Successful dispersal of freshwater sponges depends on the formation of degenerative sponge bodies (gemmules) under adverse conditions. Gemmule formulation allows the sponge to overcome critical environmental conditions, for example desiccation or freezing, and to re-establish as a fully developed sponge when conditions are more favorable. A key process in sponge development from hatched gemmules is the construction of its silica skeleton. Silica spicules form the structural support for the three-dimensional filtration system the sponge uses to filter food particles from ambient water. We studied how sponges fed with dissolved <sup>13</sup>C- and <sup>15</sup>N-labelled amino acids and non-fed sponges develop their spicule skeleton under environmental stress, using different hypergravity forces (1, 2.5, 5, 10, and 20 x g for 48 h) as stressors. The results show that freshwater sponges can withstand prolonged periods of hypergravity exposure and successfully construct their skeleton, even under 20 x g. Developing sponges were found to take up and assimilate dissolved food before forming a functional filtering system. However, fed and non-fed sponges showed no differences in skeleton formation and relative surface area growth, suggesting that the gemmules' intrinsic energy fulfills the processes of skeleton construction. Additionally, non-fed sponges formed oscula significantly more often than fed sponges, especially under higher g-forces. This suggests that the eventual formation of a filtration system might be stimulated by food deprivation and environmentally stressful conditions. These findings indicate that the process of spicule skeleton formation is energy-efficient and highly flexible, and plays an important role in how sponges can adapt their size and shape required for indeterminate growth. The uptake of dissolved food

substances by freshwater sponges may contribute to the cycling of dissolved organic matter (DOM) in freshwater ecosystems where sponges are abundant.

**Running head:** hypergravity skeleton formation freshwater sponge

**Keywords:** Freshwater sponges, gemmule, spicules, skeleton construction, hypergravity

# **Abstract**

Successful dispersal of freshwater sponges depends on the formation of degenerative sponge bodies (gemmules) under adverse conditions. Gemmule formulation allows the sponge to overcome critical environmental conditions, for example desiccation or freezing, and to re-establish as a fully developed sponge when conditions are more favorable. A key process in sponge development from hatched gemmules is the construction of its silica skeleton. Silica spicules form the structural support for the three-dimensional filtration system the sponge uses to filter food particles from ambient water. We studied how sponges fed with dissolved  $^{13}\text{C}$ - and  $^{15}\text{N}$ -labelled amino acids and non-fed sponges develop their spicule skeleton under environmental stress, using different hypergravity forces (1, 2.5, 5, 10, and 20 x g for 48 h) as stressors. The results show that freshwater sponges can withstand prolonged periods of hypergravity exposure and successfully construct their skeleton, even under 20 x g. Developing sponges were found to take up and assimilate dissolved food before forming a functional filtering system. However, fed and non-fed sponges showed no differences in skeleton formation and relative surface area growth, suggesting that the gemmules' intrinsic energy fulfills the processes of skeleton construction. Additionally, non-fed sponges formed oscula significantly more often than fed sponges, especially under higher g-forces. This suggests that the eventual formation of a filtration system might be stimulated by food deprivation and environmentally stressful conditions. These findings indicate that the process of spicule skeleton formation is energy-efficient and highly flexible, and plays an important role in how sponges can adapt their size and shape required for indeterminate growth. The uptake of

47 dissolved food substances by freshwater sponges may contribute to the cycling of dissolved  
 48 organic matter (DOM) in freshwater ecosystems where sponges are abundant.

# Introduction

Sponges are among the oldest — approximately 700 million years old — still existing metazoans on Earth (Müller, 1998; Love *et al.*, 2009; Ludeman *et al.*, 2014). Due to its ancient heritage, the sponge body plan is traditionally seen as the original blueprint for multi-cellularity (Müller, 2004; Nosenko *et al.*, 2013). Although sponges lack organs, they possess a high level of functional complexity (Leys *et al.*, 2009; Srivastava *et al.*, 2010). They have a well-developed food uptake and waste disposal system constructed of numerous small inflow openings (ostia) and chambers containing filter cells (choanocytes) with actively beating flagella to create an internal water flow. Sponges can contract their ostia and water channels to modulate this water flow (Elliot & Leys, 2007; Ludeman *et al.*, 2014). After the indrawn water has passed the choanocyte chambers, waste products are discarded through excurrent canals (oscula). Sensory cilia inside the osculum use calcium channels to adapt the sponge's water filtering capacity, for example in response to temperature changes or increased suspended sediment (Ludeman *et al.*, 2014; Cavalier-Smith, 2017).

