Dispersal is fundamental to population dynamics. However, it is increasingly apparent that, despite most models treating dispersal as a constant, many organisms make dispersal decisions based upon information gathered from the environment. Ideally, organisms would make fully informed decisions, with knowledge of both intra-patch conditions (conditions in their current location) and extra-patch conditions (conditions in alternative locations). Acquiring information is energetically costly however, and extra-patch information will typically be costlier to obtain than intra-patch information. As a consequence, theory suggests that organisms will often make partially informed dispersal decisions, utilising intra-patch information only. We test this proposition in an experimental two-patch system using populations of the aquatic crustacean, *Daphnia carinata*. We manipulated conditions (food availability) in the population's home patch, and in its alternative patch. We found that *D. carinata* made use of intra-patch information (resource availability in the home patch induced a ten-fold increase in dispersal probability) but either ignored or were incapable of using of extra-patch information (resource availability in the alternative patch did not affect dispersal probability). We also found that replicates with higher population densities experienced a small apparent increase in dispersal. Our work highlights the large influence that information can have on dispersal probability, but also that dispersal decisions will often be made in only a partially informed manner. The magnitude of the response we observed also adds to the growing chorus that condition-dependence may be a significant driver of variation in dispersal.

10 ABSTRACT

11 Dispersal is fundamental to population dynamics. However, it is increasingly apparent that, despite
12 most models treating dispersal as a constant, many organisms make dispersal decisions based upon
13 information gathered from the environment. Ideally, organisms would make fully informed decisions, with
14 knowledge of both intra-patch conditions (conditions in their current location) and extra-patch conditions
15 (conditions in alternative locations). Acquiring information is energetically costly however, and extra-
16 patch information will typically be costlier to obtain than intra-patch information. As a consequence,
17 theory suggests that organisms will often make partially informed dispersal decisions, utilising intra-
18 patch information only. We test this proposition in an experimental two-patch system using populations
19 of the aquatic crustacean, *Daphnia carinata*. We manipulated conditions (food availability) in the
20 population's home patch, and in its alternative patch. We found that *D. carinata* made use of intra-patch
21 information (resource availability in the home patch induced a ten-fold increase in dispersal probability)
22 but either ignored or were incapable of using of extra-patch information (resource availability in the
23 alternative patch did not affect dispersal probability). We also found that replicates with higher population
24 densities experienced a small apparent increase in dispersal. Our work highlights the large influence
25 that information can have on dispersal probability, but also that dispersal decisions will often be made in
26 only a partially informed manner. The magnitude of the response we observed also adds to the growing
27 chorus that condition-dependence may be a significant driver of variation in dispersal.

28 1 INTRODUCTION

29 Dispersal, like survival and reproduction, is a fundamental facet of life history (Bonte and Doherty 2017).
30 Behaviours which govern dispersal can have profound consequences for a variety of biological and ecolog-
31 ical phenomena, such as individual fitness, metapopulation dynamics, and evolutionary outcomes across
32 a species' range (Bonte and Doherty 2017; Clobert et al. 2001). For reasons of simplicity, the majority
33 of spatially-explicit ecological models assume that dispersal is both uninformed and unchanging; that
34 individuals disperse at fixed rates, and that they do so without recourse to information about environmental
35 conditions (*e.g.*, by default in models utilising reaction-diffusion or integrodifference equations; Fisher
36 1937; Skellam 1951; Kot et al. 1996; but see Fronhofer et al. 2016). There is now considerable evidence,
37 however, that dispersal decisions are routinely informed by aspects of the environment (Clobert et al.
38 2009), with such information use expected to have non-negligible effects on ensuing population and
39 evolutionary dynamics (Delgado et al. 2014; Ponchon et al. 2015; Urban et al. 2016).

40 The most common form of informed (or condition-dependent) dispersal is density-dependent dispersal
41 (Bowler and Benton 2005). Here, individuals acquire information about population density, and, if
42 conditions more favourable to survival and reproduction are likely to be found elsewhere, make the
43 decision to disperse. When all else is equal, high density – with its greater competition for resources,
44 greater rates of disease transmission and so on – will be associated with poorer conditions (Bowler
45 and Benton 2005). Many species have been shown to acquire information on density and act upon it,
46 such as the spider *Erigone atra* (De Meester and Bonte 2010), protozoa like *Paramecium caudatum*

