the corpus callosum (Crawford et al. 2009; Ruff et al. 2013). With the strong stimulus being applied on both type of axons (Ruff et al. 2013), action potentials should be triggered first in the myelinated axons.

Conclusions

This work provides novel analytical expressions of the electrically-induced transmembrane potential (V_m) for a myelin-covered axon and a bare, unmyelinated axon, under a transverse DC electric field. Results show that the myelin sheath shields the axon from extensive depolarization.

Demyelination could alter axon's sensitivity to a transverse electric field if the process of demyelination involves significant increases in the electric conductance of the myelin. The analytical solution of V_m for the unmyelinated axon can be used to improve the activation function of the current cable equation that describes electric stimulation.

Appendix - Determining unknown coefficients A_n, C_n in equation (9) using boundary conditions (A)-(D)

At an infinite distance, according to boundary condition (C), $V_o = -E_0 r \cos \theta$. Therefore, $a_0 = -E_0$. Since V was bounded at $r = 0$ (boundary condition D), $C_4 = 0$.

Expressions for the potential distribution in the five modeled regions were:

$$V_0 = -E_0 r \cos \theta + \frac{C_0}{r} \cos \theta \quad (\text{A-1})$$

$$V_1 = A_1 r \cos \theta + \frac{C_1}{r} \cos \theta \quad (\text{A-2})$$

$$V_2 = A_2 r \cos \theta + \frac{C_2}{r} \cos \theta \quad (\text{A-3})$$

$$V_3 = A_3 r \cos \theta + \frac{C_3}{r} \cos \theta \quad (\text{A-4})$$

$$V_4 = A_4 r \cos \theta \quad (\text{A-5})$$

The \vec{r} components of ∇V (from Eq. 1) were continuous across the interfaces (boundary condition A), and the normal components of the current density were continuous across the interfaces (boundary condition B). These boundary conditions yield the following set of equations:

415 On the #0#1 interface ($r=a$)

$$416 \quad -E_0 a + \frac{C_0}{a} = aA_1 + \frac{C_1}{a} \quad (\text{A-6})$$

$$417 \quad S_0(-E_0 - \frac{C_0}{a^2}) = S_1(A_1 - \frac{C_1}{a^2}) \quad (\text{A-7})$$

418 On the #1#2 interface ($r=b$)

$$419 \quad bA_1 + \frac{C_1}{b} = bA_2 + \frac{C_2}{b} \quad (\text{A-8})$$

$$420 \quad S_1(A_1 - \frac{C_1}{b^2}) = S_2(A_2 - \frac{C_2}{b^2}) \quad (\text{A-9})$$

421 On the #2#3 interface ($r=c$)

$$422 \quad cA_2 + \frac{C_2}{c} = cA_3 + \frac{C_3}{c} \quad (\text{A-10})$$

$$423 \quad S_2(A_2 - \frac{C_2}{c^2}) = S_3(A_3 - \frac{C_3}{c^2}) \quad (\text{A-11})$$

424 On the #3#4 interface ($r=d$)

$$425 \quad dA_3 + \frac{C_3}{d} = dA_4 \quad (\text{A-12})$$

$$426 \quad S_3(A_3 - \frac{C_3}{d^2}) = S_4 A_4 \quad (\text{A-13})$$

427 We solved (A-6) to (A-13) to obtain the unknown coefficients (Supplementary file 1). These
428 coefficients will be substituted into (A-1) to (A-5) to obtain the analytical expression of the
429 voltages in the five regions (Supplementary file 1).

430 List of Abbreviations

431 DC: Direct current; E_0 : Intensity of the externally applied DC electric field (V/m); V_m :
432 Transmembrane potential induced by the DC electric field across the axolemma (mV); ϕ : Potential

drop across the myelin sheath (mV); $E_{//}$: Electric field that is parallel to the axon; E_{\perp} : Electric field that is perpendicular (transversal) to the axon.