The freshwater sponge *Ephydatia fluviatilis* (Porifera, Demospongia, Spongillidae), the species used in this study, is cosmopolitan and found throughout Earth's entire northern hemisphere (Van Soest *et al.* 2017). This shows the flexibility of this sponge to endure a wide range of environmental conditions. The colonization capacity of inland waters by freshwater sponges largely depends on the formation of small (~300 µm diameter) degenerative sponge bodies (gemmules) under adverse conditions (Manconi & Pronzato, 2008; Funayama, 2013). This form of asexual reproduction allows the sponges to overcome critical environmental conditions (e.g., low water temperatures during wintertime or desiccation during hot summers) (Manconi & Pronzato, 2016). When conditions are more favorable, a fully-developed miniature sponge can be re-established from a gemmule in approximately 1 week, depending on environmental conditions

(Höhr, 1977; Ilan *et al.*, 1996; Funayama *et al.*, 2005) (Fig 1A). First, during gemmule germination, totipotent stem cells contained within the gemmule differentiate in different cell types (Wierzejski 1915, 1935; Höhr, 1977). Secondly, during a process called hatching, the cells within the gemmule migrate outwards and attach the sponge to its substrate (Rozenfeld, 1970; Höhr, 1977; Harrison *et al.*, 1981). Eventually, the migrated cells proliferate and differentiate into all types of cell to form a fully functional sponge (Höhr 1977; Funayama *et al.*, 2005).

A key process in freshwater sponge development from hatched gemmules is the formation and construction of its skeleton. The sponge skeleton forms the structural support for the three-dimensional filtering system of the sponge (reviewed by Uriz *et al.*, 2003). In demosponges, the skeleton consists of individualized elements (silica spicules), embedded in a fibrous organic matrix made from chitin and spongin (Larsen & Riisgård, 1994; Uriz *et al.*, 2003; Ehrlich *et al.*, 2013). After setting the spicules in an upright position, the developing sponge construct its filter systems and starts to obtain nutrients by active filter-feeding (Funayama *et al.* 2005).

Recently, it was shown for *E. fluviatilis* that the silica spicules are not randomly distributed throughout the developing sponge body, but are deliberately set-up in a highly-organized manner (Nakayama *et al.* 2010; 2015), similar to pitching a tent. Spicules are produced at different locations within the hatching gemmule and transported by so-called transport cells to their final position, where they are erected and cemented by a third type of specialized cells (Nakayama *et al.* 2015). This division of labor between various cell types within the sponge has revealed a fundamentally new mechanism of constructing the three-dimensional body shape of animals (Nakayama *et al.*, 2015). As stated by Nakayama (2015), the spicule skeleton construction process of *E. fluviatilis* is the only known biological mechanism in which a sequence of cooperative behaviors of individual cells leads to the active construction of a self-organized biological structure

using non-cellular materials. Moreover, the mediation of the different steps of spicule skeleton construction by specialized cells allows for high plasticity and helps to generate the morphological diversity of fully-grown *E. fluviatilis* specimens.

Gemmule formation and hatching are seasonally dependent and it appears that external factors such as water temperature, water turbidity and illumination are responsible for these processes (Harsha *et al.*, 1983; Ilan *et al.*, 1996). However, at present it is unknown how most of these external factors affect the formation and hatching of gemmules. In addition, gemmule hatching and spicule body construction up to the moment of a fully-developed filter system is presumed to be mediated by internally-stored energy and therefore independent of externally available food sources. Germination studies are therefore usually performed in medium without added food sources (Funayama *et al.*, 2005; Elliott & Leys, 2007). This hypothesis is, however, never tested and therefore it is unknown whether newly hatched sponge gemmules can obtain external energy sources before they have developed the capacity to actively filter-feed, and if this influences their development.

