Morphological variation is strongly related to variation in the ecological characteristics and evolutionary history of each taxon. To explore how geographical variation in morphology is related to different climatic gradients and phylogenetic structure, we analyzed the variation of morphological traits (body size, bill, and wing) of 64 species of tyrant flycatchers (Tyrannidae) distributed in Mexico. We measured these morphological traits in specimens from biological collections and related them to the climatic and topographic data of each collection locality. We also calculated the phylogenetic structure of flycatcher assemblages of each locality in order to explore the influence of climatic variables and the phylogenetic structure over the morphological variation of tyrant flycatchers, by means of linear mixed-effects models. We mapped the spatial distribution of the variation of morphological traits in relation to environmental gradients taking into account the phylogenetic structure. The climatic variables that better explained the morphological variation were those of temperature ranges (seasonality) and the results suggest that the phylogenetic clustering increases towards the highlands of Sierra Madre Oriental and Sierra Madre del Sur, and the lowlands of Balsas Depression. At the regional assemblage, the spatial distribution of body size shows a pattern coincident with the ecogeographical Bergmann's rule, with an increase in size from south to north. In the tropical lowland forests assemblage, body size tend to increase in seasonally dry forests (western Mexico) and decrease in the humid ones (eastern Mexico). At highland forests and other types of vegetation, morphological trait values increased. Phylogenetic structure helps to explain the variation of morphology at lower assemblages but not at the regional assemblage. The patterns of trait variation along lowlands and highlands assemblages, suggest that part of morphological variation is explained in both by the climatic gradients and lineage relatedness of communities. Morphological variation is best explained by a varied set of

variables, and regression models representing this variation and integrating phylogenetic patterns at different community levels provide new understanding into the mechanisms underlying the link between biodiversity, its geographical setting, and the environmental change.

26 **Abstract**

27 Morphological variation is strongly related to variation in the ecological characteristics and
28 evolutionary history of each taxon. To explore how geographical variation in morphology is
29 related to different climatic gradients and phylogenetic structure, we analyzed the variation of
30 morphological traits (body size, bill, and wing) of 64 species of tyrant flycatchers (Tyrannidae)
31 distributed in Mexico. We measured these morphological traits in specimens from biological
32 collections and related them to the climatic and topographic data of each collection locality. We
33 also calculated the phylogenetic structure of flycatcher assemblages of each locality in order to
34 explore the influence of climatic variables and the phylogenetic structure over the morphological
35 variation of tyrant flycatchers, by means of linear mixed-effects models. We mapped the spatial
36 distribution of the variation of morphological traits in relation to environmental gradients taking
37 into account the phylogenetic structure. The climatic variables that better explained the
38 morphological variation were those of temperature ranges (seasonality) and the results suggest
39 that the phylogenetic clustering increases towards the highlands of Sierra Madre Oriental and
40 Sierra Madre del Sur, and the lowlands of Balsas Depression. At the regional assemblage, the
41 spatial distribution of body size shows a pattern coincident with the ecogeographical Bergmann's
42 rule, with an increase in size from south to north. In the tropical lowland forests assemblage,
43 body size tend to increase in seasonally dry forests (western Mexico) and decrease in the humid
44 ones (eastern Mexico). At highland forests and other types of vegetation, morphological trait
45 values increased. Phylogenetic structure helps to explain the variation of morphology at lower
46 assemblages but not at the regional assemblage. The patterns of trait variation along lowlands
47 and highlands assemblages, suggest that part of morphological variation is explained in both by
48 the climatic gradients and lineage relatedness of communities. Morphological variation is best

49 explained by a varied set of variables, and regression models representing this variation and
50 integrating phylogenetic patterns at different community levels provide new understanding into
51 the mechanisms underlying the link between biodiversity, its geographical setting, and the
52 environmental change.

