Abstract

The Chatham Rise is a highly productive deep-sea ecosystem that supports numerous substantial commercial fisheries, and is a likely candidate for an ecosystem based approach to fisheries management in New Zealand. We present the first end-to-end ecosystem model of the Chatham Rise, which is also to be best of our knowledge, the first end-to-end ecosystem model of any deep-sea ecosystem. We describe the process of data compilation through to model validation and analyse the importance of knowledge gaps with respect to model dynamics and results. The model produces very similar results to fisheries stock assessment models for key fisheries species, and the population dynamics and system interactions are realistic. Confidence intervals based on bootstrapping oceanographic variables are produced. The model components that have knowledge gaps and are most likely to influence model results were oceanographic variables, and the aggregate species groups 'seabird' and 'cetacean other'. We recommend applications of the model, such as forecasting biomasses under various fishing regimes, include alternatives that vary these components.

1 Introduction

The goal of incorporating a holistic approach to understanding the system-wide repercussions of how we manage our marine resources is admirable and ambitious (Long et al. (2015), Link and Browman (2017)). Ecosystem Based Management (EBM) requires a range of tools, often including ecosystem models (Smith et al. (2017), Stecken and Failler (2016)). Within ecosystems there are many processes at play, and the models developed to support EBM vary in scope and complexity (Plagányi (2007), Fulton (2010), Collie et al. (2016)). End-to-end ecosystem models that can deal with bottom-up and top-down system controls have become popular for exploring scenarios involving human induced impacts including fishing and climate change (Rose, 2012).

The body responsible for fisheries management in New Zealand, Fisheries New Zealand, is seeking to move away from single species management towards a more ecosystem approach, both to fulfil Fisheries Act obligations and Marine Stewardship Council (MSC) expectations (Ministry for Primary Industries (2008), Marine Stewardship Council (2014)). The Chatham Rise is the location of several nationally important MSC certified fisheries (Deepwater Group, 2018), and a growing understanding of trophic interactions exists there (Stevens et al. (2011b), Dunn et al. (2009)).

Chatham Rise is a submarine ridge running eastwards for about 1000 km from the east coast of South Island, New Zealand, rising up from depths of about 3000 m, to about 50 m at

53 the western end, and sea level around the Chatham Islands at the eastern end (Figure 1). The
54 subtropical front (STF), a relatively broad permanent feature where warmer, more saline, and
55 nutrient poor subtropical water from the north meets nutrient rich subantarctic water from
56 the south, extends up the east coast of South Island, and then eastwards along Chatham Rise
57 (Heath (1985), Uddstrom and Oien (1999)). The demersal fish assemblage on Chatham Rise
58 has the highest fish species richness in New Zealand waters (Leathwick et al. 2006). The range
59 of habitats and depths, and the influence of the STF, are expected to provide a wide variety
60 of foraging opportunities for demersal and pelagic organisms.

61
62 The Chatham Rise is perhaps New Zealand's most productive fishing ground. It supports
63 substantial commercial fisheries for finfish and invertebrates, with notable examples being:
64 trawl fisheries for hoki (*Macruronus novaezelandiae*), orange roughy (*Hoplostethus atlanticus*),
65 hake (*Merluccius australis*), and black and smooth oreos (*Alloctytus niger*, *Pseudocyttus mac-*
66 *ulatus*); a longline fishery for ling (*Genypterus blacodes*); and a potting fishery for rock lobster
67 (*Jasus edwardsii*) (Ministry for Primary Industries 2014).

68 Analyses of trawl survey series and commercial fishery catch rates have shown that marked vari-
69 ations over time have occurred in the relative abundance of some common species on Chatham
70 Rise, e.g., hoki, hake, orange roughy, scampi (*Metanephrops challengeri*), and rock lobster
71 (Maunder and Starr, 1995; Dunn et al., 2008; Stevens et al., 2017). Some factors driving these
72 fluctuations have been identified (i.e., high exploitation levels, variation in recruitment), but
73 there will certainly be other physical and biological factors that will influence animal behaviour
74 and survivability, resulting in changes to the ecosystem. A knowledge of how particular biolog-
75 ical and ecological changes could affect the abundance and distribution of species will usefully
76 inform the management of those species.

77
78 In an ecosystem, nothing exists independently. When assessing biological risks, it is diffi-
79 cult to conceptualise risk to the whole system. A system-level model within which different
80 scenarios can be explored is an extremely valuable tool for gaining conceptual understanding
81 of economic and biological risks for a whole system, as well as for individual parts.

82
83 Atlantis is an end-to-end ecosystem modelling approach that can be used to create an en-
84 vironment in which different scenarios can be played out to test for different results and learn
85 how a system may be reacting to changes within it. Reviewed as one of the best modelling
86 frameworks for exploring 'what-if' type questions (Plagányi, 2007), it includes the ability to
87 compare social, conservation, and economic outcomes. With sufficient data, this modelling
88 approach can be extremely useful for management strategy evaluation (Plagányi, 2007), and
89 has been applied to multiple marine systems (from single bays to millions of square kilometres)
90 in Australia, the United States, Europe, and South Africa (Savina et al. (2005), Fulton et al.
91 (2007), Link et al. (2010), Ainsworth et al. (2015), Smith et al. (2015), Sturludottir et al.

92 (2018), Ortega-Cisneros et al. (2017)). Atlantis is a deterministic simulation model such that
93 for a given parameter set and model specification, the model outputs are identical. Atlantis
94 models are too complex to statistically fit to observations, although subsets of key parameters
95 can be estimated using statistical methods outside of the model. Analysing and understanding
96 the model dynamics and potential weaknesses is essential before the model can be used to learn
97 about the system.

98
99 In this paper, we describe the first end-to-end ecosystem model for the Chatham Rise, New
100 Zealand (hereafter referred to as CRAM). We present analyses of the model, comparing its
101 state and dynamics to current knowledge. We identify and assess the likely influence of current
102 knowledge gaps and uncertainties.

103
104 In developing such models, knowledge gaps become evident, and we are provided with
105 the opportunity to analyse the importance of these gaps, thus guiding direction of future re-
106 search. The model was assessed for single species dynamics and inter-species connectivity. We
107 conducted a skill assessment on species groups for which we have surveys capable of index-
108 ing abundance, and compared biomass trends as the model responded to historical fishing for
109 species groups that have stock assessments or reliable catch per unit effort (CPUE) indices. We
110 simulated changes in biomass for each species group and analysed responses throughout the
111 system. This latter part formed the basis for analysing influence and importance of knowledge
112 gaps, and where a species group performed poorly in the skill assessment it often highlighted
113 a knowledge gap.

114 115 **2 Methodological Approach**

116 The process of developing this model was not linear, but rather iterative and incremental.
117 There were five main stages to the development, each of which was re-visited until we were
118 satisfied with the performance of the model and our understanding of its dynamics. The main
119 stages can be summarised as:

- 120 1.) Data and model inputs were collated and defined.
- 121 2.) The base historical model was calibrated without fishing such that this model had stable
122 biomass trajectories over the 1900–2016 model period, realistic diets, growth rates, natural
123 mortalities.
- 124 3.) Sensitivity analyses were carried out with respect to oceanographic variables and simula-
125 tions aimed at understanding connectivity and influence between the species functional groups.
- 126 4.) Fishing was included in the model using forced catch removals.
- 127 5.) Skill assessment and comparisons to abundance indices and biomass estimates were carried
128 out.

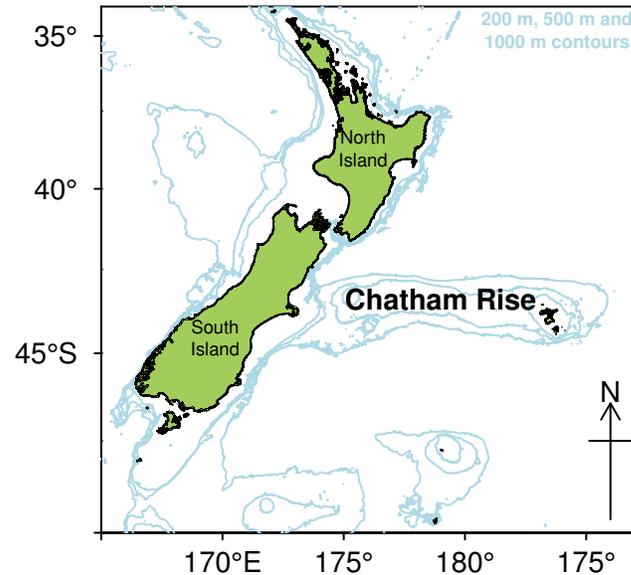

Figure 1: Map of New Zealand with Chatham Rise marked, including 200 m, 500 m, and 1000 m isobaths.

130

131 Sections 3–7 cover each of these five main stages, followed by Section 8: Bringing it together,
132 which discusses some of the implications of the models' performance, dynamics and data gaps.

133

134 3 Model design

135 An Atlantis model simulates the ecosystem through time, calculating each new state based on
136 the previous state and the events of the current timestep. This section describes the physical,
137 biological, ecological, and fishing components of the Chatham Rise Atlantis Model. Further
138 details on Atlantis can be found in the Atlantis user manual (Audzijonyte et al., 2017).

139

140 3.1 Model area

141 The Chatham Rise Atlantis model area comprises waters from the shore-line around Chatham
142 Islands (but excluding estuaries on the islands) to depths of 1300 m along the Chatham Rise,
143 New Zealand (Figure 2). The western boundary of the area is defined as the 400 m contour
144 on the western edge of the Mernoo Gap, a trough that separates the Chatham Rise from the

145 coastal shelf off the mid east coast of South Island.

146
147 An Atlantis model requires the modelled region to be split into polygons and depth layers.
148 Each polygon/depth layer is referred to as a cell. The intention of the splits is to capture
149 important aspects of the region but at a simplified level such that modelling the region over
150 many years becomes possible. If we were modelling a smaller temporal scale, we may have
151 considered a finer spatial scale. The polygons within the modelled area are referred to as dy-
152 namic polygons, and these are surrounded by non-dynamic polygons which define the boundary
153 conditions for the modelled domain.

154
155 Several investigations of fish communities or fish species richness indicated that the division
156 of the Chatham Rise into polygons for Atlantis modelling should occur primarily based on
157 depth categories, with the northern and southern slopes separated (owing to the different water
158 masses and fish communities to the north and south of the STF), and with some longitudinal
159 differentiation as well. Species communities were found to group in adjacent depth-defined
160 strata, but with differences between depths on the northern and southern Rise, as well as some
161 longitudinal differentiation (Tuck et al., 2009).

162 A large amount of data on the abundance and distribution of demersal fish and invertebrate
163 species has been collected from the series of trawl surveys of depths 200–800 m on Chatham
164 Rise in January annually from 1992 to 2014 (Livingston et al. 2002, Stevens et al. (2017)).
165 Some of the more recent surveys in the series also included strata to depths of 1300 m (Stevens
166 et al., 2017). The survey area was stratified by depth, latitude, and longitude. It was logical,
167 therefore, to base the Atlantis model polygon boundaries on the trawl survey strata boundaries.
168 This is also helpful for informing the model spatially based on trawl surveys. Consequently,
169 the model area was divided into 23 dynamic polygons based on bottom depth bins (< 200 m,
170 200–400 m, 400–600 m, 600–800 m, 800–1300 m), with bins deeper than 400 m separated into
171 northern and southern Rise polygons, and with longitudinal separation (where trawl survey
172 strata allowed) aimed at producing western, central, and eastern polygons. The dynamic poly-
173 gon area is surrounded by 6 additional non-dynamic polygons which allows for the exchange of
174 water, nutrients and biota into and out of the dynamic model domain. The final configuration
175 of the dynamic and non-dynamic polygons is shown in Figure 2.

176
177 All model polygons are further divided into water column depth layers, ranging from one
178 layer in some near-shore polygons to five layers for the deepest polygons. Depth layers are also
179 defined in Figure 2. Each box also contains one epibenthic and one sediment layer.

180

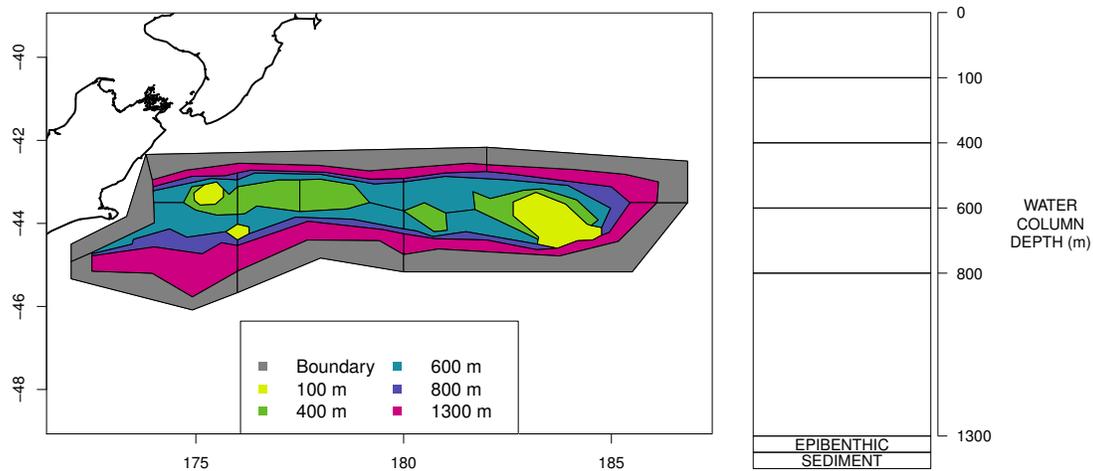

Figure 2: Polygons as defined for CRAM with maximum depths for each polygon shown by colour (left) and depth layer bins (right).