47 and *Tetrahymena thermophila* (Fellous et al. 2012; Fronhofer et al. 2017), and the plant *Heterosperma*
48 *pinnatum* (Martorell and Martínez-López 2014). In many species, this information is acquired through
49 food availability; when local resources are limited, individuals tend to be more dispersive, regardless of
50 taxa. This was demonstrated powerfully by Fronhofer et al. 2018, where resource limitation (and to a
51 lesser extent, predator presence) was shown to induce higher dispersal rates in organisms as varied as,
52 amongst others, protists, slugs, crustaceans, crickets, newts, and fish. Information on the relative merits
53 of different alternative locations can also be acquired in numerous ways, including prospecting (e.g.,
54 actively assessing potential breeding sites, as in collared flycatchers (*Ficedula albicollis*) monitoring which
55 locations are producing well-provisioned nests; Pärt and Doligez 2003) and by observing immigrating
56 conspecifics (as in the common lizard *Zootoca vivipara*; Cote and Clobert 2007).

57 Several models have now been constructed to examine the evolution of informed dispersal (e.g.,
58 Bocedi et al. 2012; Delgado et al. 2014). However, while they are in general agreement that informed
59 dispersal will often evolve, much hinges on the ease with which information is acquired, along with its
60 value (Poethke et al. 2016). In an ideal world, we would expect dispersal decisions to be made on a
61 balance of 'push' factors, such as local patch conditions, and 'pull' factors, such as the quality of other
62 patches. The quality of the new patch should be high enough (relative to the home patch) that it offsets
63 the fitness costs of moving. But organisms do not live in an ideal world: information can be costly to
64 acquire, both in terms of time and energy (Bonte et al. 2012), with a likely asymmetry of cost such that
65 information about alternative patches is harder to obtain than information about an individual's home
66 patch. Thus, it may often be the case that individuals act on the limited information that is most easily
67 acquired: intra-patch information.

68 Conversely, ecological and population dynamics may also be influenced by the relative strength of the
69 pull exerted by extra-patch information. In metapopulations with dispersers that can take advantage of
70 this kind of information, patch persistence may be expected to increase if patches with perilously low
71 population sizes – but abundant resources as a result – become more appealing to dispersers. Indeed,
72 simply being able to detect other conspecifics in these vulnerable patches may have the same effect
73 (Clobert et al. 2009), although patches with suitable habitat could also become overpopulated if they
74 attract a disproportionate number of migrants. In biological invasions, invasion speed may be boosted
75 if colonisers are able to use extra-patch information to select suitable habitats, or hindered if it instead
76 causes them to favour ecological traps (Kokko 2006). If intra-patch information is dominant in motivating
77 dispersal on the other hand, invaders may be expected to distribute themselves indiscriminately, rendering
78 the invasion highly sensitive to both the proportion of suitable habitat in the landscape and any temporal
79 fluctuations in its quality (Neubert et al. 2000; Schreiber and Lloyd-Smith 2009). Gauging the relative
80 strength of the push caused by intra-patch information and the pull caused by extra-patch information will
81 thus help to resolve questions of such a character.

82 Here, we examine their relative influence on dispersal by manipulating food resource levels in
83 experimental populations of the aquatic crustacean, *Daphnia carinata*. Dispersal in *Daphnia* is usually
84 characterised as being driven by the passive transport of ephippia (long-lived resting eggs) by water
85 fowl or other vectors (Allen 2007; Frisch et al. 2007; Van de Meutter et al. 2008); however, individuals
86 can also actively disperse between permanently or temporarily interconnected water bodies (Michels
87 et al. 2001; Cottenie et al. 2003). Although it has been demonstrated that *Daphnia* do boost ephippia
88 production in response to information cues indicating low local resource availability (Carvalho and
89 Hughes 1983; Hobaek Anders and Larsson Peter 1990; Kleiven et al. 1992), a greater range of responses
90 has been observed regarding its effects on active movement. Environments with relatively higher food
91 concentrations have been shown to increase *Daphnia* movement behaviours like swimming speed and
92 sinking rate (Dodson et al. 1997); however, in other instances, they have been shown to slow movement,
93 with much depending on the *Daphnia* species or clone line under examination (Young and Getty 1987;
94 Larsson and Kleiven 1997; Roozen and Lüring 2001). *Daphnia* have also been seen to adhere to ideal free
95 distributions under ordinary circumstances, with individuals favouring regions of high food concentration
96 so long as they fall within natural ranges (Jakobsen and Johnsen 1987; Neary et al. 1994; Jensen et al.
97 2001). It would appear likely then, that *Daphnia* exploit information to regulate their dispersal efforts
98 between patches. It is less clear however, if this behaviour is governed entirely by intra-patch information,
99 or if extra-patch information also influences dispersal propensity.