53

54

55 **Introduction**

56 A long-standing goal in ecology and evolutionary biology is to understand the relationships
57 among morphological diversity, evolutionary history, environment and geographic distribution.
58 Environmental drivers of morphological diversity across geography have been extensively
59 studied in many regions with different taxonomic groups, at different geographic, taxonomic and
60 functional scales (Losos & Miles, 1994; Cavender-Bares et al., 2009; Kluge & Kessler, 2011;
61 Violle et al., 2014; Jarzyna et al., 2015; Jarzyna & Jetz, 2016; Lawing et al., 2017; Schneider et
62 al., 2017; Seeholzer et al., 2017; Phillips et al. 2018; Mazel et al., 2018). As a result of previous
63 studies that analyze the role of environment and geography as promoters of morphological
64 diversity, patterns of gradual variation of traits have been detected for many groups. Climate
65 seems to be one of the main environmental promoters of morphological variation, strongly
66 influencing the distribution and variation of morphological traits across species and regions (e.g.
67 James, 1970; Graves, 1991; Kivelä et al., 2011; Maestri et al., 2016; Xu et al., 2017). However,
68 the role of climate and other environmental variables is poorly understood. Even though many
69 studies have demonstrated its associations with morphological traits, the question remains to
70 what extent and by which mechanisms such associations are maintained and may influence

71 distribution patterns (Violle et al., 2014). It has been suggested that several variables may act
72 simultaneously, promoting morphological variation at many taxonomic and geographic scales.

73

74 Morphological diversity across species is driven by several ecological and evolutionary
75 processes and is usually studied as the evolution of form and function, or ecomorphology (Losos
76 & Miles, 1994; Ricklefs, 2012; Dehling et al. 2014; Seeholzer et al. 2017; Phillips et al. 2018).

77 Also, variation in morphological diversity within communities can have effects in structuring
78 broad-scale biogeographical patterns of species richness along climatic and geographical

79 gradients (Deutsch et al., 2008; Cicero & Koo, 2012). Morphological variation is related to

80 ecology and reflects a response to biotic and abiotic environmental factors, and it may determine

81 species' responses to climate change (Wainwright and Reilly, 1994; Pontarotti, 2010; Cicero &

82 Koo, 2012). Climatic variables, such as temperature and precipitation, are recognized as major

83 factors determining geographical patterns of morphological variation (Hawkins et al., 2007). For

84 instance, bill size increases with higher temperatures, supporting the hypothesis that larger bills

85 are an adaptation to release heat while minimizing evaporative water loss in hot, dry

86 environments (Greenberg et al., 2012). In this way, overall bill size may be related to

87 physiological responses to regional climates, and the season of critical thermal stress may vary

88 geographically, even on relatively small spatial scales (Campbell-Tennant, Gardner & Kearney,

89 2015; Danner and Greenberg, 2015). Other factors such as evolutionary history also have been

90 found to determine geographical gradients in species variation (Jetz & Rahbek, 2002, Kissling et

91 al., 2007). For instance, habitat filtering is an ecological process by which species are eliminated

92 from a community because of morphological/ecological similarity with other established

93 members of the community (Wainwright and Reilly, 1994). Under this interpretation, the

94 variation of morphological variables across communities and geography is proportional to the
95 amount of phylogenetic dissimilarity among communities (Pillar and Duarte 2010), taking into
96 account that morphology is structured by phylogeny at the species level if there is phylogenetic
97 signal. Morphological variation occurs within and across species, so the complex interaction of
98 evolutionary history and environment makes difficult to identify the underlying causes of broad
99 scale patterns of variation (Endler, 1977; Ricklefs & Miles, 1994; Violle et al., 2014; Forister et
100 al., 2015).