3.2 Time

The model was run with a 35 year burn-in period (1865–1900) followed by a 115 year modelled period (1900–2015). The burn-in period allows for the model to adjust from potentially unstable initial conditions due to uncertainty of some of the parameters and age distributions for the age resolved groups, to a state that is more stable. A 35 year period was chosen as it covered initial fluctuations of most functional groups in the model. All results presented here are from the modelled period 1900–2015. The model used 12 hour timesteps to allow for changes in temperature, light and feeding patterns between night and day.

3.3 Oceanography

Salinity, temperature and water exchange between cells were forced in the Atlantis model using outputs from a ROMS (Regional Oceanographic Modelling System) model (Hadfield et al., 2007) that covered years 1996–2004. Water currents across each box face cause the horizontal movement of nutrients (such as ammonia and nitrate) available to primary producers. The speed and direction of currents influence the spatial distribution of plankton groups. Water temperatures influence biological processes such as respiration (Hoegh-Guldberg and Bruno, 2010). Based on sea surface temperatures (SST), the ROMS years (1996–2004) look to be fairly representative of those properties from 1961–2017 (Figure 3). The base model presented here repeated the available ROMS variables as a nine-year cycle. Averaging the ROMS variables was not sensible due to the water exchange between cells, as these change every 12-hour timestep in strength and direction, and averaging them could easily result in implausible physical dynamics. We ran sensitivities varying the order of ROMS years or repeating one ROMS year to

202 help understand the effects of inter-annual oceanographic variability on this model.

203

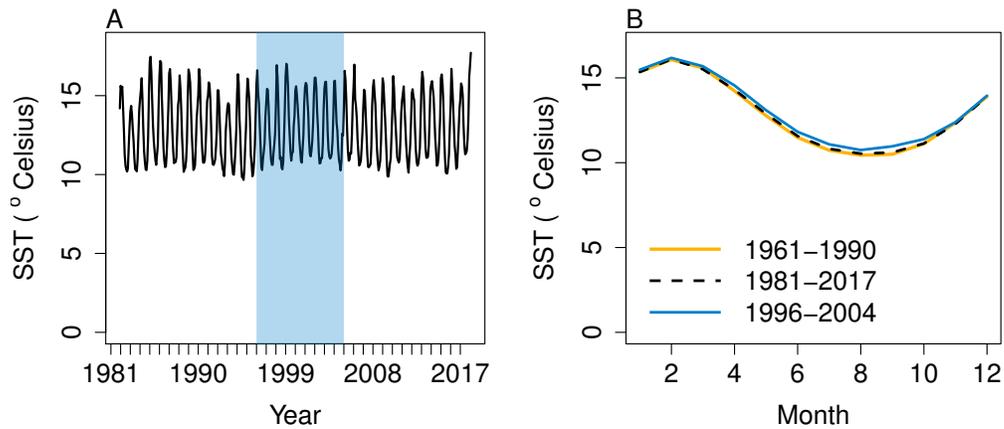

Figure 3: Sea surface temperature (SST) ($^{\circ}$ Celsius) weekly averages for 1981–2017 with ROMS years 1996–2004 shaded blue (left) and mean SST by month (right) from the same data for 1981–2017 (black dashed line), with the subset from 1996–2004 (blue solid line), and additional historical SST data from 1961–1990, which were only available as monthly averages (orange solid line).

204 3.4 Nutrients

205 Atlantis models use nitrogen, an important and often limiting nutrient in marine systems
 206 (Moore et al., 2013), to track the transfer of energy throughout the system. The nitrogen cycle
 207 can be seen in Figure 4. When biomass pools are tracked in the model, they are done so in
 208 mg N m^{-3} . When a fish (for example) eats another fish, it is nitrogen that is transferred up
 209 the food chain, with some nitrogen going to detritus and carrion, thus providing nitrogen to
 210 micro-organisms and filter feeders to fuel the cycle over again.

211 3.4.1 Nutrient data

212 Oxygen (O_2), nitrates (NO_3), ammonium (NH_4^+) and silica (SiO_2) were simulated in the
 213 model, and required spatially defined initial conditions (values for each cell in the model do-
 214 main). Table 1 has a summary of the data sources for these nutrients. We used values from
 215 the World Ocean Atlas (WOA) for initial conditions for nitrate values down to 500 m, oxygen
 216 down to the full model depth of 1300 m, and silica down to 1300 m. The WOA contains
 217 objectively analysed climatological fields of *in situ* oxygen, temperature, salinity, and some
 218 nutrients (Locarnini et al., 2013; Zweng et al., 2013; Garcia et al., 2013a,b). $NO_3 \mu\text{mol/m}^3$
 219 were converted to mg N/m^3 by multiplying by 14 as the molecular mass of nitrogen is 14 g/mol .

220

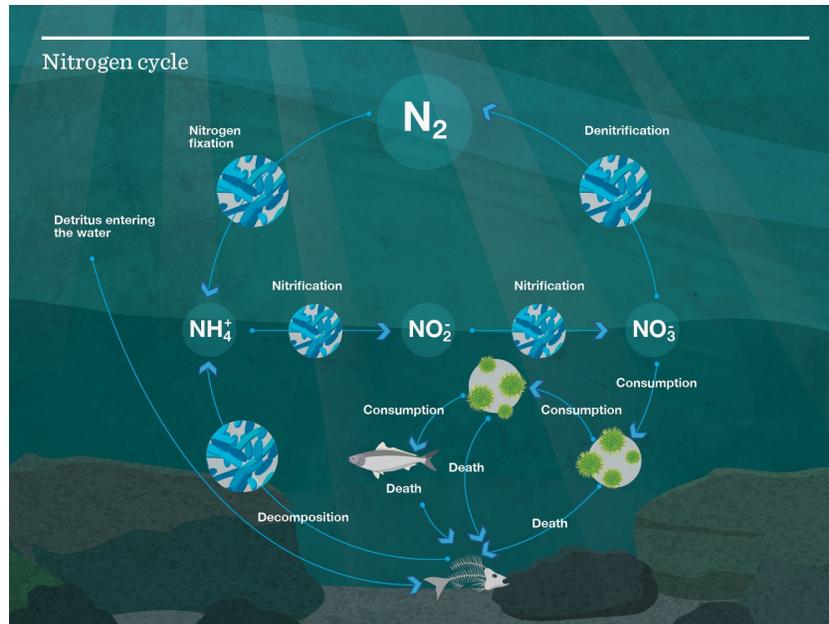

Figure 4: Nutrient cycle as modelled in Atlantis.

221 World Ocean Circulation Experiment (WOCE) (Deutsches Ozeanographisches Datenzen-
 222 trum, 2006) data were used for nitrates at depths greater than 500 m, which were not covered
 223 by WOA. WOCE data were also used to compare values for oxygen, to inform initial conditions
 224 for silica, and to compare with salinity, temperature and chlorophyll *a*.

225

226 Ammonium values were available from NIWA (National Institute of Water and Atmospheric
 227 Research) oceanographic surveys, but only down to 50 m. This was not too concerning as am-
 228 monium is a small component of the nitrogen budget.

229

Table 1: Sources of data for Oxygen, Nitrates, Ammonium and Silica. WOA, World Ocean Atlas; WOCE, World Ocean Circulation Experiment; NIWA, National Institute of Water and Atmospheric Research.

| Variable | Source | Depth | Latitude | Longitude |
|----------|-------------|--------|----------|--------------|
| Oxygen | WOA | 1300 m | 42–47 S | 172 E –170 W |
| Oxygen | WOCE | 1300 m | 42.5 S | 180 E |
| Nitrate | WOA | 500 m | 42–47 S | 172 E –170 W |
| Nitrate | WOCE | 1300 m | 42.5 S | 180 E |
| Silica | WOCE | 1300 m | 42.5 S | 180 E |
| Ammonium | NIWA survey | 0–50 m | 43–46 S | 172 E –180 E |

230 3.5 Species groups

231 CRAM uses 53 functional groups to model the biological processes. Of these 53 groups,
 232 15 vertebrates, and one invertebrate comprised single species; all other groups comprised
 233 two or more species. The main component species of the groups are shown in Tables 2
 234 –5. All vertebrate groups and five invertebrate groups were modelled with age-structure
 PeerJ reviewing PDF | (2018:08:30338:1:2:NEW 19 Dec 2018)
 235 using up to 10 age-classes and varying number of years per age-class, depending on

Table 2: List of functional vertebrate groups for CRAM. Name is the species group name which is the same as the main species name for single-species groups but without punctuation. Lifespan is the assumed maximum number of years an individual in that group may live. Ben, benthic; Dem, demersal; invert, invertivore; pisc, piscivore.

| Name | Main species | Lifespan (years) |
|---------------------|--|------------------|
| Baleen whales | Southern right whales (<i>Eubalaena australis</i>) | 80 |
| Basketwork eel | Basketwork eels (<i>Diastobranchus capensis</i>) | 30 |
| Baxters dogfish | Baxter's dogfish (<i>Etmopterus baxteri</i>) | 50 |
| Ben fish deep | Four-rayed rattail (<i>Coryphaenoides subserrulatus</i>) | 20 |
| Ben fish shal | Oblique banded rattail (<i>Coelorinchus aspercephalus</i>) | 10 |
| Black oreo | Black oreo (<i>Alloctytus niger</i>) | 120 |
| Bollons rattail | Bollons' rattail (<i>Caelorinchus bollonsi</i>) | 20 |
| Cetacean other | Primarily sperm & pilot whales & dolphins | 30 |
| Dem fish pisc | Giant stargazer (<i>Kathetostoma giganteum</i>) | 20 |
| Elasmobranch invert | Primarily skates & dogfish | 20 |
| Elasmobranch pisc | Primarily semi-pelagic sharks | 50 |
| Epiben fish deep | Spiky oreo (<i>Neocyttus rhomboidalis</i>) | 100 |
| Epiben fish shal | Common roughy (<i>Hoplostethus atlanticus</i>) | 10 |
| Ghost shark | Dark ghost shark (<i>Hydrolagus novaezealandiae</i>) | 20 |
| Hake | Hake (<i>Merlucciidae</i>) | 30 |
| Hoki | Hoki (<i>Macruronus novaezealandiae</i>) | 20 |
| Javelinfish | Javelinfish (<i>Coelorinchus australis</i>) | 10 |
| Ling | Ling (<i>Molva molva</i>) | 30 |
| Lookdown dory | Lookdown dory (<i>Cyttus traversi</i>) | 30 |
| Mackerels | Slender jack mackerel (<i>Trachurus murphyi</i>) | 30 |
| Orange roughy | Orange roughy (<i>Hoplostethus atlanticus</i>) | 120 |
| Pelagic fish lge | Southern bluefin tuna (<i>Thunnus thynnus</i>) | 20 |
| Pelagic fish med | Barracouta (<i>Thyrstites atun</i>) | 10 |
| Pelagic fish sml | Myctophids (<i>Myctophidae</i>) | 4 |
| Pinniped | NZ fur seal (<i>Arctocephalus forsteri</i>) | 20 |
| Reef fish | Blue cod (<i>Parapercis colias</i>) | 20 |
| Seabird | Seabirds & shorebirds | 20 |
| Seaperch | Seaperch (<i>Helicolenus</i> spp.) | 50 |
| Shovelnosed dogfish | Shovelnosed dogfish (<i>Deania calcea</i>) | 40 |
| Smooth oreo | Smooth oreo (<i>Pseudocyttus maculatus</i>) | 100 |
| Spiny dogfish | Spiny dogfish (<i>Squalus acanthias</i>) | 30 |
| Warehou | Silver, white & blue warehou | 20 |

Table 3: List of functional invertebrate groups for CRAM. Name is the species group name which is the same as the species name for single-species groups. Description includes main species. Lifespan is the maximum number of years an individual in that group may live. Those groups with no value for lifespan are modelled as biomass pools and hence do not have a lifespan defined as this is only relevant when modelling numbers. Zoo, zooplankton; Invert comm, commercial invertebrates; herb, herbivore; scav, scavenger.

| Name | Description | Lifespan (years) |
|------------------|---|-------------------------|
| Arrow squid | Arrow squid | 2 |
| Benthic Carniv | Benthic carnivores | |
| Carniv Zoo | Planktonic animals (size 2–20 cm) | |
| Cephalopod other | Squid & octopus | 2 |
| Deposit Feeder | Detritivores and benthic grazers | |
| DinoFlag | Dinoflagellates | |
| Filter Other | Non-commercial benthic filter feeders | |
| Gelat Zoo | Salps, ctenophores, jellyfish | |
| Invert comm herb | Paua & kina | 10 |
| Invert comm scav | Primarily scampi & crabs | 14 |
| Meiobenth | Benthic organisms (size 0.1–1 mm) | |
| MesoZoo | Planktonic animals (size 0.2–20 mm) | |
| MicroZoo | Heterotrophic plankton (size 20–200 μm) | |
| Rock lobster | Rock lobster | 12 |