Figure legends

Figure 1. Model setup for a myelin-covered axon (A) and a bare axon (B) under transverse electric field stimulation. The cylindrical coordinate system that was used to define the orientation of the electric field and the axon.

Figure 2. Polarization of a myelin-covered axon (A) and a bare axon (B) in a transverse electric field. The V_m was calculated by equations 11 and 13, for the myelin-covered axon and the bare axon, respectively. ϕ was calculated by equation 12. All calculations were based on the standard parameters in Table 1. The color maps represented the amount of polarization (in mV). (C) Effect of transverse electric field intensity on axonal polarization in myelin-covered and bare axons. (D) Log plot of (C).

Figure 3. Dependency of V_m on the biophysics properties of the axon. (A) Axolemma diameter. (B) Axolemma thickness. (C) Axolemma conductivity.

Figure 4. Effects of decreased myelin thickness on axonal polarization. Reduction of myelin thickness from 3.4 μm to 0.1 μm (and linear increase of its conductivity) caused a significant reduction in ϕ , but not V_m . For the inset example, axon diameter = 0.6 μm . Myelin thickness = 0.1 μm .

Figure 5. Effects of a leaky myelin sheath on axolemma polarization in a transverse electric field. Conductivity of each myelin layer was (A) 5×10^{-5} S/m, (B) 5×10^{-3} S/m, and (C) 5×10^{-1} S/m, respectively. For the inset two examples, axon diameter = 0.6 μm . Myelin diameter = 0.7 μm and 4.6 μm , respectively.

Supplementary file 2 [Mathematic derivations for ϕ for the myelin sheath (equation 12).]

Supplementary file 3 [Mathematic derivations for V_m in the bare axon (equation 13).]

Figure 1

Model setup for a myelin-covered axon (A) and a bare axon (B) under transverse electric field stimulation.

The cylindrical coordinate system that was used to define the orientation of the electric field and the axon.

Figure 2

Polarization of a myelin-covered axon (A) and a bare axon (B) in a transverse electric field.

The V_m was calculated by equations 11 and 13, for the myelin-covered axon and the bare axon, respectively. f was calculated by equation 12. All calculations were based on the standard parameters in Table 1. The color maps represented the amount of polarization (in mV). (C) Effect of transverse electric field intensity on axonal polarization in myelin-covered and bare axons. (D) Log plot of (C).