Access to the large diameter centrifuge (LDC) of the European space agency (ESA) in Noordwijk, the Netherlands, enabled us to test the influence of increased mechanical stress (i.e. increased hypergravity (*g*) forces) on the construction of the siliceous skeleton of developing sponges. Hypergravity is an artificially created condition in which the acceleration exceeds the common terrestrial gravitational acceleration of  $9.81 \text{ m s}^{-2}$  ( $1 \times g$ ) and this creates a force working directly against the hatching sponge trying to erect its spicules. Furthermore, hypergravity has been shown to alter the intracellular transport and delivery of cell wall material in plants (Chebli *et al.*, 2012), polyp growth in stony corals (Meroz *et al.*, 2002) and effects skeletal architecture and bone-repair in mammals (Prodanov *et al.*, 2013; Canciani *et al.*, 2015). Exposure to hypergravity acts

on the whole cell mass, and cells exposed to several  $g$ 's can adapt by decreasing the height of their microtubule network, but increasing the thickness of their actin fibers without affecting cell viability (Kacena *et al.*, 2004; Searby *et al.*, 2005; van Loon *et al.*, 2009). We hypothesize that 1) increased  $g$ -forces decrease the ability of the sponge to transport their spicules to their correct orientation and to erect them due to the higher energy costs involved, preventing the formation of a fully-developed filter system (e.g., no osculum formation) and 2) that food addition will partially relieve developing sponges from the expected energy shortage caused by hypergravity (Fig 1B).

To study the effects of external stress on skeleton formation in developing freshwater sponges, we tested how prolonged exposure (48 h) to different hypergravity forces (1, 2.5, 5, 10, and 20 x  $g$ ) influenced 1) relative surface area increase (as measure of growth) 2) the presence of a set-up skeleton and 3) the presence or absence of an osculum in hatched gemmules of *E. fluviatilis*. In addition, we tested the ability of the developing sponges under above-mentioned conditions of hypergravity exposure to take up dissolved food (i.e.  $^{13}C$ - and  $^{15}N$ -enriched amino acids) and whether additional feeding affects skeleton and osculum formation.

# Materials & Methods

## Gemmule harvesting and preparation

Gemmules were collected in the winter months (November 2013 to March 2014), from specimens of *E. fluviatilis* kept in outdoor aquaria at the University of Amsterdam. Sponge tissue containing the gemmules was collected and cleaned by rubbing the sponge tissue between two pieces of corduroy to free the gemmules from the sponge tissue scaffold that can inhibit germination. Detached gemmules were sterilized in 1% H<sub>2</sub>O<sub>2</sub> for 5 min on a shaker at 4°C to remove bacterial and fungal contaminants included in the coat (Funayama *et al.*, 2005).

## Gemmule hatching

A total of 420 gemmules from one individual sponge were plated on sterile 12-well culture plates in sterile M-Medium (Rasmont, 1961; 1 mM CaCl<sub>2</sub>, 0.5 mM MgSO<sub>4</sub>, 0.5 mM NaHCO<sub>3</sub>, 0.05 mM KCl, 0.25 mM Na<sub>2</sub>SiO<sub>3</sub>) under ambient conditions. The plates were sealed by parafilm. Each well of the 12-well culture plates contained one gemmule in approximately 4 mL of M-medium. After four days, before placing the gemmules in the LDC, the individuals that did not hatch were discarded and of the remaining hatched specimens, only the sponges in stage II were selected (i.e. the sponges that had not yet erected any spicules nor formed an osculum, see Fig. 1 for a description of developmental stages). 72% of the plated gemmules hatched (302 out of 420), of which  $n = 277$  sponges developed to stage II that were subsequently used for the experiment in the LDC (Table 1). Before placing the selected gemmules in the LDC, the medium was refreshed to prevent accumulation of waste products in the well plates.

157

# **158 Sponge feeding with <sup>13</sup>C- and <sup>15</sup>N-enriched amino acids**

159 For each gravitational condition (see below), one group (i.e. approximately half) of the gemmules  
160 was fed with isotopically-enriched (<sup>13</sup>C and <sup>15</sup>N) dissolved amino acids in order to study nutrient  
161 uptake, whereas the other group remained unfed (Table 1). The fed groups were randomly selected  
162 and received M-Medium with 390 µg L<sup>-1</sup> tracer <sup>13</sup>C- (11 µmol L<sup>-1</sup>) and <sup>15</sup>N- (2.2 µmol L<sup>-1</sup>) enriched  
163 dissolved amino-acids added prior to the LDC runs.