Table 4: List of functional phytoplankton and algae groups for CRAM. Name is the species group name which is the same as the main species name for single-species groups. Description includes main species.

| Name | Description |
|--------------------|-------------------------------|
| Diatoms | Diatoms (large phytoplankton) |
| Macroalgae | Macroalgae |
| Microphytobenthos | Unicellular benthic algae |
| Pico-phytoplankton | Small phytoplankton |

Table 5: List of functional bacteria and detritus groups for CRAM. Name is the species group name which is the same as the main species name for single-species groups. Description includes main species.

| Name | Description |
|---------------------|---|
| Carrion | Dead and decaying flesh |
| Labile detritus | Organic matter that decomposes at a fast rate |
| Pelagic bacteria | Pelagic bacteria |
| Refractory detritus | Organic matter that decomposes at a slow rate |
| Sediment bacteria | Sediment bacteria |

3.5.1 Initial conditions and biological parameters for species groups

Initial biomasses for each species group were estimated using a single species stochastic stock assessment model, CASAL (Bull et al., 2012). Biomass estimates for the entire Chatham Rise were derived by using known biological parameters and a catch history to project back from an absolute abundance estimate in 2003. Values of relative abundance were available for most species groups from trawl surveys conducted annually from 1992 to 2014 (see O’Driscoll et al. (2011)). For each survey, these abundance estimates were converted to absolute values using trawl catchability quotients (specific to each group) derived by our expert opinion, as fisheries scientists with experience dating back more than 30 years. Estimated absolute abundance for each group in 2003 (the midpoint of the survey series) was taken as the mean from all the survey estimates. For each species group, the initial biomass estimate was distributed across polygons in proportion to the survey series estimates (i.e., the mean proportion of total biomass by polygon over the survey series). The distribution of biomass by depth layer in each polygon was derived using our expert opinion. Where there was no available catch history (e.g. seabirds), or no useful estimates of relative abundance from the trawl surveys (e.g. rock lobster), initial biomasses (and their distribution by model polygon) were estimated using our expert opinion. For age-structured groups, initial biomass estimates were assigned to age-classes using estimates of instantaneous natural mortality (M). Initial average weights at age were calculated using Von Bertalanffy growth and length-weight conversion parameters. Values used for these parameters are in Table 6. Weights at age were split into reserve and structural components using ratio $R_N : S_N = 2.5 : 1$. This allows for an individual’s body mass to decrease by approximately 70% before starving, which is within the 60–80% range suggested by Broekhuizen et al. (1994).

All age-structured groups were modelled with Beverton-Holt recruitment, the steepness (h) values for which are in Table 6. These values are not ever well known, and scenarios explored using this model should consider sensitivities for these.

Table 6: Biological parameters assumed for age-structured species groups. VB, von Bertalanffy; M, instantaneous natural mortality rate; h, steepness value for the Beverton-Holt stock recruitment relationship. Length-weight parameters are: $W = aL^b$ (weight W in g, length L in cm). Where Reference is ‘Trawl db’ some data have been derived from the NIWA trawl survey database (see Mackay (2000)). Species group matches ‘Name’ in Tables 2 and 3 and are without punctuation.

| Species group | VB Growth | Length-weight | M | h | Reference |
|---------------|-----------|---------------|---|---|-----------|
|---------------|-----------|---------------|---|---|-----------|

| | Linf (cm) | K | T_0 | a | b | | | | |

3.6 Predation

Simulated predation was a four step process that occurred within each cell and at each timestep. From the predator's perspective the steps modelled can be summarised as: 1.) Am I allowed to eat it? 2.) Is it in the same place at the same time as me? 3.) Does it fit in my mouth? 4.) How much can I eat? Full details are in the Atlantis User's Guide (Audzijonyte et al., 2017). Step 4 uses a feeding functional response, of which there are 12 options currently available in Atlantis. We have applied the Holling Type II functional response to all age-structured species groups in this model, thus influencing the amount of prey consumed by prey abundance, and the predators search rate and handling time.

Diets of each species group were summarised in categories Algae, Bacteria, Bird, Cetacea, Coelenterate, Crustacean, Detritus, Echinoderm, Elasmobranch, Microzooplankton, Mollusc, Phytoplankton, Polychaete, Teleost, and Tunicate similar to that done in the diet study of Stevens et al. (2011a) (Figure 5). While this summary misses the temporal, spatial, age and size components of the predator-prey interactions, it is useful to check overall diets. For example, warehou and smooth oreos eat mostly salps (tunicates) as expected; Baxter's dogfish eat mostly fish, crustaceans, molluscs and tunicates as expected; and invertebrate herbivores (kina and paua) eat mostly algae, although they should also eat some phytoplankton, which they do but it is lost in the detail.

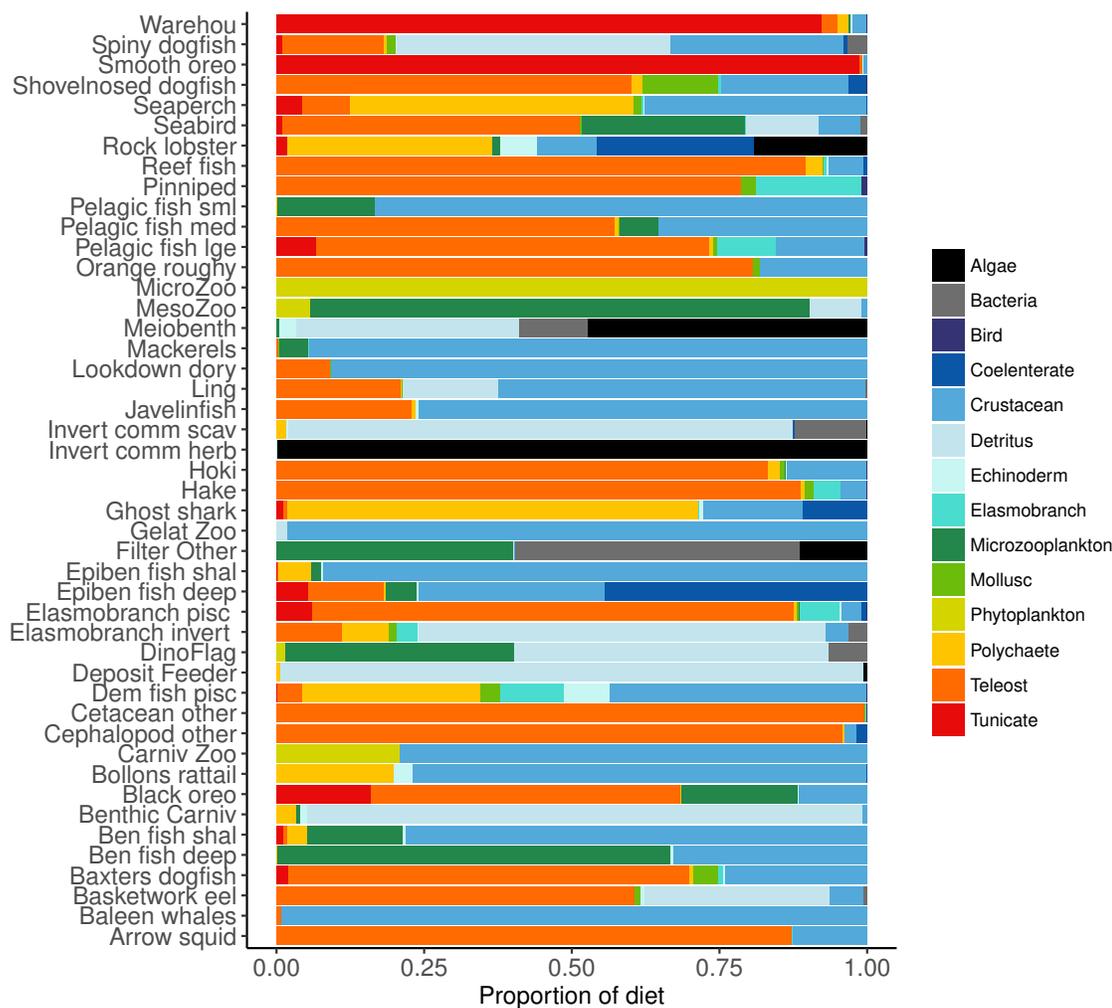

Figure 5: Summary of the proportion of prey groups in the diets of species functional groups (Tables 2 and 3) over model years 1900–2016 from the fished model where the proportion is by mg N consumed.

4 Calibration

Calibration of the model included ensuring stable biomass trajectories when applying no fishing; realistic realised diets; realistic growth and mortality (size-at-age and proportions-at-age); and biomass decreasing with increasing trophic level following the PREBAL (Link, 2010) guidelines.

Biomass trajectories should reach a quasi-equilibrium when modelled with constant oceanography and no fishing (Kaplan and Marshall, 2016). While oceanography is not constant in our non-fishing model as it changes by year (Section 3.3), most of the age-structured groups should still be fairly stable. This was generally the case; all biomass trajectories remained within CVs of 20% over the simulated 1900–2016 model period, except for invertebrate scavengers (commercial) and seaperch. Invertebrate scavengers (commercial) are primarily scampi, and they are likely responding to changes resulting from the oceanographic variables. Biomass trajectories for all age-structured groups from the un-fished model are in Appendix A. Seaperch biomass was trending downward initially, but they seem to have reached an equilibrium by about 1950, with expected growth and mortality rates.

Atlantis simulates growth rates of age-structured groups as a function of consumption. If growth is too slow, there may be insufficient food available, the feeding search rate could be too low or handling time too high, and the reverse of these when growth is too fast. Simulated growth rates of age-structured species groups were assessed by comparing the simulated size-at-age with those expected based on growth curve estimates from the literature (Table 6). The overlaid simulated and ‘observed’ figures were generally very similar (Appendix B). For each species group, we estimated CVs required to satisfy the hypothesis that the modelled size-at-age were not significantly different from the ‘observed’ with probability of 0.95. The required CVs were all less than 30% except for epibenthic fish (deep and shallow), invertebrate herbivore (commercial), invertebrate scavenger (commercial), ling, rock lobster and small pelagic fishes. For all these groups, the first age class, and sometimes the first few, were larger in size than expected. Deep epibenthic fish were larger than expected at all age classes, but for all other groups the characteristic of larger than expected size at age had been remedied by the time they were adults.

Natural mortality in the model consists of mortality intrinsic within the model from predation, starvation, and light, oxygen or nutrient deprivation, and additional forced

331 mortality. The latter was applied for modelled species groups that would not other-
 332 wise suffer sufficient natural mortality within the model, such as those that have little
 333 known predation. Age-structured simulated natural mortality rates from the stable base
 334 model were compared to estimates of M from the literature where available (Table 6) by
 335 comparing the proportions-at-age. The overlaid simulated and ‘observed’ figures were
 336 generally very similar (Appendix C), although rock lobster and invertebrate herbivore
 337 commercial (primarily paua and kina) had slightly more mortality in the model, and
 338 demersal piscivores, epibenthic fish small, pelagic fish medium, and warehou had slightly
 339 less mortality.

341 We summarised biomass by trophic level for the base model as at 2016 on a log-scale,
 342 and biomass reduced with increasing trophic level with a fitted slope of -1.6 (Figure 6).
 343 This was close to the recommended range of PREBAL of (-1.5, -0.5). The biomass at
 344 trophic level 4 was slightly higher in this summary than in the model, as the summary
 345 was based on adult trophic level and many of the fish species are trophic level 4 as
 346 adults, but lower as juveniles. This resulted in the biomass of the juveniles for these
 347 fish adding to the level 4 biomass whereas in the model they were perhaps functioning
 348 as a level 3.

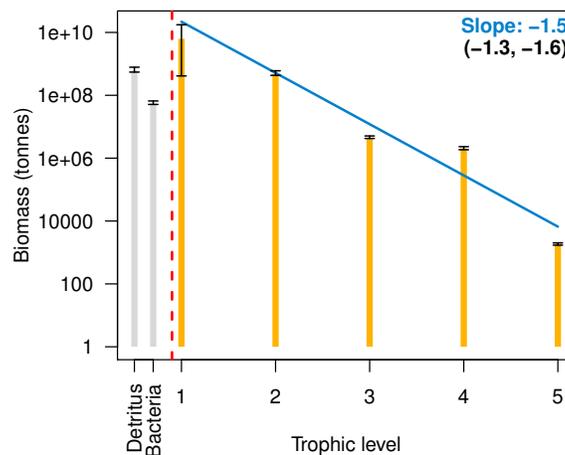

Figure 6: Biomass by trophic level with 95% confidence intervals from the 1900–2016 Chatham Rise Atlantis model simulation. The blue line is the fitted linear model to the median biomasses by trophic level, the slope which is in blue. The slopes of the linear models to fitted to the upper and lower 95% confidence interval limits are given in brackets.