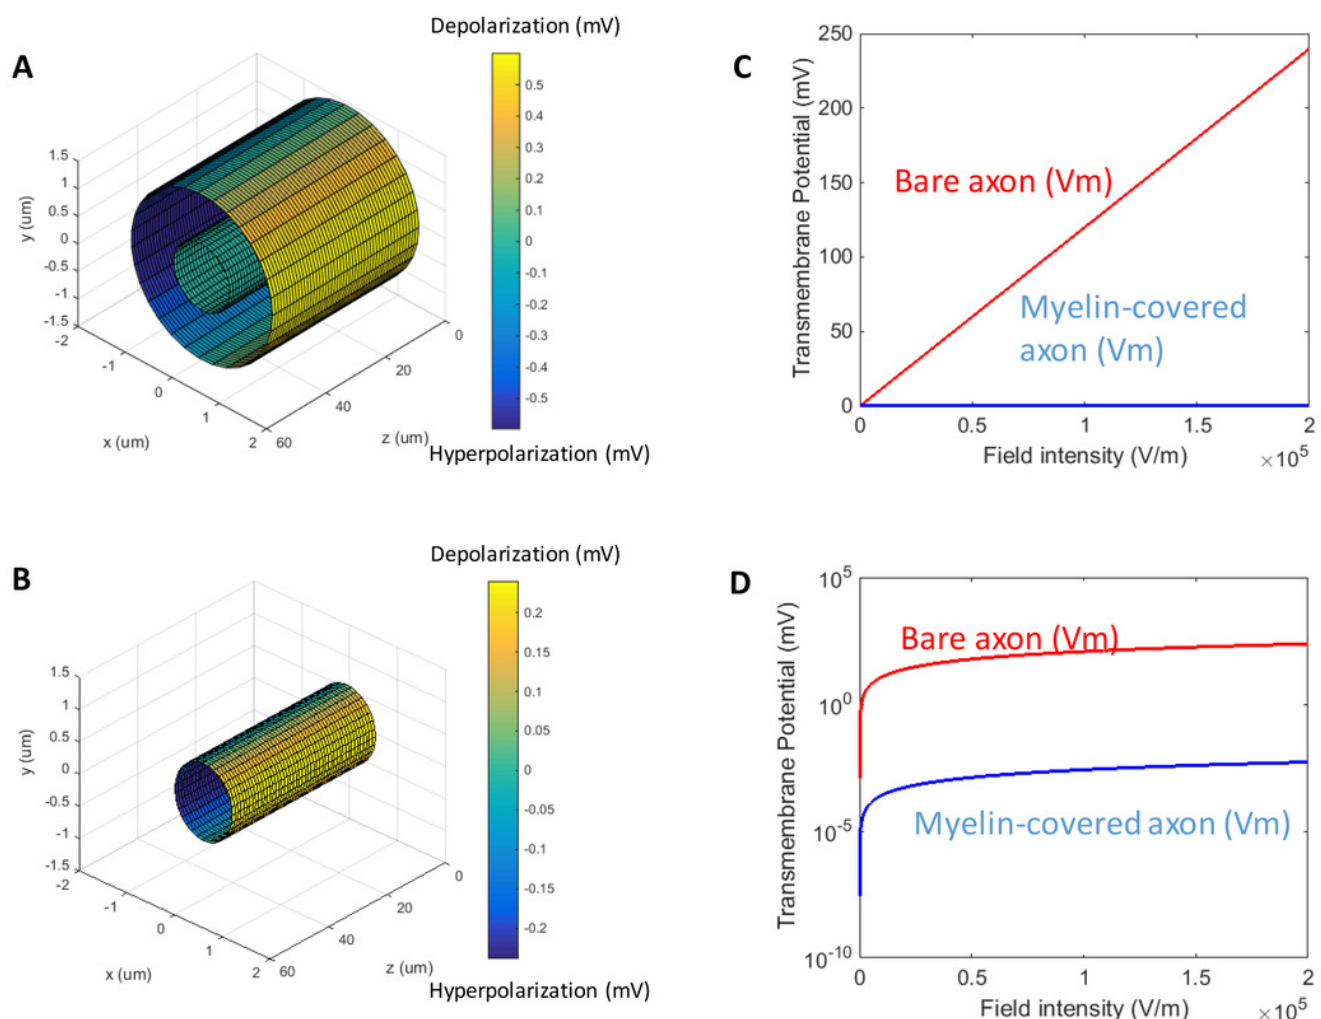

Figure 3

Dependency of V_m on the biophysics properties of the axon.

(**A**) Axolemma diameter. (**B**) Axolemma thickness. (**C**) Axolemma conductivity.