164

# **165 Hypergravity experiment in large diameter centrifuge**

166 Hypergravity experiments were performed using the large diameter centrifuge (LDC) of the  
167 European Space Agency (ESA, Noordwijk, The Netherlands) following a predetermined protocol  
168 (Fig. 2A). The LDC has a diameter of 8 m and comprehends four large arms fitted with outward  
169 swinging gondolas. The rotational movement of the arms creates an artificial acceleration field at  
170 the well plates positioned inside the gondolas, simulating different g-forces depending on gondola  
171 placement on the arms and rotational speed (Fig. 2B). Experiments were performed in two 48-h  
172 runs. In the first 48-h run developing sponges were exposed to 1 (i.e. as hypergravity control;  
173 placed at the center of the rotating LDC), 2.5 and 5 x g and in the second run to 10 and 20 x g (Fig.  
174 2B). Per hypergravity level, both fed and non-fed sponges were tested simultaneously. To assess  
175 the effect of rotation on the development of the gemmules, a control experiment without feeding  
176 was performed where gemmules were hatched on a non-rotating lab bench, in addition to the  
177 rotating control at 1 x g. As conditions did not vary in the LDC room between the first (2.5 and 5  
178 x g) and the second run (10 and 20 x g) no additional hypergravity control at 1 x g was performed  
179 during the second run.

180

# **Sponge surface area measurements**

Before and after placement in the LDC, the surface area of the substrate covered by the sponges (in mm<sup>2</sup>) was determined by light microscopy. We are aware that sponge volume is a better metric for growth of sponges building a three-dimensional structure (i.e. the skeleton). However, we were unable to accurately measure volume and therefore used substrate area covered by the sponge as a proxy for sponge size/growth. All sponges were photographed and visually checked to assess substrate area cover, the set-up/no set-up of the sponge skeleton, and the presence/absence of an osculum under a stereoscopic microscope (*Olympus SZH-ILLD* with *infinity1* microscopy camera). Surface area measurements were performed using *Image J* software (<https://imagej.nih.gov/ij/>).

# **Stable isotope analysis of sponges**

After LDC exposure and microscopy imaging, the labeled M-medium was replaced with non-labeled M-medium in which the sponges were placed for 30 mins to remove any residual label. Sponges were then taken out of the well-plates, rinsed with M-medium and pooled per treatment, freeze-dried, homogenized, and stored at -20°C in silver boats. Pooling was necessary to ensure that sufficient carbon and nitrogen was available for the stable isotope analysis. Silver boats were acidified with 5% HCl to ensure removal of inorganic carbon, oven-dried at 60°C, pinched closed and stored frozen before analysis on an Elemental Analyser (*EA, Firma Thermo Electron, Flash EA 1112 analyzer*) that was coupled to a Delta V isotope ratio mass spectrometer (IRMS) for simultaneous measurement of <sup>13</sup>C:<sup>12</sup>C and <sup>15</sup>N:<sup>14</sup>N ratios. Reproducibility for the EA-IRMS analysis was 0.25‰ for <sup>15</sup>N and 0.2‰ for <sup>13</sup>C.

The uptake of dissolved amino acid C or N was expressed as uptake of  $\mu\text{mol}$  isotopically-enriched C or N  $\text{mmol sponge}^{-1} \text{ d}^{-1}$ . Rates are calculated from the delta notations obtained from the IRMS as  $\delta X (\text{‰}) = (R_{\text{sample}}/R_{\text{ref}} - 1) \cdot 1000$ , in which X is the element (C or N),  $R_{\text{sample}}$  is the heavy : light isotope ratio in the sample and  $R_{\text{ref}}$  is the heavy : light isotope ratio in the reference material ( $R_{\text{ref}} = 0.0111797$  for C and  $R_{\text{ref}} = 0.0036765$  for N). The atomic fraction of the heavy isotope (F) in a sample is calculated as  $F = R_{\text{sample}}/(R_{\text{sample}}+1)$ . The excess (above background) atomic fraction is the difference between the F in an experimental sample and the atomic fraction in a control (i.e. non-enriched) sample:  $E = F_{\text{sample}} - F_{\text{control}}$ . The excess incorporation of  $^{13}\text{C}$  and  $^{15}\text{N}$  was multiplied by 1,000 to express rates in  $\mu\text{mol}$  tracer C or N per  $\text{mmol}$  sponge C or N and divided by the incubation time to convert to daily rates.

## Statistical analysis

To analyze the effect of rotation without hypergravity exposure on the sponges, a two sample t-test was performed to compare the means of the two (rotating/non-rotating) groups. A chi-square test was used to compare osculum development between the two groups. Both tests were performed in *SPSS version 25 (IBM Corp. Released 2011. IBM SPSS Statistics for Windows, Version 25.0. Armonk, NY: IBM Corp.)*.