100 Using *D. carinata*, we determine if individuals modify their rates of active dispersal between patches
101 in small multi-patch mesocosms when exposed to different intra-patch resource levels. We also ask

102 whether this response is contingent upon extra-patch conditions; the presence or absence of *ad libitum*
103 food in the neighbouring patch.

104 2 MATERIALS & METHODS

105 2.1 Laboratory population of *D. carinata*

106 All *D. carinata* used were genetically identical members of a single clone line. The founding member
107 of this lineage was collected at 38°10'34.3"S, 144°21'14.1"E (a lake in Geelong, Victoria, Australia) in
108 October 2016. Its offspring were used to establish laboratory stock cultures, which were housed in glass
109 jars containing 300 ml of ADaM zooplankton medium (according to the recipe of Klüttgen et al. 1994; as
110 modified by Ebert 1998 using only 5% of the recommended SeO₂ concentration) and kept within growth
111 chambers maintained at 22°C on a 12.30 light:11.30 dark photoperiod. Stocks were fed the non-motile
112 green algae *Scenedesmus*. In order to reduce any potential impact of maternal effects, all individuals used
113 in the experiment were taken from stocks that were maintained under these conditions for at least two
114 generations.

115 2.2 Experimental materials and conditions

116 We set up two-patch microcosms within which to measure dispersal of *Daphnia*. Each patch was a 950
117 ml plastic Cryovac XOP-0980 container filled with 600 ml of ADaM and kept on bench tops in an open
118 air laboratory. The laboratory was maintained at 22°C and each container was covered with a transparent
119 plastic sheet that was only removed during feeding and data collection. Each container measured 90 mm
120 x 75 mm at the base, was 110 mm high and widened gradually towards the top to 100 mm x 90 mm. A
121 circular hole with a diameter of 15 mm was centrally located 35 mm above the base on one of the long
122 sides of each container. This was connected to plastic PVC piping of an identical internal diameter that
123 linked one container to the next, acting as a 117 mm long tunnel through which *D. carinata* could disperse
124 between the two containers. For *Daphnia* generally, such a length would be easily traversable within less
125 than a minute for an individual swimming in a straight line (O'Keefe et al. 1998). At the commencement
126 of the experimental trials, dispersal between containers was prevented by inserting cotton balls into the
127 openings of the connecting tunnel.

128 2.3 Food availability experiment

129 Within this two-patch system, we examined the effects of intra- and extra-patch food availability on the
130 dispersal rate of *D. carinata*. We seeded one half of each two-patch system with 10 adult females taken
131 from stock cultures, and allowed this population to grow for 9 days in the experimental system while
132 dispersal was blocked. This resulted in each population containing individuals of a variety of age and
133 size classes when dispersal commenced (*D. carinata* have a lifespan of 1–2 months depending on the
134 conditions at which they are maintained, and generally reach reproductive maturity when between 5 and
135 10 days old; Venkataraman and Job 1980). On the 10th day, we then unblocked the dispersal tunnels and
136 made one exhaustive count by eye of the number of adult (*i.e.*, individuals large enough to reproduce) and
137 juvenile *D. carinata* in each patch every 24 hours thereafter for four days.

138 Our patch pairs were allocated to four treatment combinations ($n = 5$ per combination) according to a
139 two factor crossed design in which we independently modified food availability in the two patches. Factor
140 1 was intra-patch food availability: once the dispersal tunnel was unblocked, half of the populations no
141 longer received food in their starting patch. Factor 2 was extra-patch food availability: here we either
142 daily added food to the second patch (commencing on day 7, three days before dispersal was allowed)
143 or withheld food altogether from this patch. This meant that half of the populations were dispersing
144 into patches that contained no food at all, and the other half into patches with an abundance of food.
145 Food in this case was a daily fed mixture of 8 million *Scenedesmus* sp. cells (an unidentified Australian
146 *Scenedesmus*) and 12 million *Scenedesmus obliquus* cells.