349

5 Sensitivity analyses

5.1 Oceanography

Oceanographic variables from a ROMS (Regional Oceanographic Modelling System) model for years 1996–2004 were used to define temperature, salinity and flux (water exchange). As our model spanned more than these years, we needed to recycle the ROMS variables in some way. The purpose of this section has two parts: 1.) establishing confidence intervals for our model simulations with respect to oceanographic variability; 2.) assessing the effect of repeating oceanographic variables from any one year, and whether these take the model outside of the established confidence intervals.

To retain realistic within-year dynamics, the ROMS variables from each year were kept together as a unit, and the years covered by the ROMS model were considered the samples. We ran two sets of simulations: the first sampled ROMS years at random with replacement for each model year simulated (bootstrapped the ROMS years) and repeated this for 50 model runs; the second repeated one ROMS year for all model years simulated and did a separate model run for each of the nine ROMS years. In both cases, the 2003 ROMS was repeated for a 35-year burn-in period, followed by a 50 year simulation. The 2003 ROMS was chosen for the burn-in period as this year had the closest sea temperatures to the means from all ROMS years (Figure 7). Bootstrapping the ROMS years was used to establish confidence intervals with respect to between-year oceanographic variability. Repeating each ROMS year in turn was testing the effect of multiple years being different to the other years in some consistent way, such as cooler or warmer.

The established biomass confidence intervals were fairly narrow for most species groups, with CVs $< 10\%$. Of the exceptions, diatoms had the highest CV of 79%, followed by carnivorous zooplankton (46%), labile detritus (23%), sediment bacteria (13%), invertebrate scavengers (commercial) (12%), refractory detritus (12%), meso-zooplankton (11%) and pelagic bacteria (11%). That these groups were found to be most sensitive to oceanographic variability in the model is a plausible and sensible result.

The years with cooler sea temperatures (1996, 1997, and 2004) when repeated for 50 years produced the most species groups that went above the established biomass confidence intervals, with the on average warmer years (1999, 2000, and 2001) having the most species groups that went below (Figure 8). These species groups affected by

385 warmer or cooler years had quite a bit of overlap, with meso-zooplankton, meiobenthos,
 386 and black oreo most often affected. All of the species groups that went lower in warm
 387 years also went higher in cool years. The reverse was not true; three species groups
 388 (arrow squid, labile detritus, and ghost shark) went higher in the cool years, but not
 389 lower in the warm years.

390 Years 2003 and 1998 were closest to the average sea temperatures and had the least
 391 number of species groups outside the bootstrap confidence intervals. The Base Model
 392 that repeated the ROMS from all nine years in order for the entire model simulation had
 393 16 species groups that exceeded the bounds at some point (less than the warm years)
 394 and six species groups that went below the bounds at some point (less than the cool
 395 years) (Figure 8).

396

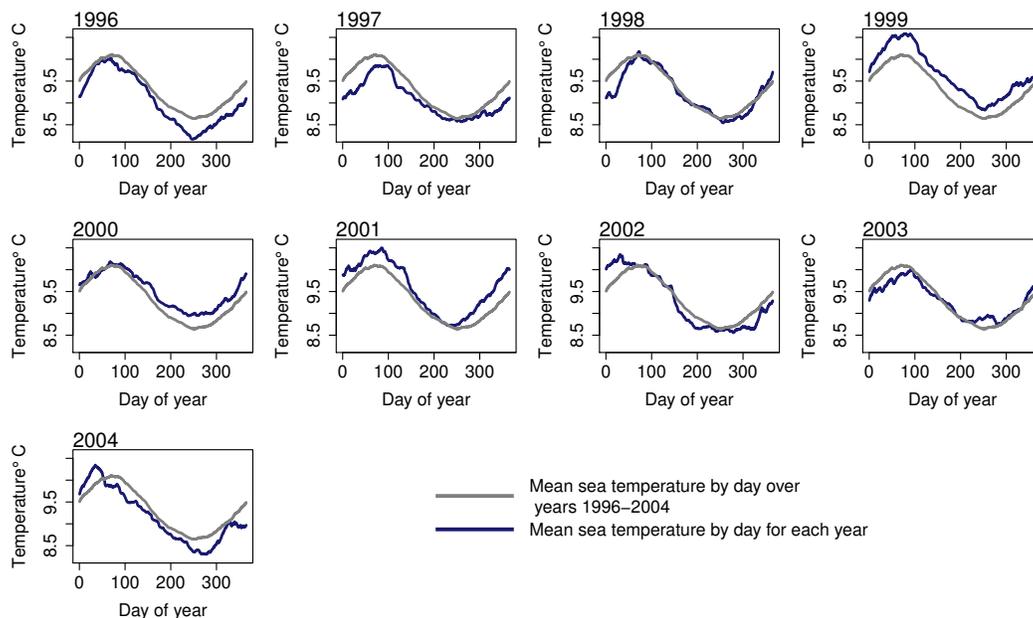

Figure 7: Sea temperature ($^{\circ}\text{C}$) from ROMS model outputs by day for each year 1996–2004 (dark blue line) and median sea temperature over all ROMS model years 1996–2004 (grey line).

397 5.2 Connectivity and influence

398 Understanding which species groups are most influential or responsive in the model is
 399 another test for realistic dynamics, and may be useful to help understand results of
 400 scenarios explored using this model in the future. To do this, we need to perturb each
 401 species group in turn, then assess the responses of the other groups in the system. For
 402 each age-structured species group, we ran two simulations, one with a small additional

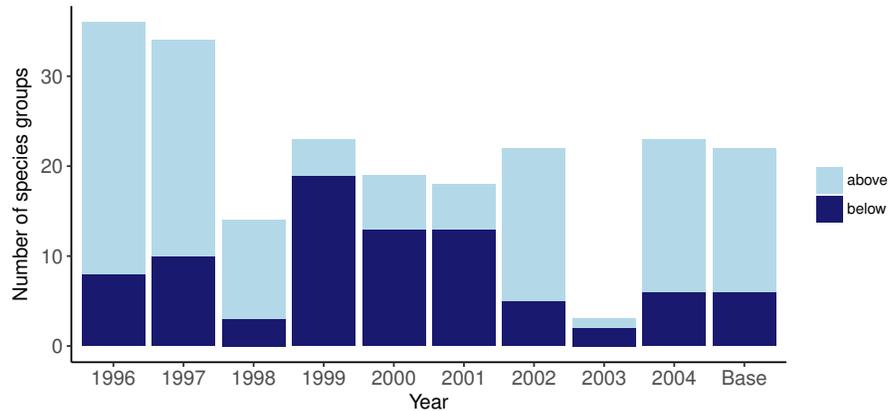

Figure 8: Number of species groups for each simulation with one ROMS year repeated that went above (light blue) or below (midnight blue) the limits of bootstrapped ROMS simulations and for the Base Model where the years were repeated in order for the entire model simulation.

403 mortality and one larger; $M(\text{per year}) + (0.1, 0.005)$. We assessed responses of the
 404 groups with respect to the Base Model at the completion of 50-year simulations. We
 405 analysed the ‘keystoneness’ and responsiveness of the groups based on biomasses relative
 406 to the Base Model.

407
 408 We calculated keystoneness using an adaption of the method in Libralato et al.
 409 (2006). It is a measure of the effect the group has on the rest of the system (change in
 410 biomass of the other species groups), that takes into account its proportion of the total
 411 biomass. For example, if two species groups have the same effect, but one has a large
 412 biomass and one a small biomass, the smaller would have a larger keystoneness. We
 413 used simulation outputs to estimate the total effect (ϵ) of each species group (Equation
 414 1) which used the change in biomass of each group relative to the Base Model (Equation
 415 2). The simulated change in biomasses ($S_{f,g}$) were used in place of the mixed trophic
 416 impact values calculated from mass balanced models and used by Libralato et al. (2006).
 417 As the additional mortality applied in our simulations caused larger and smaller changes
 418 to the focus groups, we scaled the focus groups’ biomass proportions by their change in
 419 biomass ($S_{f,f}$ in Equation 4). Hence, the resulting keystoneness allowed for the effect
 420 changing each group had on the other groups, the focus groups biomass as a proportion
 421 of the total, and the proportional change in biomass of the focus group relative to the
 422 base model.

423

$$\epsilon_f = \sqrt{\sum_{g \neq f}^G S_{f,g}^2} \quad (1)$$

$$S_{f,g} = \frac{B_{f,g} - B_{b,g}}{B_{b,g}} \quad (2)$$

$$\kappa_f = \log(\epsilon_f(1 - p_f)) \quad (3)$$

$$p_f = \frac{B_{b,f}}{\sum_{g=1}^G B_{b,g}} \times |S_{f,f}| \quad (4)$$

424

425 ϵ_f , effect group f has on the other groups426 $S_{f,g}$, proportional change in biomass of group g when group f was reduced, relative to
427 the Base Model428 $B_{b,g}, B_{b,f}$, biomass in base model of group g, f 429 $B_{f,g}$, biomass of group g in model with group f mortality increased430 κ_f , keystone-ness of group f 431 p_f , biomass proportion of group f

432

433 There were four species groups that stood out as having more effect than the other
434 groups: orange roughly, hoki, pelagic fish small (primarily myctophids) and spiny dog-
435 fish. These remain the top four for keystone-ness, but the order changes due to the
436 proportional biomasses (Figure 9).437 We calculated responsiveness in a similar way to keystone-ness, but from the perspec-
438 tive of the response group (Equation 5).

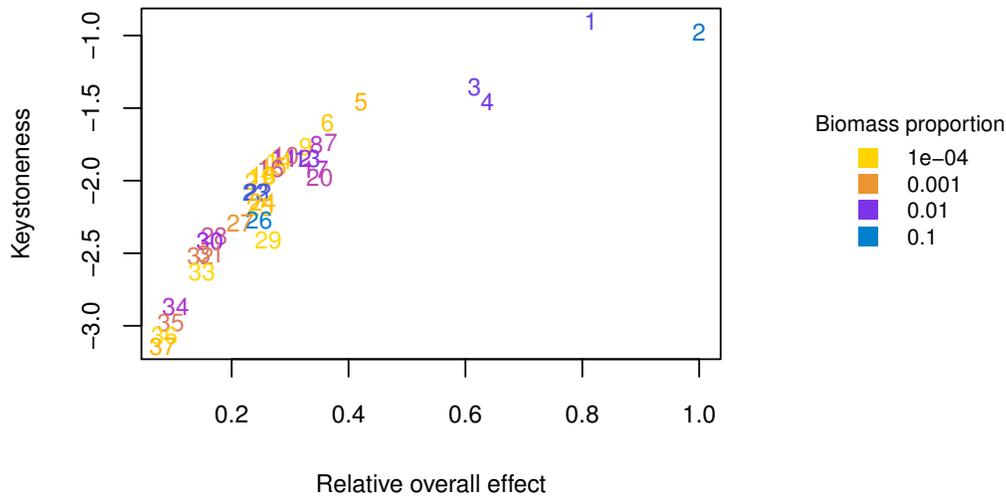

439

$$R_g = \sqrt{\sum_{f \neq g}^G (m_{f,g}^2 \times p_f)} \quad (5)$$

440 R_g responsiveness of group g to increased mortality in all other groups

441

442 The most responsive group was pelagic fish small (primarily myctophids), followed
443 by smooth oreo, invertebrate scavengers commercial (primary scampi), and pelagic fish
444 medium (primarily barracouta) (Figure 10). The pelagic fish small species group ranked
445 high for keystone-ness and responsiveness, and so may be most important and influential
446 in scenarios explored with this model.

6 Fishing

448

449

450

451

452

453

454

455

Most of the fisheries on the Chatham Rise became established after the mid-1970's, with the exception of the blue cod (*Paraperis colias*) (reef fish species group) fishery which extends back to the early 1900's. Individual catch histories are in Appendix D and Figure 11 presents a summary of catches from the Chatham Rise with the top six species by total catch shown in colour and the others combined into an 'other' category. Hoki had the largest total catch, followed by orange roughy, smooth oreo, ling, black oreo, then barracouta. Orange roughy comprised the largest individual fishery in the late-1970's-early-1990's after which it declined markedly; from the 1990's hoki was the

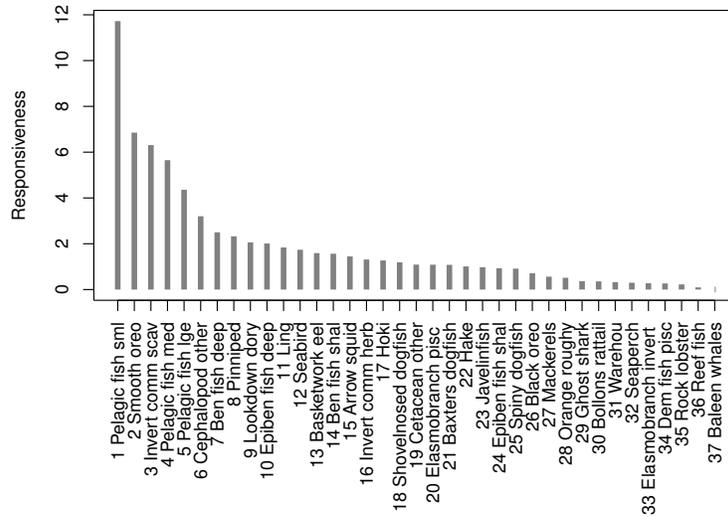

Figure 10: Responsiveness of age-structured species groups after 50 years of perturbation, as calculated in Equation 5.