Surface area increase is expressed as a percentage relative to the original surface of each hatched gemmule in stage II at the start of the LDC experiment. The effect of hypergravity on percentage surface increase was investigated by a linear model, adopting a 0.05 significance level. Besides evaluation of the overall model significance, also the pairwise differences among the treatment-levels were made through a Tukey HSD test with a 95% family-wise confidence level.

Osculum formation was analyzed with a generalized linear model using a binomial error function. To address the effect of osculum formation and *g*-force on the mean dissolved organic matter uptake (measured by  $^{13}\text{C}$  and  $^{15}\text{N}$  enrichment), an additive linear model was evaluated, using a 0.05 significance level.

In the results, means and proportions are reported in combination with the standard deviation between brackets. All analyses were carried out in *Rstatistics programming environment* R 3.3.2(*The R Foundation for Statistical Computing, 2004-2013*).

## Results

### Sponge development under hypergravity exposure

The non-rotating and rotating controls at 1 x g did not show a significant difference in sponge growth (two-sample *t*-test,  $t(31) = -0.341$ ,  $p > 0.1$ ), skeleton formation (in both groups 100% of sponges set up a skeleton) or osculum development (chi square test,  $\chi^2(2, n = 33) = 1.8397$ ,  $p > 0.1$ ). Over all levels of (hyper)gravity exposure, 96% ( $\pm 1\%$ ) of stage II hatched gemmules developed to stage III sponges (i.e. with erected skeleton), 66% ( $\pm 7\%$ ) of all sponges reached stage IV, (i.e. build an osculum) and formed a fully functional sponge during their 48-h treatment (Table 1). Although all sponges showed a relative increase in surface area that they covered of on average 196% ( $\pm 70\%$ ), the net surface area decreased slightly, but significantly, with increasing hypergravity exposure ( $R^2 = 0.07$ ,  $n = 227$ ,  $p < 0.01$ ) (Figs. 3, 4). Comparing the different treatment levels (using a Tukey HSD test), only the relative surface area change between 1 versus 20 x g (-47%,  $p < 0.01$ ) and 5 versus 20 x g (-45%,  $p < 0.01$ ) were significant. No effect of feeding on surface area cover increase was found (Fig. 4). A significant interaction effect of g-force and feeding on mean osculum formation per group was observed, where fed sponges formed oscula less frequently than non-fed sponges, especially at higher g-force ( $\text{logit}(\text{osculum formation}) = 0.71 - 0.13 \cdot \text{feeding} + 0.06 \cdot \text{g-force} - 0.10 \cdot \text{feeding} \cdot \text{g-force}$ ; Nagelkerke- $R^2 = 0.08$ ,  $n = 227$ ,  $p < 0.05$ ).

### Tracer isotope incorporation

Amino acid assimilation was confirmed by significant enrichment in both  $\delta^{13}\text{C}$  ( $42.5 \pm 11.1\text{‰}$ ) and  $\delta^{15}\text{N}$  ( $1202.8 \pm 280.2\text{‰}$ ) in the tissues of all fed sponges versus background, non-fed, sponge tissue ( $-30.5\text{‰}$   $\delta^{13}\text{C}$  and  $18.2\text{‰}$   $\delta^{15}\text{N}$ ). On average, hatching *E. fluviatilis* assimilated  $0.4 \pm 0.1 \mu\text{mol C}_{\text{amino acids}} \text{ mmol C}_{\text{sponge}}^{-1} \text{ d}^{-1}$  and  $4.3 \pm 1.0 \mu\text{mol N}_{\text{amino acids}} \text{ mmol N}_{\text{sponge}}^{-1} \text{ d}^{-1}$  (Fig. 5). In

257 total,  $9.1 \pm 3.7\%$  and  $41.2 \pm 18.5\%$  of the amino acid carbon and nitrogen, respectively, that was  
 258 added was processed by the sponges during the 48-h incubations. No significant effect of *g*-force  
 259 was found for  $^{13}\text{C}$ -uptake, while the overall effect for  $^{15}\text{N}$  incorporation rates was significant (*C*~*g*-  
 260 force,  $n = 10$ ,  $p = 0.165$ ; *N*~*g*-force,  $n = 10$ ,  $p < 0.05$ ) (Fig. 5). When comparing the effects on  $^{15}\text{N}$   
 261 for different treatment levels (using a Tukey HSD test), only the difference between 5 x *g* versus  
 262 20 x *g* ( $-2.7$ ,  $p < 0.01$ ) appeared significant.