147 We examined the effect of feeding regimes on absolute population sizes using ANOVA. There were
148 two response variables: the total population size at 96 hours (summed across both patches); and the
149 population size in patch 2 at 96 hours. We verified that they did not violate standard ANOVA assumptions
150 by testing each for normality and homogeneity of variances using the Shapiro-Wilk test and Levene's test.
151 Neither assumption was violated for population size at 96 hours (Shapiro-Wilk: $W = 0.92659$, $P = 0.133$;
152 Levene's: $F = 0.910$, $P = 0.458$) nor population size in patch 2 at 96 hours (Shapiro-Wilk: $W = 0.93031$,
153 $P = 0.157$; Levene's: $F = 1.620$, $P = 0.224$). We also compared the proportion of individuals that had

154 reached patch 2 after 96 hours between treatment combinations using a generalised linear model with
155 binomial errors and a logit link, with each individual in each patch being characterised as a trial in which
156 either success (dispersing into patch 2) or failure (remaining in patch 1) had resulted. All statistical tests
157 were performed in R version 3.5.0 (R Core Team 2018). All experimental data is available in the figshare
158 repository at <https://doi.org/10.4225/49/5b0f62dc23b4c>.

159 3 RESULTS

160 Over the course of the dispersal phase, total population sizes across both patches generally increased or
161 decreased according to whether patch 1 was fed or not, with fed treatments overall growing in size and
162 unfed treatments shrinking (Figure 1). At 96 hours, we found a significant effect of food availability in
163 patch 1 on total population size across both patches ($F_{1,16} = 10.826$, $P < 0.01$; Table 1), but not of food
164 availability in patch 2 ($F_{1,16} = 0.013$, $P = 0.912$; Table 1). The interaction between feeding treatments in
165 the two patches was also not significant with regard to total population size ($F_{1,16} = 0.481$, $P = 0.498$;
166 Table 1).

167 Examining the proportion of individuals dispersing after 96 hours, we found no significant effect of the
168 interaction between intra- and extra-patch feeding treatments ($z = 1.073$, $P = 0.283$; Table 2), and likewise
169 no significant effect of food availability in patch 2 ($z = 0.138$, $P = 0.890$; Table 2). We did however find a
170 significant effect of food availability in patch 1 ($z = 10.843$, $P < 0.001$; Table 2), with intra-patch food
171 deprivation resulting in an approximately ten-fold higher proportion of the total population dispersing
172 (food-deprived patch 1, mean = 0.259, SE = 0.0374; well-fed patch 1, mean = 0.0218, SE = 0.00718;
173 Figure 2).

174 Since total population size did differ based on food availability in patch 1, we also examined its
175 relationship with the proportion of *D. carinata* dispersing. In both the patch 1 fed and unfed groups, the
176 proportion of dispersers appeared to increase with higher densities (food-deprived patch 1, $r^2 = 0.234$;
177 well-fed patch 1, $r^2 = 0.401$; Figure A1). This increase was also steeper when patch 1 was not fed,
178 suggesting an interactive effect of density and food availability in patch 1 may have been present.

179 An analysis based on absolute numbers in patch 2, rather than proportions, yielded the same overall
180 trends in dispersal across our feeding treatments. Here, we found a significant difference in the total
181 number of individuals in patch 2 according to whether patch 1 had been fed or not ($F_{1,16} = 13.605$,
182 $P < 0.01$; Table 1), but no significant effect of food availability in patch 2 ($F_{1,16} = 0.102$, $P = 0.754$;
183 Table 1). Indeed, patch 1 unfed groups had a far higher number of individuals in patch 2 despite their
184 significantly lower total population sizes (individuals in patch 2: food-deprived patch 1, mean = 25.1, SE
185 = 5.12; well-fed patch 1, mean = 4.3, SE = 1.73). Dispersers were also overwhelmingly juveniles (Figure
186 A2).

187 4 DISCUSSION

188 In our system, there was a significant increase in inter-patch dispersal when *D. carinata* were deprived of
189 food (Figure 2), indicating that *D. carinata* exploited intra-patch information to inform their dispersal
190 decisions. By contrast, extra-patch conditions (food either abundant or entirely absent) had no effect on
191 dispersal rates. Thus it appears that *D. carinata* either did not use, or were incapable of using, extra-patch
192 information to inform their dispersal decisions.

193 Our first result – that animals increase dispersal propensity when faced with local resource shortages –
194 has been well established empirically. Studies on taxa ranging from plants to invertebrates and vertebrates
195 either imply, or experimentally demonstrate, that resource shortage is a powerful piece of information
196 motivating dispersal (e.g., Bowler and Benton 2005; Martorell and Martínez-López 2014; Fronhofer et
197 al. 2018). Our study adds *D. carinata* to the long list of organisms that exploit this piece of intra-patch
198 information. Due to the seeming generality of this phenomenon across taxa (as established by Fronhofer
199 et al. 2018), it also appears likely that comparable results would be seen for other species of *Daphnia*,
200 although additional studies using different clone lines or species of *Daphnia* may be prudent. Indeed, our
201 result can only strictly be said to apply to a single clone line of a single species.