456 dominant fishery.

457

458 The fisheries were modelled with six fleets, defined in Table 7. The demersal line
 459 fishery was dominant until mid-late 1960's when the demersal trawl fishery became
 460 dominant, catching approximately 70 000 tonnes per year (Figure 12). The historical
 461 catches from these fleets were forced in the model using spatially and temporally resolved
 462 inputs.

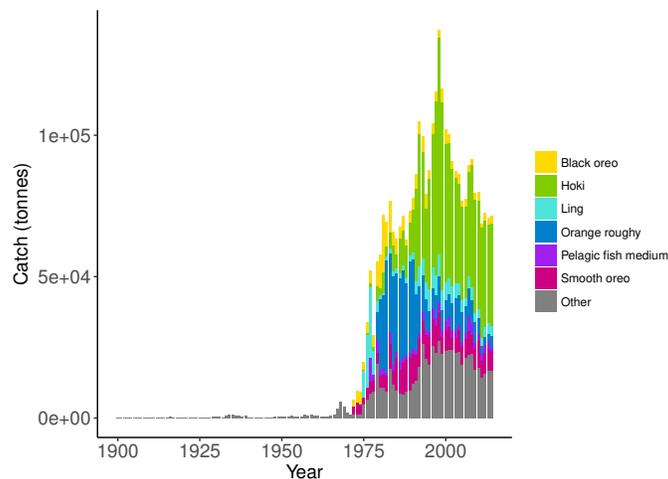

Figure 11: Tonnes caught from Chatham Rise 1900–2014 for all species with top six species groups by total catch coloured separately.

Table 7: Fishing fleets defined for Chatham Rise Atlantis model. Number of species groups is the number of species groups that have been caught by each fishing fleet; total catch is the total tonnes caught by each fishing fleet from 1900–2014.

| Code | Description | Number of species groups | Total catch (t) |

6.1 Comparison with fisheries CPUE and Stock Assessment indices

CRAM model estimates of biomass trends for key fisheries species were compared to CPUE and/or stock assessment indices where these were available. The Atlantis model captures the main biomass trends of hoki in response to historical fishing (Figure 13). Hoki are the largest fishery on the Chatham Rise, and has one of the most complex stock assessment models in New Zealand, with multiple areas, intricately defined migration, and annual recruitment deviates (McKenzie, 2016). The Atlantis model results are very similar to the stock assessment model results for hake and ling, and although the stock assessment models for these are not as complicated as hoki, they still have between-year recruitment deviates (Horn, 2013; McGregor, 2015) that are not present in the Atlantis model. The species group ‘Invertebrate scavengers (commercial)’ is primarily scampi, and the matched increase in the late 1990s–early 2000s is particularly pleasing as catches were fairly constant over this time (Tuck, 2016), so the increase is coming from dynamics within the model. Orange roughly is a close match to the stock assessment, even though this stock assessment model also has between-year recruitment deviates (Dunn

479 and Doonan, in press) that are not in the Atlantis model. The magnitude of the stock
 480 assessment biomasses (unscaled) are compared to the CRAM biomasses in the inset
 481 boxplots in Figure 13. Hoki, hake, and invertebrate scavengers (commercial) were all
 482 close to one, indicating matched magnitudes between the stock assessment and CRAM
 483 biomasses. Ling were generally less than one, indicating the CRAM biomasses were
 484 larger than the stock assessment biomasses. Orange roughly were greater than one, in-
 485 dicating CRAM biomasses were smaller than the stock assessment biomasses.

486

487 7 Skill assessment

488 Quantitative skill assessments have become popular as part of assessing the performance
 489 of Atlantis models (Sturludottir et al., 2018; Ortega-Cisneros et al., 2017; Olsen et al.,
 490 2016). A quantitative skill assessment was carried out, comparing model biomass esti-
 491 mates with those from trawl surveys where available (O’Driscoll et al., 2011; Stevens
 492 et al., 2017). The trawl surveys target hoki, hake and ling, and as such the biomass in-
 493 dices are most reliable for these three species. The metrics selected were three of those
 494 suggested in Olsen et al. (2016) and Stow et al. (2009): Modelling efficiency (MEF)
 495 used to asses model predictions relative to the mean of the observations (Equation 6);
 496 Reliability index (RI) gives the average factor the model predictions differ from obser-
 497 vations (Equation 7); Pearson’s correlation (r) assesses whether model predictions are
 498 correlated with observations (Equation 8). The full set of CRAM biomass trajectories
 499 with historic catches and trawl survey indices are in Appendix D.

500

$$MEF = \frac{\sum_{y=1}^Y (O_y - \bar{O})^2 - \sum_{y=1}^Y (O_y - P_y)^2}{\sum_{y=1}^Y (O_y - \bar{O})^2} \quad (6)$$

$$RI = \exp \sqrt{\frac{1}{Y} \sum_{y=1}^Y \left(\log \frac{O_y}{P_y} \right)^2} \quad (7)$$

$$r = \frac{\sum_{y=1}^Y (O_y - \bar{O}) (P_y - \bar{P})}{\sqrt{\sum_{y=1}^Y (O_y - \bar{O})^2 \sum_{y=1}^Y (P_y - \bar{P})^2}} \quad (8)$$

501 where

502 Y is the number of years for which there are observations,503 O_y is the observed biomass in year y ,

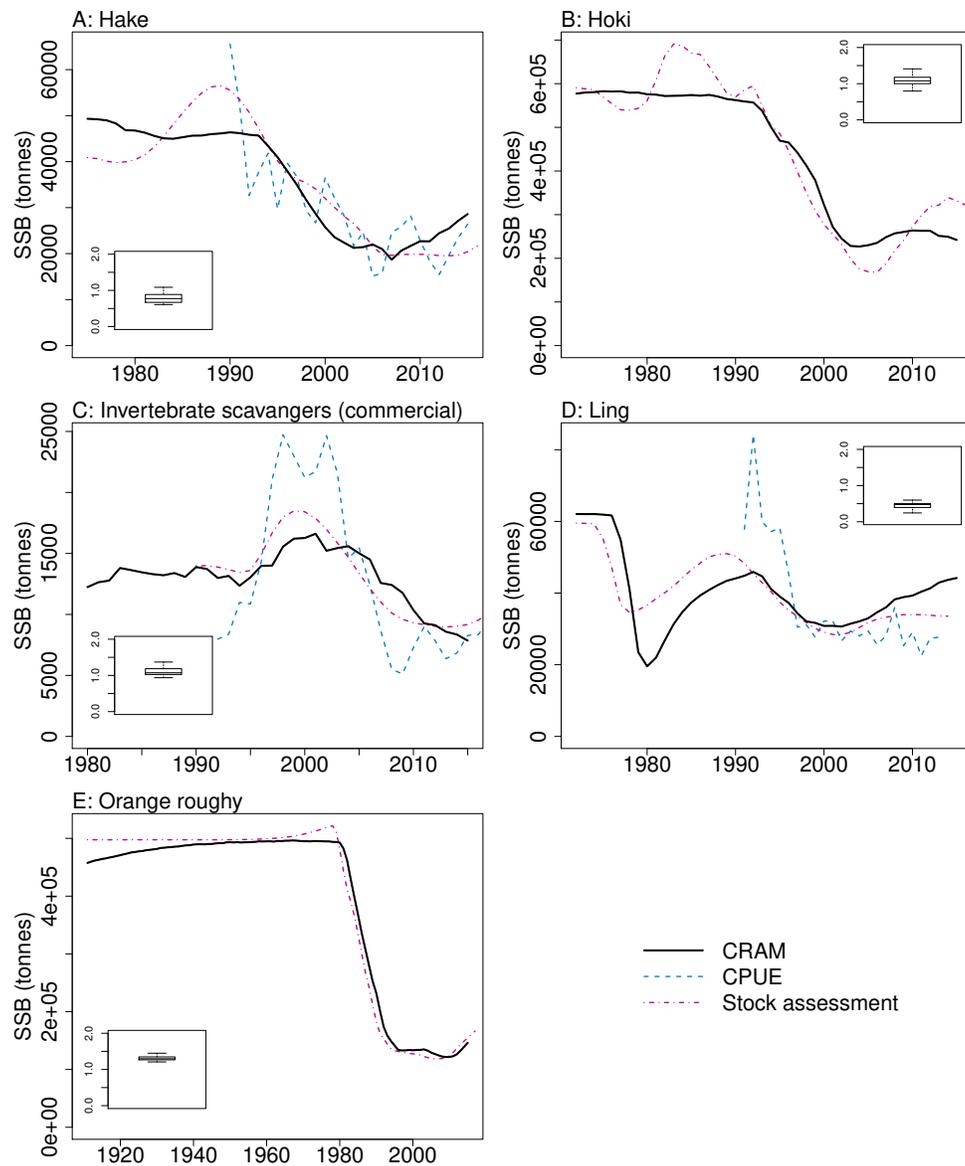

Figure 13: CRAM estimated spawning stock biomass (SSB) (black solid), stock assessment estimated SSB (red dot-dash), and CPUE (blue dash) where available for the hake (A), hoki (B), invertebrate scavengers (commercial) (primarily scampi) (C), ling (D), and orange roughy (E). CPUE and stock assessment SSB were rescaled to match the mean of the CRAM estimated SSB. Inset boxplots show the range of values for the corresponding unscaled stock assessment SSB divided by the CRAM estimated SSB.

504 P_y is the model biomass in year y

505

506 Each skill assessment metric was calculated using single point estimates from the
 507 trawl survey, and variants on RI and MEF were calculated allowing for the trawl survey

508 estimated 95% confidence intervals. Both variants only penalised the skill metric for
509 terms outside of the 95% confidence intervals of the trawl survey.

510
511 An MEF close to one indicates a close match between model predictions and ob-
512 servations, with zero indicating the mean of the observations is as close as the model
513 predictions, and a negative value indicating the model predictions fit the observations
514 worse than the mean of the observations. When the observed values are roughly sta-
515 tionary about the mean, as was the case for Ling, it is difficult for the predictions to
516 improve on the mean of the observations. Ling stands out at approximately -2.5 when
517 compared to the trawl survey point estimates, but as all the predicted points for ling sit
518 within the 95% confidence interval, it receives a score of one when taking the bounds
519 into account (Figure 14). Benthic invertivores (shallow) and lookdown dory are slightly
520 negative with respect to the trawl survey point estimates.

521
522 A reliability index (RI) of one indicates the model predictions are exactly equal to
523 the observations. RI greater than one (it cannot be less than one) indicates the factor
524 by which observations are on average different to predictions. Since $\log(O/P)$ is equal
525 to $-\log(P/O)$ and the RI squares these terms, an observation that is, for example, half
526 the prediction will contribute exactly the same to this index as an observation that is
527 twice a prediction. Hence, a RI of 2 indicates the observations differ from the predictions
528 on average by 2, but these could be generally twice as big or half as big, or both. All
529 groups had RIs between 1 and 1.5 (Figure 14), indicating the observations are at worse
530 on average $1.5\times$ the predictions or $(2/3)\times$ the predictions.

531
532 A Pearson's correlation close to one indicates trends in the predictions vary with
533 those in the observations, close to zero indicates there is little relationship between the
534 trends, and negative indicates the predicted trends tend to be opposite from the ob-
535 served trends. Hake and hoki had good correlation, close to 0.8. The other groups were
536 either close to zero or negative (Figure 14). This is neither surprising nor concerning as
537 the trawl survey estimates for these groups tend to have high variability and high CVs
538 which are not taken into account here.

539

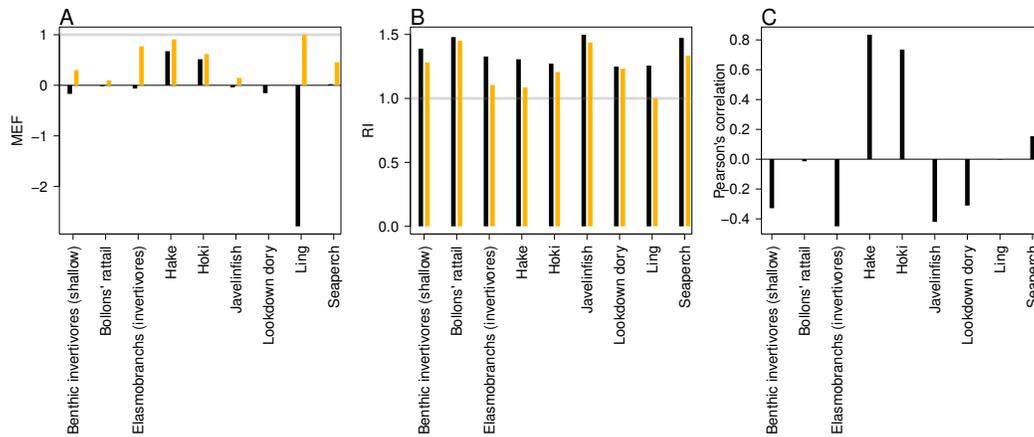

Figure 14: Skill assessment metrics MEF (A), RI (B) and Pearson's correlation (C) for CRAM species groups that have trawl survey indices for abundance. Metric definitions in Equations 6–8. The black bars are the skill metrics with respect to single point estimates from the trawl survey. The orange bars are the skill metrics with respect to the trawl survey 95% confidence intervals. The grey horizontal lines in the MEF and RI figures mark the value for a perfect fit, which is 1 for both of these.