## 263 Discussion

### 264 Spicule skeleton construction and osculum formation under hypergravity

265 Sponges are known for their enormous plasticity and opportunistic nature when it comes to food  
 266 selection (e.g., Ribes *et al.* 1999; McMurray *et al.* 2016) and regeneration after environmental  
 267 stress (e.g., Ayling *et al.* 1983; Wulff 2010; Alexander *et al.* 2015). This is particularly important  
 268 in ecosystems with large seasonal fluctuations in water temperature and food availability, where  
 269 the formation of gemmules by freshwater sponges is a very successful strategy to survive these  
 270 adverse and possibly lethal conditions. When conditions are more favorable, gemmules hatch and  
 271 develop into fully grown sponges in order to enter a successful sexual reproductive stage and  
 272 obtain sufficient biomass to gemmulate (Funayama *et al.*, 2005; Manconi & Pronzato, 2016). The  
 273 formation of the spicule skeleton is a crucial feature of the morphogenesis of freshwater sponges,  
 274 resulting eventually in the formation of an active filter-feeding system (Rozenfeld, 1980;  
 275 Funayama *et al.*, 2005), enabling the sponge to grow and reproduce. Albeit the hypergravity forces  
 276 used in our experiment are not naturally occurring, this is the first *in vivo* study of freshwater  
 277 sponges to show that a pivotal step in the seasonal life-cycle of *E. fluviatilis* is highly resilient  
 278 under extreme levels of mechanical stress. Even after the hatched gemmules were exposed to  
 279 hypergravity forces up to 20 x g for 48 h, they managed to survive, grow, create and organize their  
 280 spicules, and develop a functional food-uptake system. In comparison, a well-trained human  
 281 astronaut has a g-force tolerance of approximately 9 x g for only short periods of seconds to  
 282 minutes (Wu *et al.*, 2012). Sponges showed a significant decrease in surface area under increased  
 283 g-force exposure, but almost all specimens ( $96\% \pm 1.2\%$ ) were able to set-up their spicule skeleton.

284 It is noteworthy that, although this study focused on the siliceous spicules of the  
 285 *E. fluviatilis* skeleton, the fibrous matrix of sponging and chitin in which the spicules are embedded,

may also play a role in withstanding environmental stress (Ehrlich *et al.*, 2010, 2013). The presence of chitin is known to be responsible for the rigidification of skeletal structures in invertebrates and marine demosponges (Brunner *et al.*, 2009; Ehrlich *et al.*, 2010) and has since long been known to be an important component of *E. fluviatilis* gemmules (Zykoff, 1892). However, it is at present unknown whether or how the fibrous matrix of the skeleton changes in response to environmental conditions.

### **Fed versus non-fed sponges under hypergravity**

We also show that hatching *E. fluviatilis* can take up dissolved nutrients (i.e. amino acids). Previous evidence corroborates that freshwater sponges can feed on dissolved organic food sources, such as dissolved proteins (Weissenfels, 1976; Manconi & Pronzato, 2008). However, this study shows, for the first time, that newly hatched gemmules take up and incorporate dissolved food sources in their tissue *before* arranging their filter system and start active pumping. The dissolved <sup>13</sup>C- and <sup>15</sup>N-labeled amino acids were most likely acquired either via passive diffusion or through phagocytosis by choanocytes or surface pinacocytes (Willenz & van de Vyver, 1982; Smith & Tiffon, 2013). However, the uptake of dissolved amino acids did not result in a significant difference in the sponges' ability to erect their skeleton nor in their surface area growth throughout the exposure to increasing levels of hypergravity, compared with non-fed sponges. This suggests that the process of erecting the spicule sponge skeleton relies mainly on intrinsic energy. However, fed sponges developed oscula significantly less frequently compared with non-fed sponges, especially at exposure to the highest (10 and 20 x) g-forces. We speculate that under extremely stressful conditions, when energy costs are highest, sponges invest in the formation of an active filtration system to acquire new energy. Additional food can help prologue the process of hatching

and skeleton development, which might increase their chances of survival throughout severe stress conditions.