101 The recognition of the promoters of broad scale patterns of morphological variation is
102 challenging due to the differential response of organisms' traits to environmental variation and
103 geographical settings (Violle et al. 2014). This limits our ability to elucidate the causes and
104 consequences of the patterns of species' morphological diversity. For instance, the geographical
105 patterns of community structure and morphological variation in response to climatic gradients
106 has shown contrasting effects of the same environmental variables (e.g. Forister et al., 2015; van
107 de Pol et al., 2016; Lawing et al., 2017). To understand how morphological diversity arises, it is
108 necessary to explore and quantify how species' morphological traits are related to their ecology,
109 how they vary geographically along environmental gradients, consider both large and small
110 spatial scales in the same region, and account for the historical contingencies limiting the
111 distribution of species assemblages and their traits (Cavender-Bares et al., 2009). In this sense,
112 phylogenetic structure and distributional data provide the historical framework to quantify
113 ecological, geographical and evolutionary patterns, in order to infer the processes that established
114 them (Saito et al. 2016; Sobral & Cianciaruso 2016, Phillips 2018). Also, quantifying the
115 geographical distribution of morphological variation may help disentangle trade-offs found in the
116 relationship between morphology and environmental and phylogenetic variables. Then, analyses

117 of the distribution of morphological variation are necessary for improving regional and global
118 predictions of morphological and functional change (Diniz-Filho, 2004; Rodríguez & Ojeda,
119 2014).

120 To evaluate broad scale patterns of morphological variation and the underlying processes
121 which promote them, it is necessary to quantify the distribution of morphological traits in
122 relation to the ecology of related functional groups of species. In that sense, some authors have
123 found that the global patterns of functional richness are associated with environmental variables
124 (Kissling et al., 2009; Brum et al., 2012). To describe how morphology varies geographically
125 with environment, we explored the spatial distribution of a set of morphological variables in
126 relation to climatic gradients of a mainly insectivorous assemblage of birds, the tyrant flycatchers
127 (Tyrannidae). The tyrant flycatchers constitute a functional group of species that use insects and
128 arthropods as their main food resource (Hespenheide 1971; Sherry 1984). This taxon includes
129 more than 400 species distributed across the Americas (IOU, 2018) occurring in almost every
130 habitat. They are adapted to different elevations and occupy all vertical forest strata (Fitzpatrick
131 et al., 2004, Ridgely and Tudor, 2009). We chose the Tyrannidae of Mexico as a model system
132 because: (1) they are widely distributed in the country (Ridgely et al., 2005; Berlanga et al.,
133 2008); (2) the natural history, phylogenetic structure, and functional significance of their
134 morphological traits is relatively well known (Ohlson, Fjeldså & Ericson, 2008; Tello et al.,
135 2009); (3) their morphology can be related to their ecology (e. g., Fitzpatrick 1980, 1981, 1985);
136 and (4) their morphology varies across environmental and geographical gradients (Brum et al.,
137 2012).

138 Our main goal was to investigate the variation of morphology across geography and to
139 determine the relationship of environmental climatic gradients as explanatory factors of

140 morphological function-related traits. We have considered the phylogenetic structure of Mexican
141 flycatchers as a factor that may help explain how broad scale patterns in species variation are
142 established and how historical contingencies influence the response of morphological variation
143 to the environment. Our specific objectives were to test (1) whether climate conditions
144 (temperature, precipitation, and their seasonality), are associated with the observed variation in
145 morphology across tyrant flycatchers assemblages; (2) the influence of the phylogenetic structure
146 of assemblages on the geographic distribution of morphological variation and its response to
147 climate; and (3) to map the spatial distribution of morphological variation along climatic
148 gradients. Because traits are related to the ecology of the organism, for instance foraging
149 behavior or habitat use (Fitzpatrick, 1985), morphological variation is expected to reflect
150 species' responses to environmental gradients. Then, the approach we used takes into account
151 varied ranges in climate and seasonality within a lineage, abiotic variables influencing the
152 geographic distribution of species, and the phylogenetic relationships among the tyrant
153 flycatchers. Taking into account phylogenetic relationships within a community by accounting
154 for phylogenetic structuring, may help to understand the influence of the composition of a
155 community on the response of traits to environmental variation (Bonetti & Wiens, 2014; Maestri
156 et al., 2016).