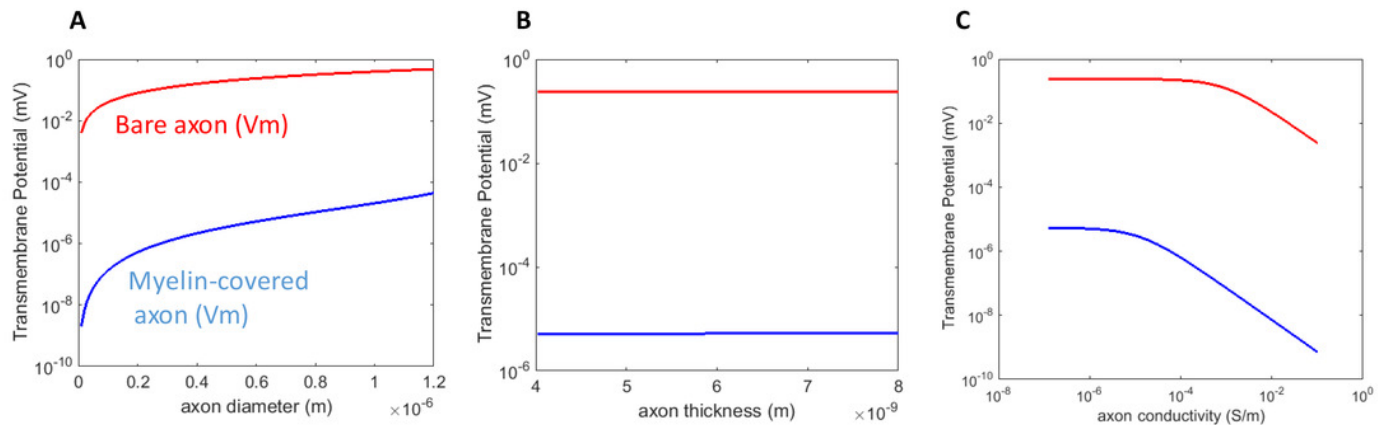

Figure 4

Effects of decreased myelin thickness on axonal polarization.

Reduction of myelin thickness from 3.4 μm to 0.1 μm (and linear increase of its conductivity) caused a significant reduction in f , but not V_m . For the inset example, axon diameter = 0.6 μm . Myelin thickness = 0.1 μm .

Figure 5

Effects of a leaky myelin sheath on axolemma polarization in a transverse electric field.

Conductivity of each myelin layer was **(A)** 5×10^{-5} S/m, **(B)** 5×10^{-3} S/m, and **(C)** 5×10^{-1} S/m, respectively. For the inset two examples, axon diameter = $0.6 \mu\text{m}$. Myelin diameter = $0.7 \mu\text{m}$ and $4.6 \mu\text{m}$, respectively.