### **The role of dissolved food in the diet of freshwater sponges**

The capacity of *E. fluviatilis* to readily take up dissolved food sources could be a valuable addition to their daily natural diet. Evidence is accumulating that many sponge species utilize dissolved organic matter (DOM) as major part (71–94 %) of their daily carbon intake (Yahel *et al.* 2003; De Goeij *et al.* 2008; Mueller *et al.* 2014; McMurray 2016), however, these studies were all done on marine sponge species. It has also been shown that mainly sponges with high numbers of associated bacteria (high microbial abundance (HMA) sponges) utilize DOM as food source, as opposed to the low microbial abundance (LMA) sponges (Hoer *et al.* 2018), unless sponges have an encrusting growth form (De Goeij *et al.* 2017). The freshwater sponge *E. fluviatilis* is a LMA species, but the algal symbionts of *E. fluviatilis* are not an obligate requirement for survival of the host (Wilkinson, 1980). Moreover, *E. fluviatilis* can be both encrusting and massive, depending on its stage of development. Therefore, it would be interesting to assess whether *E. fluviatilis* adjusts its diet depending on its algal symbionts or at various phases of its yearly life-cycle, and if it is able to process DOM continuously.

In tropical coral reefs, sponges play a key role in the cycling of nutrients by converting predominantly DOM into particulate organic matter (POM) through high cell turnover and detritus production, which is subsequently shunted to higher trophic levels – a process termed the sponge loop (de Goeij *et al.*, 2013). Since detritus production and rapid division of choanocytes by mitosis have been reported for *E. fluviatilis* (Weissenfels, 1976; Tanaka & Watanabe, 1984), it is likely

that similar sponge-loop processes also occur in freshwater systems. Additionally, the C:N ratio of the amino acids (5:1) in the medium was significantly lower than the assimilated C:N ratio by *E. fluviatilis* (1:5), and the sponge assimilated up to 4 times more nitrogen from the amino acids (41%) as compared with amino acid carbon (9%). Carbon could have been partly lost to respiration, but *E. fluviatilis* most likely assimilated nitrogen selectively from the amino acid source. As sponge detritus in eutrophic tropical ecosystems was found relatively enriched in nitrogen compared to sponge tissue (de Goeij *et al.*, 2013), and the current view is that limitation of nitrogen is also common in eutrophic freshwaters (Downing & McCauley, 1992), freshwater sponges might fertilize their surrounding ecosystems in the same way as their marine counterparts.

## Conclusions

Our results demonstrate that the process of skeleton formation in freshwater sponges plays an important role in their development towards a fully grown, actively pumping, and filter-feeding sponge. The finding that sponges are able to cope with extreme g-forces of up to 20 x g for as long as two days has to our knowledge never been found in a multicellular invertebrate aquatic organism. These results also support the ideas of Nakayama *et al.* (2015) that the mechanisms of self-construction shown by *E. fluviatilis* are adjusted by its (micro)environment and are potentially useful in other fields of research such as (bio)engineering. The underlying cellular and molecular mechanisms of processes such as spicule displacement, arrangement and cementing as well as their adaptive potential are at present unknown. In addition, this study supports the findings of Skelton & Strand (2013) that freshwater sponges may serve as an important energetic link between pelagic and benthic food webs in systems where sponges are abundant. The uptake of dissolved food may

be an important factor in the daily diet of freshwater sponges and they may contribute significantly to the cycling of dissolved nutrients in freshwater ecosystems.

# Figure 1

Developmental stages of germination in the freshwater sponge *Ephydatia fluviatilis*.

A: modified from Funayama *et al.* (2005). Stage 0: resting gemmule. Stage I: (approximately 2-d post-hatching): cells migrate outwards from the gemmule and differentiate into epithelial cells. Stage II: (3–4 d): cells start to proliferate and begin to differentiate into different cell types. This stage includes the development of the spicule-making sclerocytes. Spicule production generally starts around stage II and continues thereafter (Funayama *et al.*, 2005; Mohri *et al.*, 2008). Stage III: (4–5 d post-hatching): the canal system and choanocyte chambers are starting to form. Stage IV: (6–7 d post-hatching): The osculum is created approximately one week after hatching, creating a fully functional sponge. B: Hypothesized response of the influence of mechanical stress on developing sponges in combination with feeding. We hypothesize sponges will not be able to set up their spicule skeleton after prolonged exposure to increasing levels of hypergravity, but counteract this inability after additional feeding on dissolved food sources before forming a fully functional active filter-feeding system.