202 That the dispersal we observed was largely driven by resource shortage, rather than density, becomes
203 obvious when examining patch 1 population sizes across treatments. Density, independent of resource
204 shortage, has been demonstrated to cause changes in life-history in *Daphnia* spp. (Matveev 1993; Burns
205 1995, 2000); but here, intra-patch resource shortage proved to be a far more powerful driver of dispersal

206 than density in and of itself. Since the nature of our experimental design precluded any attempt to control
207 density, those treatments that were well fed in patch 1 kept growing over time compared to those that
208 were not, manifesting in a significantly higher total population sizes by the end of the experiment (Figure
209 1). Despite these higher densities, which would not only have created more potential dispersers but also
210 exacerbated any density-driven push effect, a significantly greater number of individuals dispersed in the
211 treatments experiencing lower densities. Still, density did appear to drive some dispersal, with higher total
212 population sizes increasing the proportion of the population dispersing regardless of whether patch 1 was
213 fed or not (Figure A1). There may have also been an interaction between density and food availability in
214 patch 1 such that density was much more important in the unfed treatment; however the low value of the
215 coefficient of determination in that case means that conclusions concerning any such interaction, as well
216 as the apparent general increase in dispersal with density, should only be drawn with caution.

217 The seemingly odd result that food availability in patch 2 had no effect on final patch 2 population
218 size (which should have been influenced by both births and deaths within the patch) was likely due a
219 combination of factors. Since almost all dispersers were juveniles (Figure A2), there was no practical
220 potential for births to occur in patch 2, regardless of food availability there. Moreover, even if coming
221 from a starved patch 1, those individuals that migrated to patch 2 had to be healthy enough to disperse
222 in the first place, presumably depressing the death rate there. Nonetheless, had we recorded population
223 sizes in patch 2 beyond 96 hours, it seems likely that some difference would have soon become apparent
224 between fed and unfed patch 2 populations.

225 The magnitude of the dispersal increase we observed also indicates that the effect of local resource
226 information on dispersal rates may be pronounced. In terms of the proportion of dispersers, 25.9% of
227 individuals dispersed into patch 2 under food deprivation, whereas less than a tenth of that (2.18%) did so
228 under well-fed conditions (Figure 2). Although this particular measure may have been inflated by the
229 population growth that continued to occur in the well-fed treatments, the large difference in the absolute
230 number of dispersers (food-deprived patch 1, 25.1 dispersers; well-fed patch 1, 4.3 dispersers) despite
231 the afore-mentioned higher density in the well-fed treatments reiterated the strength of the effect. This
232 suggests that ecological models may benefit substantially by accounting for conditional factors, like
233 resource availability, that may have a large effect on dispersal behaviour.

234 Parameterising models using these or similar results should only be undertaken with great care
235 however. Much is likely to depend upon the size or arrangement of the experimental set-up. Additionally,
236 this study and comparable efforts using *Daphnia* or other organisms typically rely upon highly unnatural
237 environments within which to measure dispersal and movement (Young and Getty 1987; Dodson et
238 al. 1997; Larsson and Kleiven 1997; Roozen and Lüring 2001; Fronhofer et al. 2018), which may
239 prompt aberrant behaviours. In our set-up in particular, it is possible that some individuals may not have
240 recognised the dark tunnel opening as a dispersal avenue, and the length and width of the connections
241 between our patches were likewise considerably smaller and narrower in scale than dispersal avenues
242 might be expected to be in natural settings (Michels et al. 2001). Conducting equivalent experiments in
243 natural environments and at scales relevant to the dispersal of the organisms under examination is likely
244 to be useful, although admittedly difficult in practice.