8 Bringing it together

We qualitatively graded the species groups by how well they performed in the model and how well informed they were by data, information and other research (referred to as 'informance'). We compared these gradings with the keystone and responsiveness from Section 5.2. Figure 15 gives a visual guide for how well the most influential or responsive species groups did for informance and performance. While poor knowledge may not be concerning if paired with high responsiveness providing keystone is low (since the effects may be more limited to this single species group), the triple of highly responsive, a keystone species, and poorly defined may need consideration for future scenarios.

The groups that were highest for keystone and highest for informance and performance were hoki, orange roughy, benthic fish shallow (primarily oblique banded rattail), and hake. These all have abundance indices available, biological parameters, diet information, and all perform well with respect to these in the model. Hoki, orange roughy and hake (groups 1, 2, and 10 for keystone) have full stock assessments, which the model matches well. These are important groups for fisheries and will likely feature strongly in any fisheries scenarios explored with this model.

559 Species groups Pelagic fish small (primarily myctophids) and Pelagic fish medium
560 (primarily barracouta) were both high with respect to keystone-ness and responsiveness,
561 and while both were fairly well defined, these had some areas of poor model performance
562 and do not have abundance indices to compare. The estimated length at age 1 from
563 CRAM for small pelagic fish is larger than expected. This may be due to the size of
564 recruits being larger than they should be, or the fish eating (and hence growing) more
565 than they should in this first year. They are not so big that the effect transfers to the
566 age-2's, as the age-2's are the correct size (Appendix B), so this is probably not influ-
567 ential on the model overall. Medium pelagics have slightly less natural mortality in the
568 model than they should (Appendix C), and may be less responsive to fishing mortality
569 as a result. As they are 7th with respect to keystone-ness and high for responsiveness,
570 they could affect scenario outcomes and are worth considering when analysing results.
571 They make up approximately 1% of the age-structured biomass.

572
573 Spiny dogfish were third for keystone-ness, and low for responsiveness. They fit well
574 to mortality and growth curves, but we do not have an index of abundance with which
575 to compare the model simulated biomass in response to historical fishing. They make
576 up approximately 5% of the age-structured biomass.

577
578 Epibenthic fish shallow (primarily common roughy) were 8th for keystone-ness, but
579 low for responsiveness. They compare reasonably well to the trawl survey abundance
580 index, but have less natural mortality in the model than they should. They make up
581 approximately 1% of the age-structured biomass.

582
583 Species groups 'Seabird' and 'Cetacean other' are both poorly defined and rank
584 within the top 10 for keystone-ness, although lower for responsiveness. They are both
585 composite groups, with Seabird consisting of all sea and shore birds, and Cetacean other
586 consisting primarily of sperm whales, pilot whales and dolphins (Table 2). Scenarios
587 explored in the future may benefit from sensitivity analysis with respect to these two
588 groups to understand their effect on the outcomes, or perhaps some more work to better
589 define them.

590

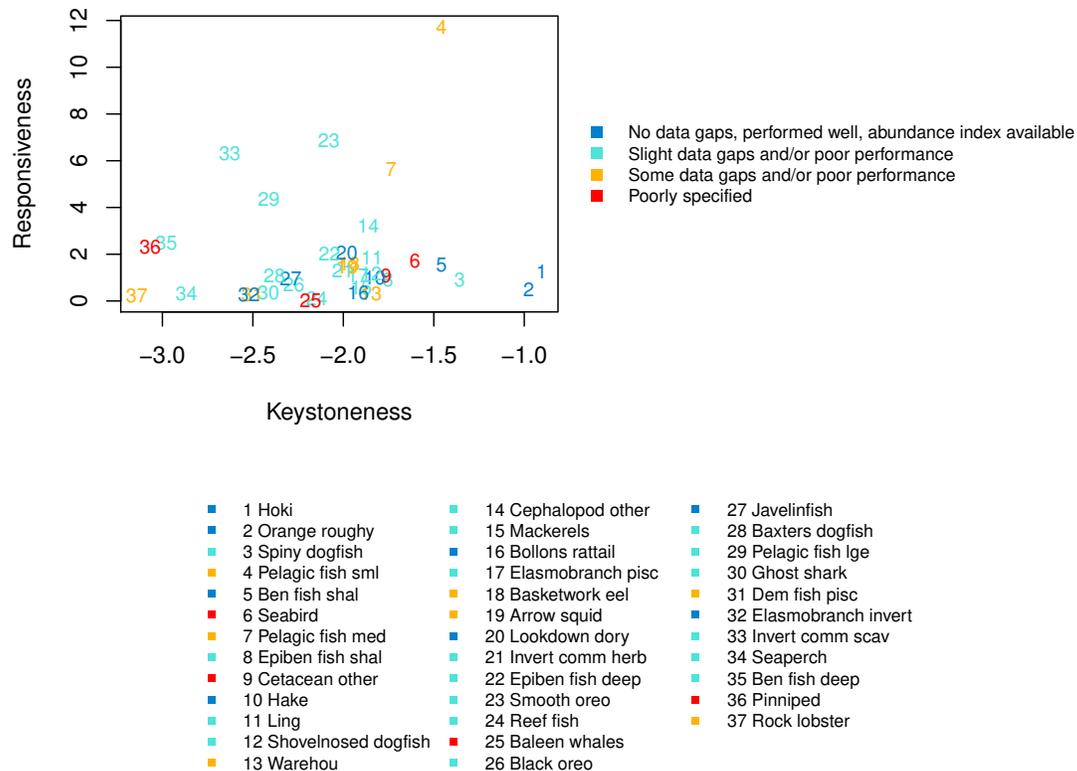

Figure 15: Keystoneness (x-axis) and responsiveness (y-axis) with numbers showing keystone ranking and colours how well each species group was informed and/or performed in the model (legend).

9 Discussion

Ecosystem-based fisheries management (EBFM) is most likely to be achievable with the best information and modelling available (Heymans et al., 2010). The Chatham Rise Atlantis model presented here uses the wealth of data and information available for the Chatham Rise and its fisheries, and one of the best ecosystem models for exploring ‘what-if’ type questions (Plagányi, 2007) and ecosystem-level management strategy evaluation (Fulton et al., 2014). This comprehensive ecosystem model with realistic population dynamics and flow-on effects has the potential to be a valuable tool for understanding potential system-wide responses to fisheries management strategies in one of New Zealand’s largest fishing grounds.

Some key aspects of this model performed convincingly well, such as responses of key fisheries species under fishing, realised diets, and the keystone rankings. That the key

604 fisheries species results were very similar to the corresponding stock assessment results
605 gives confidence that the model can respond to fishing in a way that is realistic, and that
606 the ecosystem effects relative to these species are realistic. The stock assessment models
607 fit data such as proportions at length and biomass indices with the help of between-
608 year recruitment deviates, which are not present in the Chatham Rise Atlantis model.
609 Conversely, the stock assessment models do not have time-varying natural mortality or
610 growth rates, which are present in the Chatham Rise Atlantis model. As such, both
611 modelling approaches achieve similar results but in very different ways. It is possible
612 that the recruitment deviates in the stock assessments are proxy's for the other ecosys-
613 tem dynamics that the Atlantis model is able to capture (or vice versa). However, the
614 Atlantis model is too complex to fit comprehensively to data and is entirely determin-
615 istic. Hence, the Chatham Rise Atlantis model's ability to achieve the same results as
616 the stock assessment models, that were fitted to data, is the best outcome.

617
618 Realistic diets and the influence of species groups on the rest of the ecosystem are
619 key to the model's potential to explore and gain understanding of flow-on and cascading
620 effects. It may be possible, for example, for a species to have realistic growth rates,
621 but it is not very useful in an ecosystem modelling context if they do so by eating the
622 wrong things. While they might respond realistically to direct pressure such as fishing,
623 the flow-on effects would not likely reflect reality. Due to the complex nature of the
624 Atlantis model, the summary of realised diets, together with analysing the keystone-
625 ness and responsiveness, are appropriate for determining whether species interactions are
626 generally realistic, at a level of complexity that can be comprehensible. The Chatham
627 Rise Atlantis model has realistic diet summaries for all species groups, and the top
628 keystone species groups were all those we would expect to be most influential within
629 this ecosystem. This is not to say the model could not benefit from further future work
630 examining the realised diets at a finer scale - spatially, temporally, and by age-class.

631
632 Exploring the models sensitivity to initial conditions, while not an insignificant
633 amount of work, may be worth doing at some stage in the future to add to our un-
634 derstanding of the models stability and persistence of dynamics. This has not, to the
635 best of our knowledge, been done for Atlantis or OSMOSE models, likely due to the
636 enormous complexity and computing resources required for the task. Sensitivities to ini-
637 tial conditions have been explored using Ecopath (Essington, 2007) and Ecopath with
638 Ecosim (EwE) (Steenbeek et al., 2018). We are in the early stages of developing an EwE
639 verison of CRAM, and it may be more feasible to explore ranges of initial conditions

640 within the EwE framework, with the possibility of then adapting the analyses to the
641 Atlantis model. Sensitivities of high-ranking keystone species, such as spiny dogfish,
642 would be simpler to implement and may produce greater understanding of the model.

643
644 While there are some knowledge gaps, we have identified those most likely to influ-
645 ence scenario outcomes through analysing how influential (keystoneness) and influenced
646 (responsiveness) the species groups are on and to each other. The composite groups
647 ‘cetacean other’ and ‘seabirds’ were highly influential while poorly specified. Two solu-
648 tions would be to a.) split these groups into smaller groups that can be better specified;
649 b.) run sensitivities with respect to these groups when exploring scenarios using this
650 model. As option a.) would require more data than we currently have available, option
651 b.) is the only currently viable option.

652
653 The oceanographic variables based on years 1996–2004 were found to be influential
654 on the simulated biomasses of the species groups, and the order they were repeated
655 changed the results, with CVs of up to nearly 80%. This suggests scenarios carried
656 out using this model need to consider oceanographic variability in simulated results,
657 using multiple runs with different oceanographic years repeated or changing the order.
658 This may be true for many ecosystem models, but we are unaware of similar analyses
659 completed elsewhere. Further work understanding which species groups and/or spatial
660 areas of the model are most affected by oceanographic variability might be helpful in
661 understanding potential impacts on scenario results.

662
663 As Atlantis is spatially resolved, there is scope for a greater emphasis on the effects
664 of features such as habitats, depth, and oceanographic features on responses to fisheries
665 management scenarios. Kaplan et al. (2012) explored spatially resolved fisheries man-
666 agement scenarios using an Atlantis model of the California Current, including areas
667 closed to bottom-contact fishing gear, and varying spatial management specification
668 relating to Marine Protected Areas (MPAs). In the Chatham Rise ecosystem, it may
669 be that repeating cooler or warmer years such as carried out in this study could influ-
670 ence the spatial distribution of some species. This could in turn influence the range of
671 plausible responses to fisheries management scenarios that have a spatial aspect, such
672 as MPAs, the effects of different fishing gear, serial depletion of fishing grounds, and
673 potential effects on by-catch species that may overlap spatially with species that are
674 targeted by fisheries.

675

676 While we have confidence in this model for exploring fisheries type scenarios in sup-
677 port of an ecosystem based approach to fisheries management, the model still stands to
678 benefit from further exploration. Key to understanding the implications of any results
679 from such a complex model is to first ask what in the model is producing the results,
680 before asking what it tells us about the system.

682 10 Conclusions

683 The analyses presented in this paper are intended to set the stage for an understand-
684 ing of how the model is specified and how it behaves, but it is not exhaustive. The
685 model produces similar results to fisheries stock assessment models for key fisheries
686 species, and the population dynamics and system interactions are realistic. Confidence
687 intervals based on bootstrapping oceanographic variables were fairly narrow for most
688 species groups, with diatoms, carnivorous zooplankton and labile detritus having the
689 largest CVs. The species groups with the highest keystone-ness were orange roughy, hoki,
690 pelagic fish small (primarily myctophids) and spiny dogfish. The model components that
691 have knowledge gaps and are most likely to influence model results were oceanographic
692 variables, and the aggregate species groups ‘seabird’ and ‘cetacean other’. We recom-
693 mend applications of the model include alternatives that vary these components. It is
694 expected that any future use of the model will add first to our understanding of the
695 model, and then possibly to our understanding of the ecosystem.