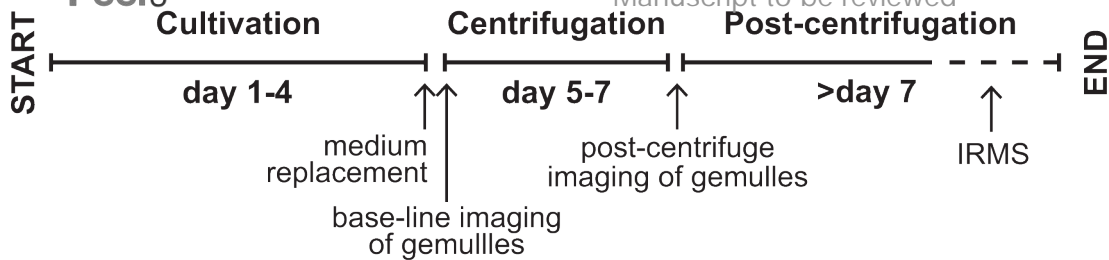

## Figure 2 (on next page)

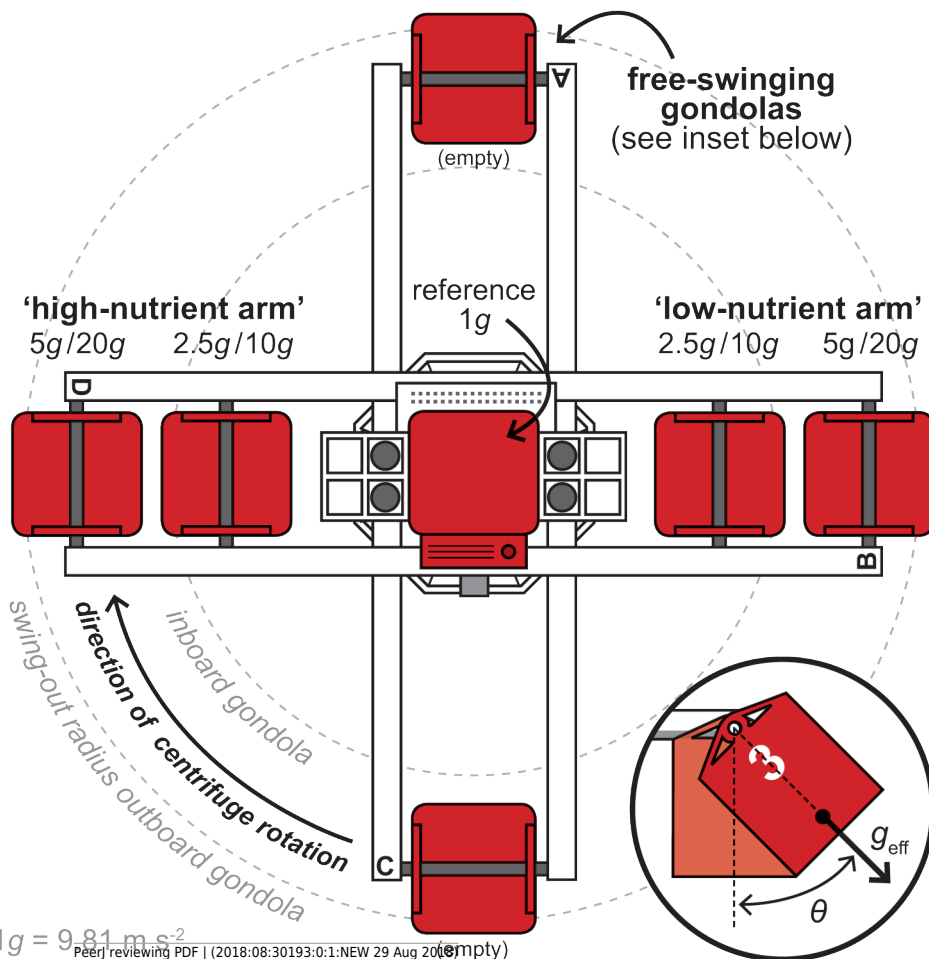

Schematic set-up of the experimental procedure using the large diameter centrifuge (LDC) at the European space agency (ESA), Noordwijk, the Netherlands.

A: Timeline of the experiment. B: Configuration of the LDC gondolas (top-view). The LDC has four arms each of which can accommodate two gondolas carrying the well plates with the gemmules. When the centrifuge is spun, the gondolas swing out at an angle ( $\theta$ ) and a hypergravity field ( $g_{\text{eff}}$ ) inside the gondolas is created by the centripetal forces due to the rotation.