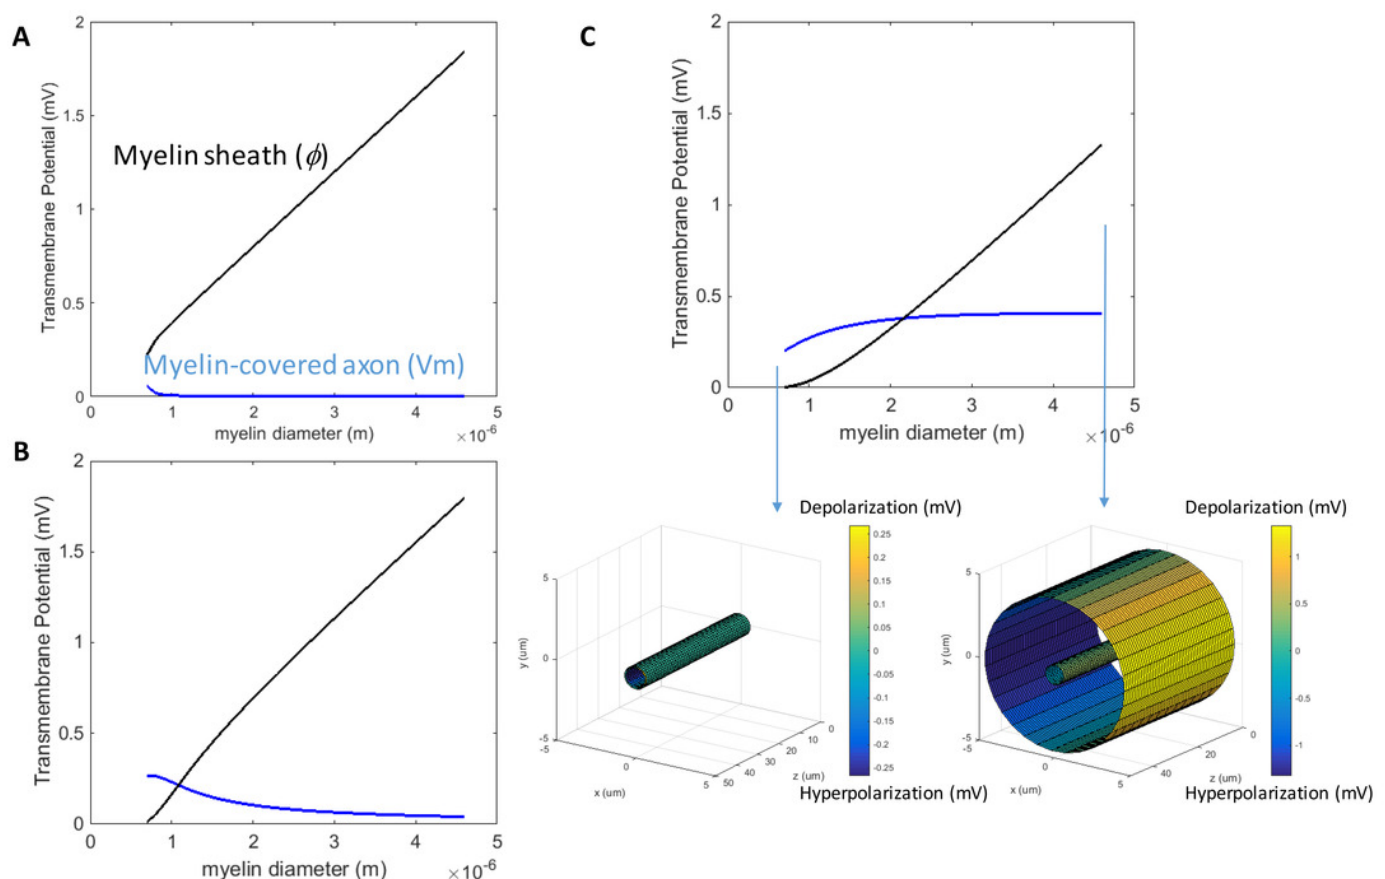

Table 1(on next page)

Model parameters.

Parameters	Standard value	Lower limit	Upper limit
Extracellular conductivity (σ_0 , S/m) ^{a,b}	0.2	5×10^{-4}	2.0
Myelin conductivity (σ_1 , S/m) ^{a,b}	$5.0 \times 10^{-7}/n$ ^g	$1.0 \times 10^{-8}/n$	$1.2 \times 10^{-6}/n$
Periaxonal conductivity (σ_2 , S/m) ^{a,b}	0.2	2.0×10^{-2}	1.0
Axonal conductivity (σ_3 , S/m) ^{a,b}	5.0×10^{-7}	1.0×10^{-8}	1.2×10^{-6}
Cytoplasmic conductivity (σ_4 , S/m) ^{a,b}	0.2	2.0×10^{-2}	1.0
Extracellular dielectric permittivity (ϵ_0 , As/Vm) ^{a,b}	6.4×10^{-10}	3.5×10^{-10}	7.0×10^{-10}
Myelin dielectric permittivity (ϵ_1 , As/Vm) ^{a,b}	4.4×10^{-11}	1.8×10^{-11}	8.8×10^{-11}
Periaxonal dielectric permittivity (ϵ_2 , As/Vm) ^{a,b}	6.4×10^{-10}	3.5×10^{-10}	7.0×10^{-10}
Axonal myelin dielectric permittivity (ϵ_3 , As/Vm) ^{a,b}	4.4×10^{-11}	1.8×10^{-11}	8.8×10^{-11}
Cytoplasmic dielectric permittivity (ϵ_4 , As/Vm) ^{a,b}	6.4×10^{-10}	3.5×10^{-10}	7.0×10^{-10}
Myelin diameter (a, nm)	1.5	0.7	4.6
b. Axonal membrane thickness (nm) ^c	6	4	8
Axonal radius (c, μm) ^d	0.6	0.1	1.2
Periaxonal space width (μm) ^e	0.004	0.004	0.004

Number of myelin layers (n) ^f	40	0	40
Electric field intensity (V/m)	200	0	200000 ^h