913

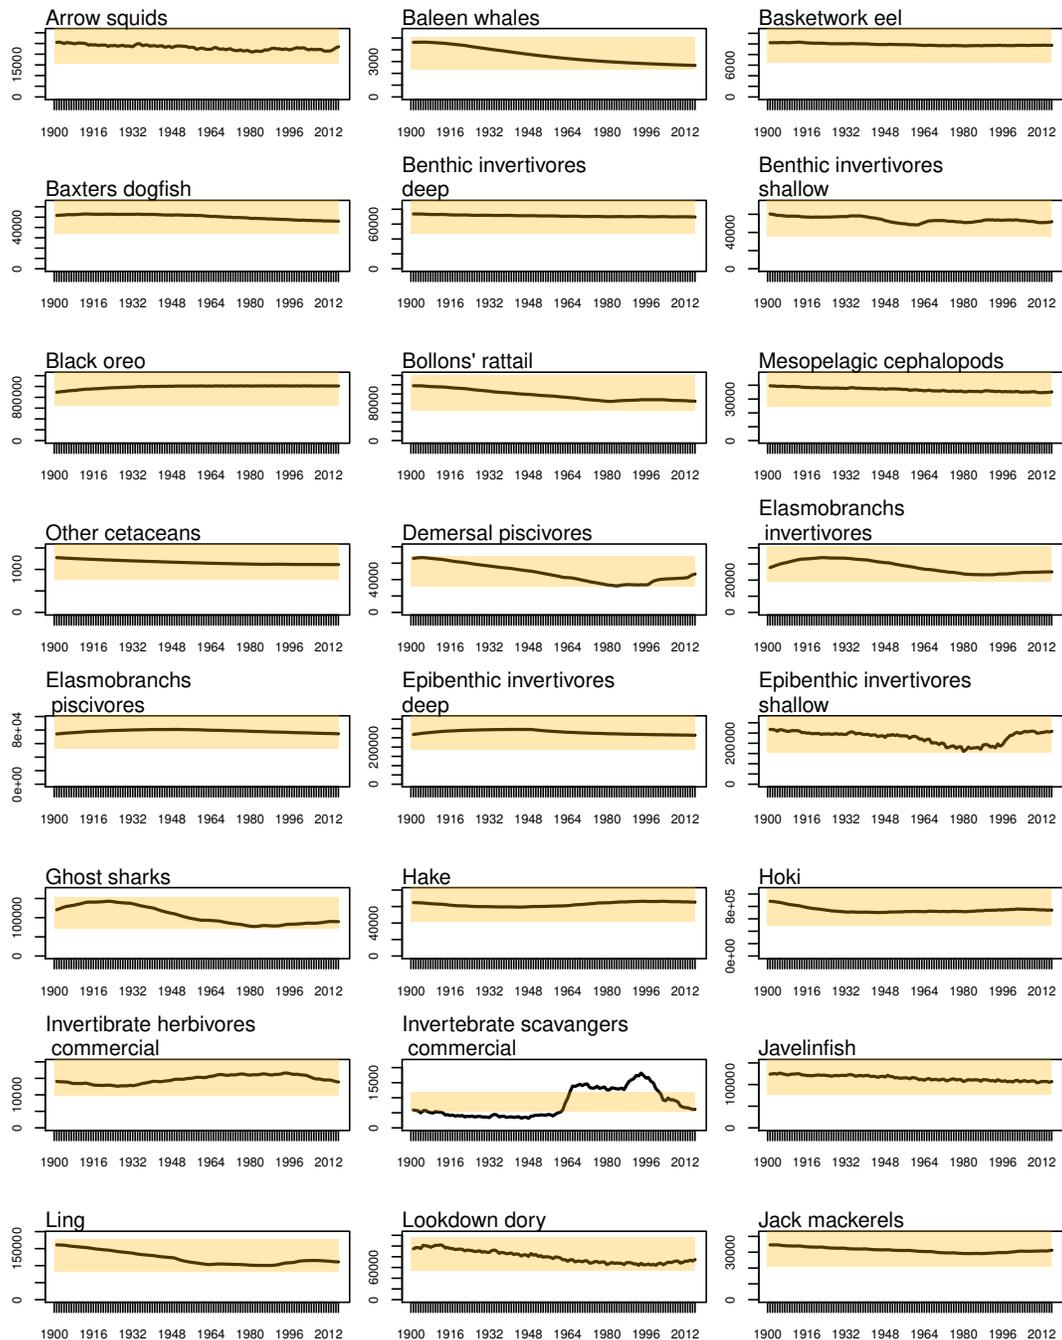

Appendix A: Simulated biomass by species group from no-fishing model

914

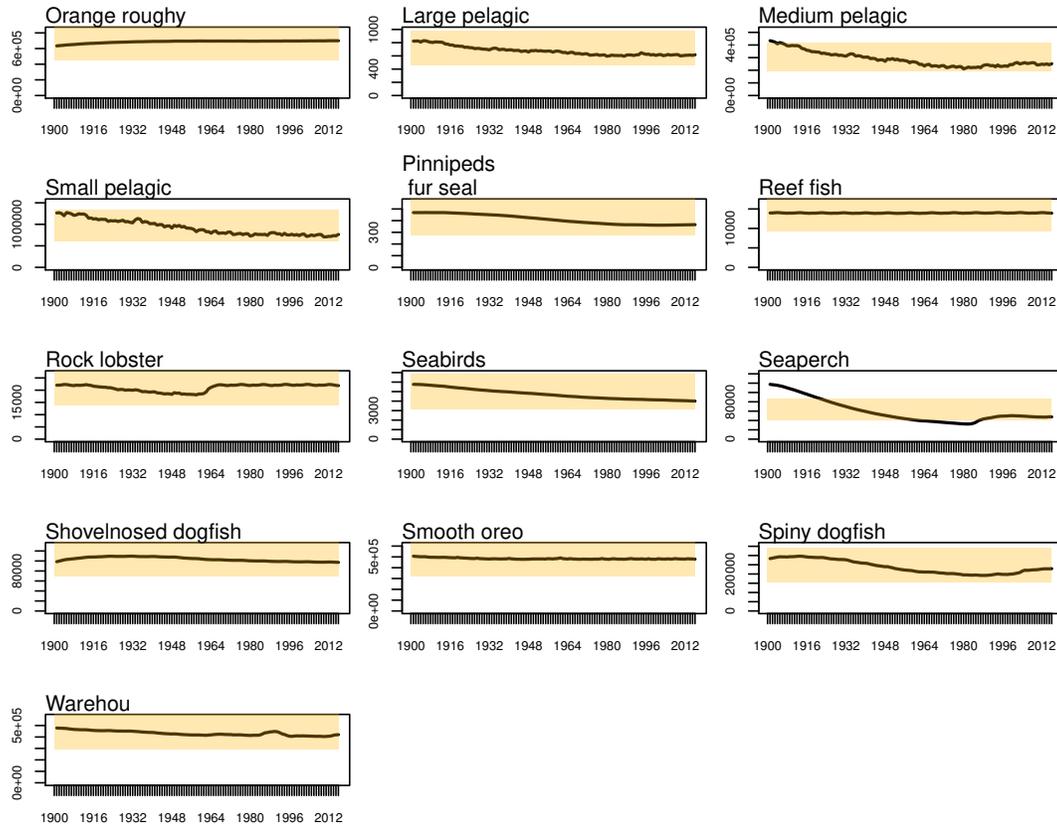

915

Simulated biomass from the un-fished model (black line) with 95% confidence intervals based on 20% CVs (Coefficient of Variation) shaded orange by species group.

916

917

918

Appendix B: Size-at-age

919

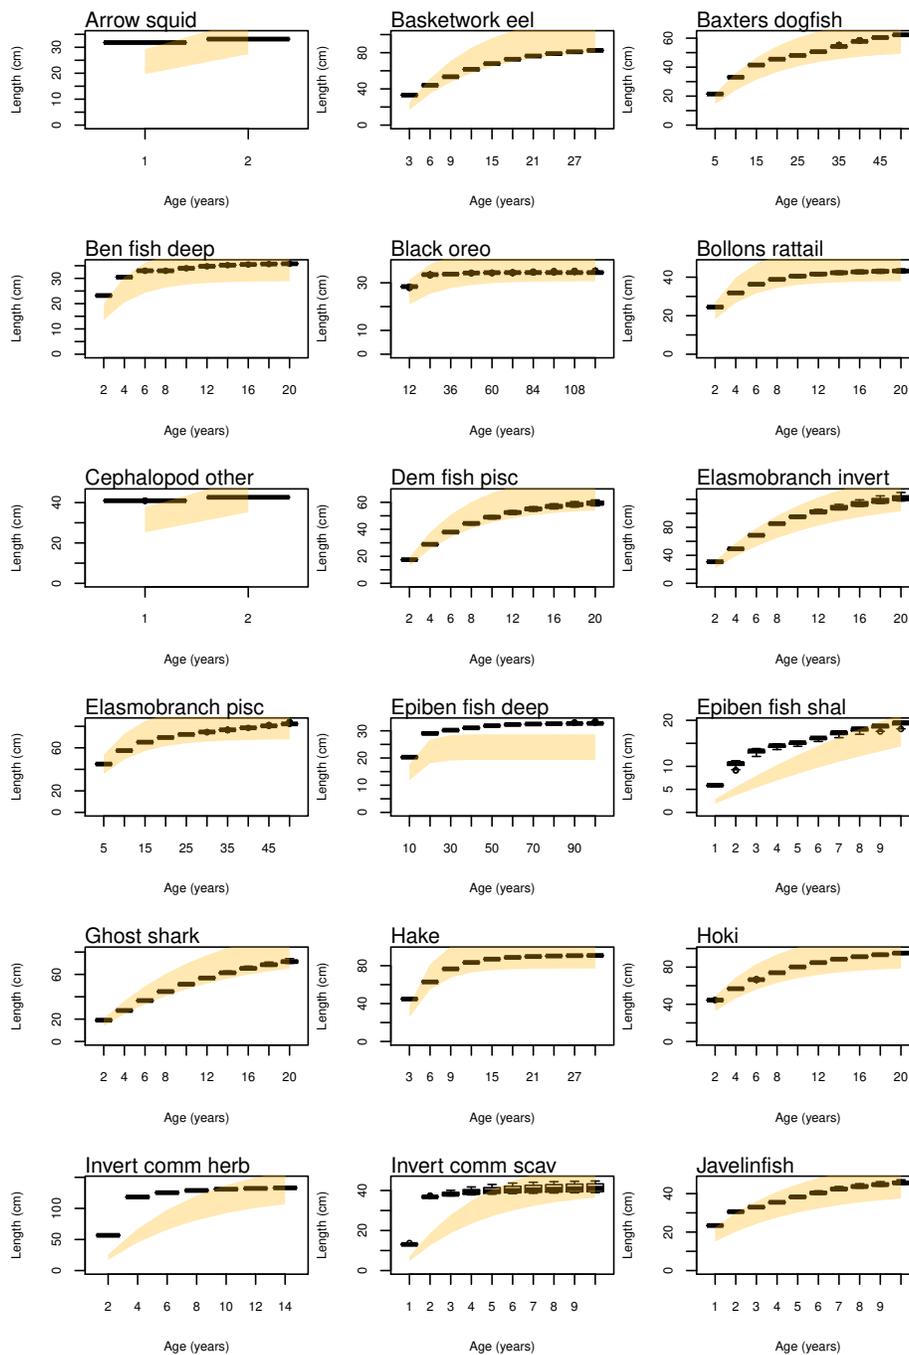

Size-at-age using values based on literature (Table 6) where available (orange shaded

920

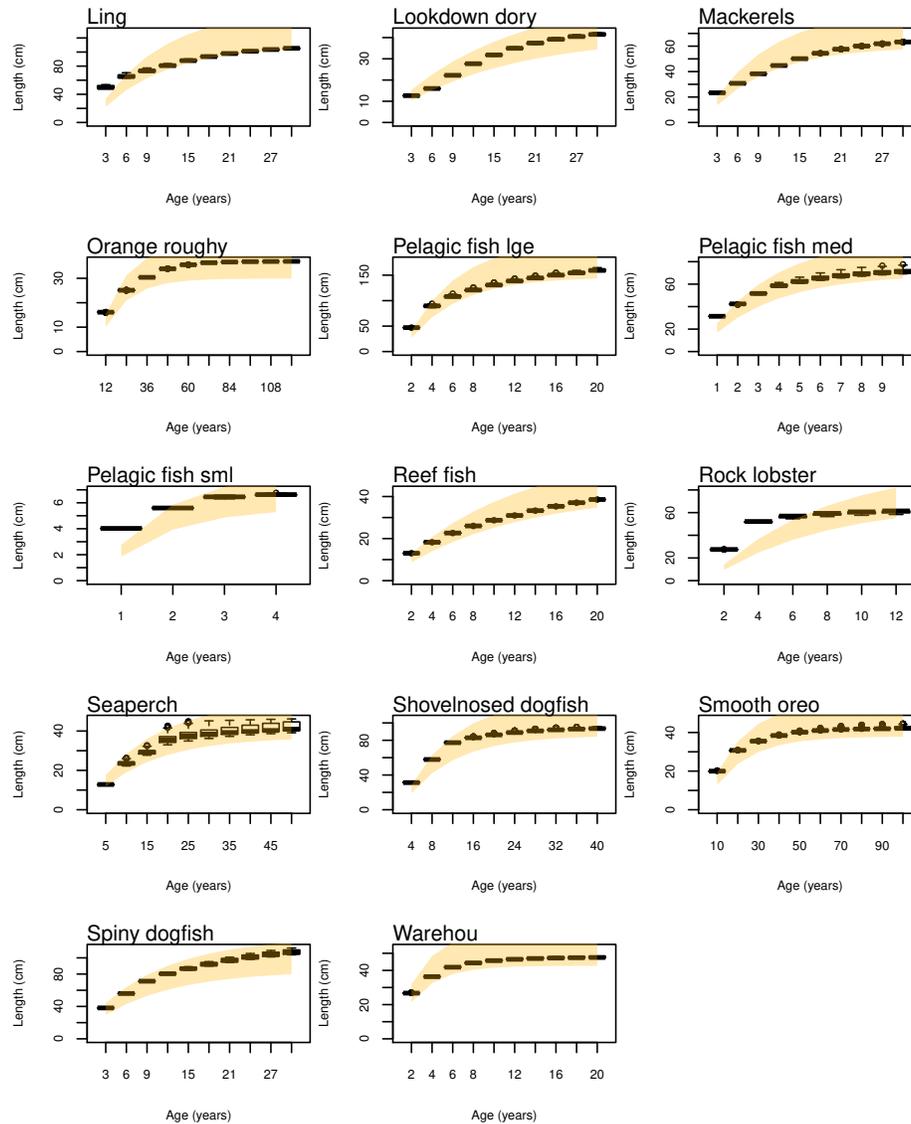

shows 95% confidence intervals using CV 10%) and from CRAM simulated years 1900–2015

921

(boxplots).