245 Our second result – that favourability of conditions in the second patch had no effect on dispersal –
246 highlights the apparent importance of push versus pull factors in driving a population's movement. In the
247 present case, to obtain information that would draw *D. carinata* into the second patch individuals either
248 had to engage in prospecting within the inter-patch tunnel and the second patch, or to sense extra-patch
249 conditions remotely. We found no evidence to suggest that *D. carinata* was capable of exploiting either
250 source of information. In terms of more direct means of gathering information, extra-patch information
251 gathering behaviours like prospecting are predicted to be costly due to the threat of predation that comes
252 from moving into novel environments (Bonnet et al. 1999; Hiddink et al. 2002; Bonte et al. 2012), or
253 the simple energetic cost of having to move to assess new patches (Delgado et al. 2014). In *D. carinata*
254 specifically, it seemed much more likely that chemoreception would serve as the primary means of
255 ascertaining extra-patch conditions, as chemical signals from both conspecifics and other organisms have
256 been demonstrated to have a multitude of effects on *Daphnia* growth and behaviour (Larsson and Dodson
257 1993; Dodson et al. 1994). Indeed, it has been previously shown that *Daphnia magna* and *Daphnia pulex*
258 are unaffected by olfactory cues from algae (Roozen and Lüring 2001), but that a *Daphnia galeata* and
259 *Daphnia hyalina* hybrid responds to them (van Gool and Ringelberg 1996). Here however, the dominance
260 of resource limitation in pushing dispersal from the local patch indicated that the pull to move into new

261 patches was relatively weak in comparison, either because obtaining more information was costly, or
 262 because that information was in some way imperceptible or ignored.

263 4.1 Conclusions

264 In conclusion, our results add to the growing body of evidence that condition-dependent dispersal is the
 265 norm amongst taxa, and that it is moreover capable of generating substantial differences in dispersal
 266 behaviour (Legrand et al. 2015; Fronhofer et al. 2018). This growing empirical consensus warns
 267 against the simplifying assumption – used in the majority of ecological and evolutionary models – that
 268 dispersal rate is constant with respect to conditions. Relaxing that assumption is now well justified
 269 on empirical grounds, and the magnitude of shift in dispersal resulting from condition dependence
 270 suggests that it will have non-trivial effects when incorporated into mechanistic models of evolution,
 271 population dynamics, invasion spread, and so on. Amongst others, these effects may include increased
 272 local adaptation within populations (Armsworth 2008; Armsworth and Roughgarden 2008), heightened
 273 risk of overcrowding (Armsworth 2008), greater metacommunity stability (Fronhofer et al. 2018), and
 274 differences in metapopulation and invasion dynamics (Neubert et al. 2000; Kokko 2006; Clobert et al.
 275 2009; Schreiber and Lloyd-Smith 2009). In this light, the relative use of extra- vs intra-patch information
 276 is important because, when we move to a conditional dispersal model, the obvious simplifying assumption
 277 is that organisms exploit only intra-patch information. Our results suggest that intra-patch information is
 278 dominant in *D. carinata*, but the degree to which this is true generally will determine how complex our
 279 models of dispersal really need to be.

280 5 ACKNOWLEDGEMENTS

281 We thank Katrina-Lee Ware and Hannah Edwards for their invaluable assistance in the preparation of the
 282 experimental set-up. We also thank Andrew Byrne, Christina Buesching, and Nicolas Schtickzelle for
 283 their comments on an earlier draft of the manuscript.

410 **7 TABLES**

Table 1. Statistical results for total population sizes and absolute number of dispersers after 96 hours of dispersal. ANOVA test results for differences in the total *D. carinata* population sizes and absolute number of dispersers after 96 hours of dispersal, depending on food availability in patch 1 and food availability in patch 2. Replicates with food available in patch 1 produced a significantly higher number of dispersers ($P < 0.01$) despite having significantly lower total population sizes ($P < 0.01$). Standard ANOVA assumptions were not violated.

Source	<i>df</i>	<i>F</i> stat	<i>P</i> value
Total population sizes			
<i>Food available in patch 1</i>	1	10.826	<0.01
<i>Food available in patch 2</i>	1	0.013	0.912
<i>Food available in patch 1</i> × <i>Food available in patch 2</i>	1	0.481	0.498
	16		
Absolute dispersers			
<i>Food available in patch 1</i>	1	13.605	<0.01
<i>Food available in patch 2</i>	1	0.102	0.754
<i>Food available in patch 1</i> × <i>Food available in patch 2</i>	1	0.408	0.532
	16		

Table 2. Statistical results for proportion of individuals dispersing after 96 hours of dispersal. Test results for differences in the proportion of *D. carinata* dispersing after 96 hours depending on food availability in patch 1 and food availability in patch 2. A generalised linear model was used with parameter estimates on the logit scale and binomial errors. Food being available in patch 1 led a significantly lower proportion ($P < 0.001$) of individuals dispersing. Model variance was checked for overdispersion and did not violate standard GLM assumptions.