922

923

Appendix C: Proportion-at-age

924

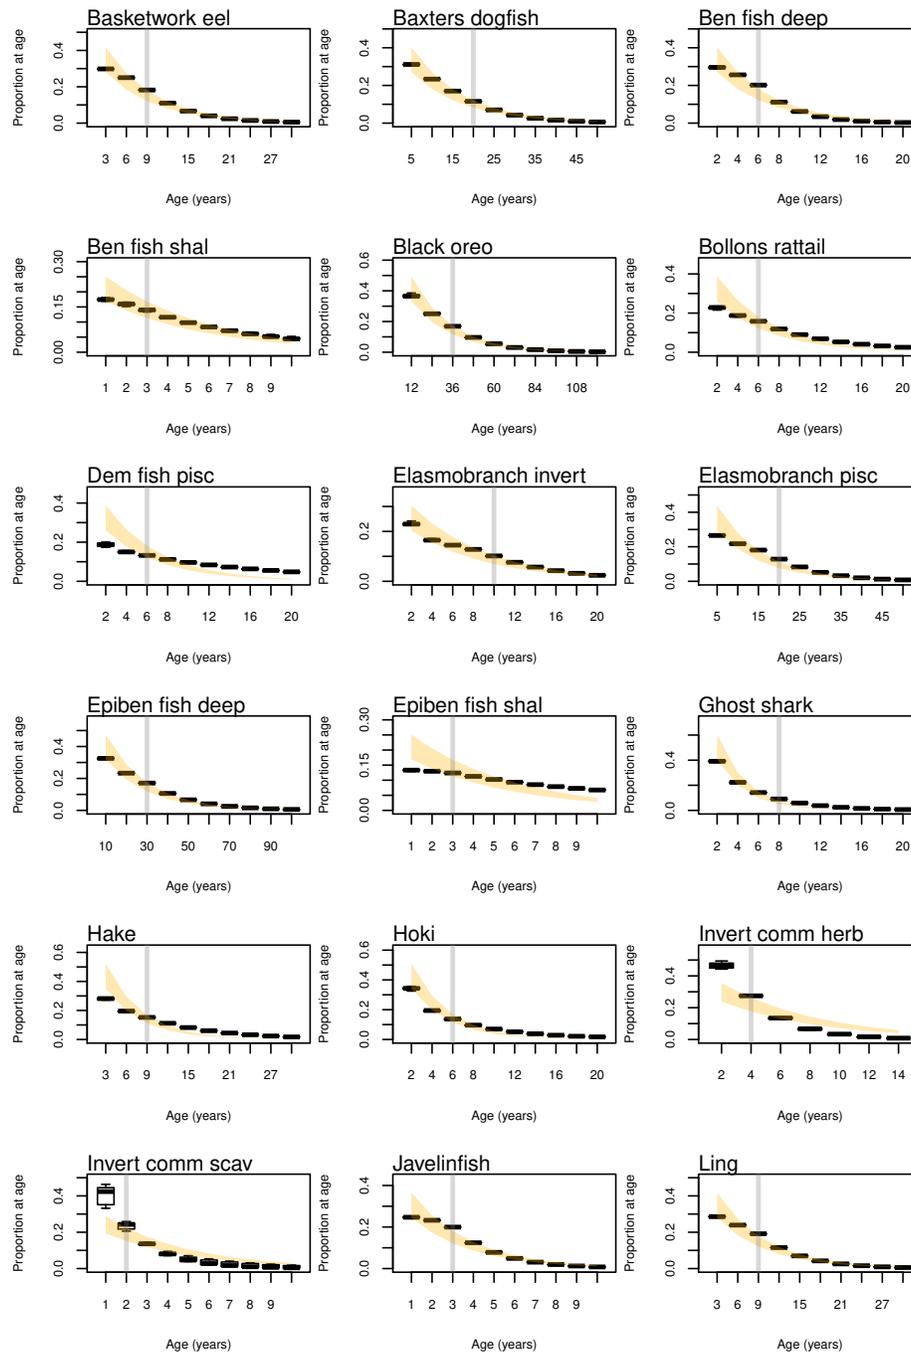

Proportions at age using M based on literature (Table 6) where available (orange

925

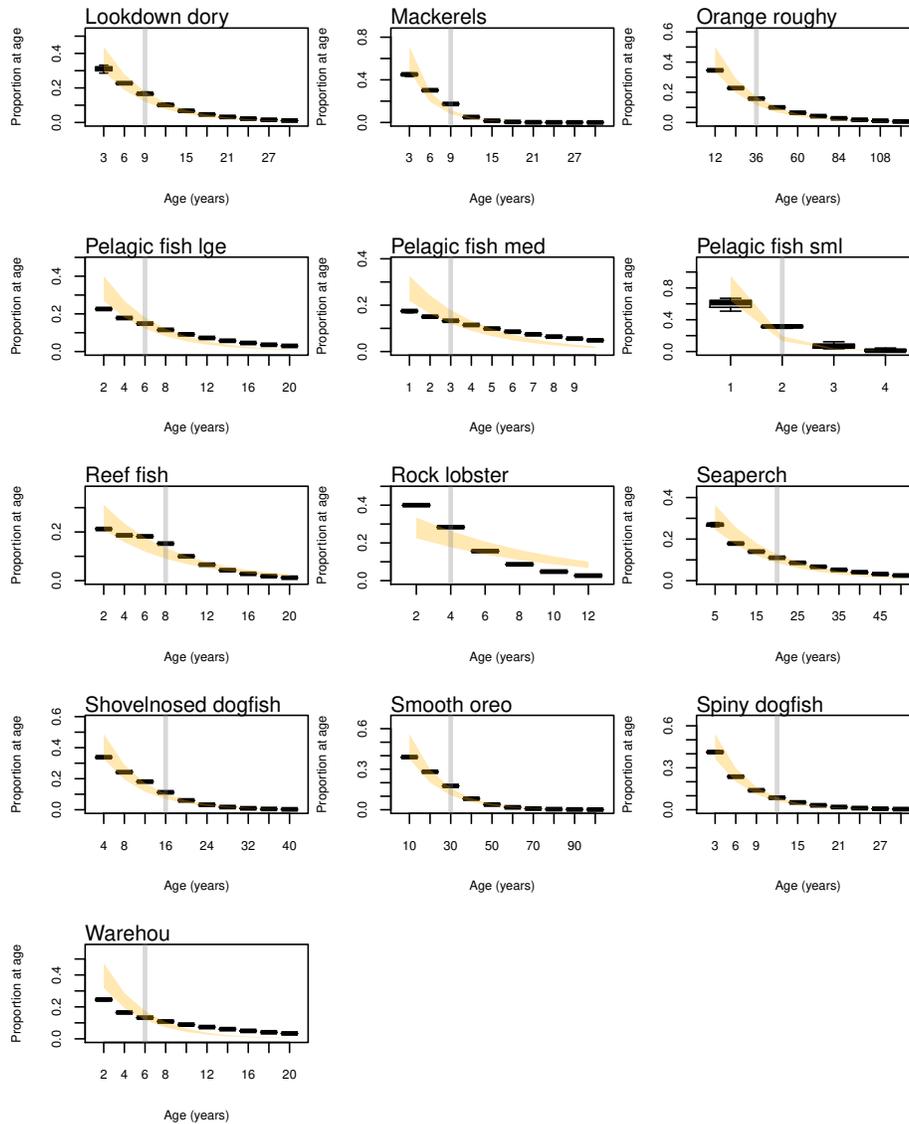

shaded shows 95% confidence intervals using CV 10%) and from CRAM simulated years

926

1900–2015 (boxplots).

927

928

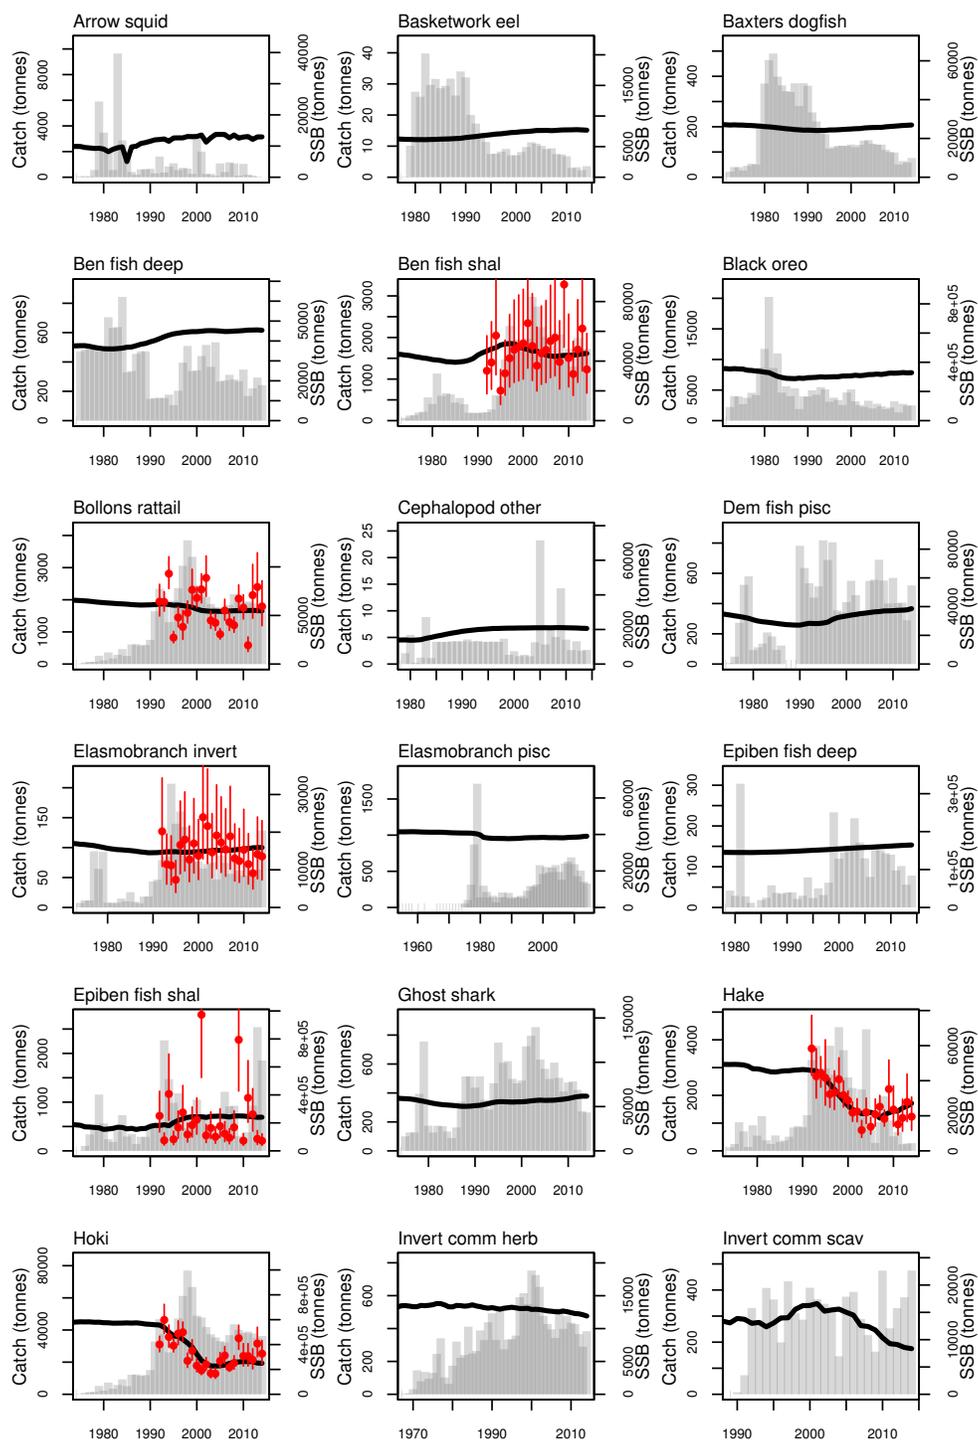

Appendix D: Observed vs estimated

929

Observed biomass estimated from trawl surveys (red), estimated biomass from CRAM

930

(black) and forced catch history (grey) for all groups with trawl survey estimates.

931