Parameter	Estimate (SE)	<i>z</i> stat	<i>P</i> value
<i>Intercept</i>	-0.938 (0.100)	9.371	<0.001
<i>Food available in patch 1</i>	-2.872 (0.265)	10.84	<0.001
<i>Food available in patch 2</i>	-0.0206 (0.150)	0.138	0.890
<i>Food available in patch 1</i> × <i>Food available in patch 2</i>	0.375 (0.350)	1.073	0.283

411 8 FIGURES

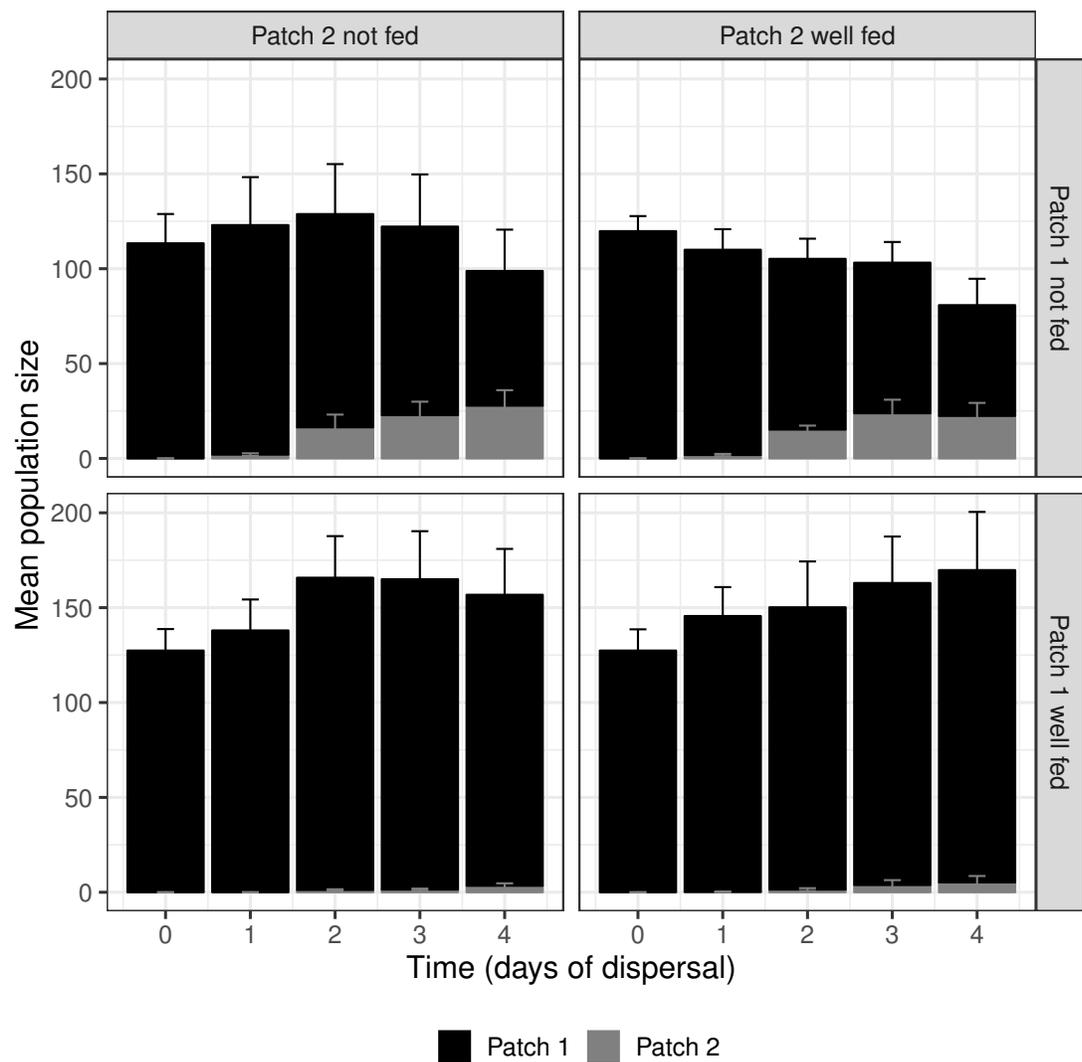

Figure 1. *D. carinata* population size over time and space across distinct feeding regimes. The effect of feeding regime on mean population size across both patch 1 and patch 2 over the dispersal phase ($n = 5$ container pairs per treatment combination). Bars are stacked, such that both patch 1 (black) and patch 2 (grey) population sizes combine to indicate mean population size. Error bars show SE for each patch's mean population size, rather than for stacked mean population size. Replicates where patch 1 was not fed produced higher numbers of dispersers despite having lower total population sizes (Table 1).

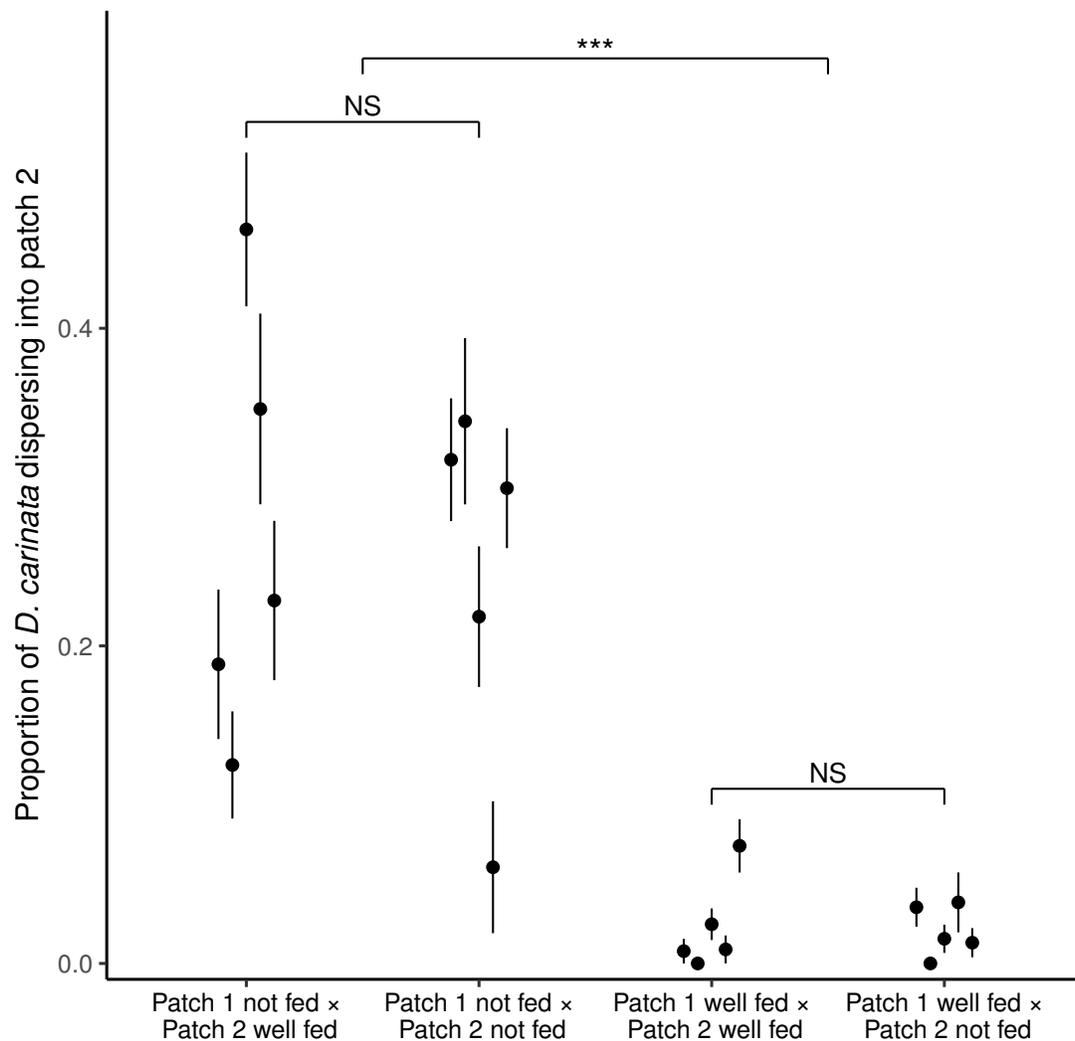

Figure 2. Proportion of *D. carinata* dispersing after 96 hours across distinct feeding regimes.

The effect of 96 hours of food deprivation on the proportion of *D. carinata* that had dispersed into patch 2, both with and without food available in patch 2 ($n = 5$ container pairs per treatment combination). Each point and line is given by the mean number of *D. carinata* individuals in patch 2 as a proportion of the total population size between the two patches \pm SE. SE was calculated as $SE = \sqrt{\frac{p(1-p)}{n}}$, where p is the proportion of dispersers and n is the number of individuals in the container pair. Food availability in patch 1 alone was found to have a significant effect on the proportion of the population that dispersed (Table 2).