157

158 ***Hypothesis and assumptions***

159 Given that climatic gradients and phylogenetic structure of an area potentially play a role as
160 promoters or constrainters of morphological variation, and because this role may vary in strength
161 and direction, we analyzed the morphological data by constructing regression models in order to
162 explain the relationship between morphology, environment and phylogenetic structure. We

163 hypothesized that once historical and geographic factors are accounted for: Hypothesis 1) climate
164 gradients explain morphological change across geography; and hypothesis 2) phylogenetic
165 structure of a community should influence morphological variation of the co-occurring species.
166 For hypothesis 1, we assumed that morphology would show clinal variation related to one or
167 more climatic variables, then a latitudinal pattern when the model is translated to a map.
168 Conversely, for hypothesis 2, we assumed that morphological change cannot solely be explained
169 by climatic variables, but also phylogenetic structure would also be significantly associated to
170 variation in morphology (evidence for hypothesis 2). Latitudinal variation in morphology is
171 likely to be affected by the phylogenetic composition of the area, that is, the variation of
172 morphological traits across geography is expected to be proportional to the amount of
173 phylogenetic dissimilarity among communities (Duarte, 2011). Phylogenetically clustered areas
174 are expected to show different patterns of morphological variation than areas that are
175 phylogenetically overdispersed. Because of the tendency of species to remain in an
176 environmental space similar to that of their ancestors (Wiens & Graham, 2005) we expect that
177 morphological variation within assemblages will be constrained. Phylogenetically clustered
178 assemblages are more likely to be restricted in their climatic ranges, whereas phylogenetically
179 overdispersed assemblages are more likely to be found in the transition zones where there is a
180 high species turnover (Graham et al., 2009) species competition influences the local trait
181 composition of a community (Wainwright & Reilly, 1994). Phylogenetic structure alone is
182 unlikely to explain the variation of morphology; instead it is expected to influence morphology
183 along with climatic variables, meaning that the response of the trait could be driven by either
184 environmental filtering (species are filtered from a community due to morphological or

185 ecological similarity with other co-occurring species), other biotic interactions (e.g. competition),
186 or random factors (Cavender-Bares et al., 2009; Lawing et al., 2017).

187

188 **METHODS**

189 *Morphological traits data and data treatment*

190 *Morphological data.* In order to construct regression models of environmentally-related
191 morphological variation, the morphological traits were associated to locality-specific climate,
192 topographic and phylogenetic structure data. We obtained morphological data from a sample of
193 296 skin specimens from 60 species of Tyrannidae distributed in Mexico (Table S1). We
194 measured five traits (Claramunt, 2010, following recommendations by Eck et al., 2011): body
195 size (using mass data as a proxy), bill length, bill width, and bill depth (the last two taken at the
196 anterior border of the nostrils), and wing chord (wing length from the carpal joint to the tip of the
197 longest primary feather without flattening the wing). We selected these traits because they have
198 been associated use of environmental space in birds (Miles & Ricklefs, 1984). Size is a
199 significant attribute at all levels of organization, as it predicts and explains the variation of many
200 organismal and species traits, from the proportion of parts to metabolic rates to the distribution
201 patterns (Schmidt-Nielsen, 1975; Brown, 1995; Diniz-Filho, 2004; Bonner, 2011). Bill size can
202 be positively correlated with temperature in avian taxa (Allen's rule), and the common
203 explanation for this pattern is that larger surface area of the appendage functions to dissipate
204 excess heat in warm climates and small area to retain heat in cold climates (Symonds &
205 Tattersall, 2010; Greenberg, 2012). The bill is also the functional trait by which birds obtain
206 food, so it can be related to habitat and ecomorphological variation (Mazer & Wheelwright,
207 1993; Jones, 2012). The relative variation of bill measures represents its variation in size and

208 shape. Finally, wing chord plays a role in determining the aerodynamics and mechanical aspects
209 of the avian wing, thus it interacts with the effective exploitation of habitat; so it is strongly
210 related with ecology and behavior (Hamilton, 1961; Lockwood, 1998, Swaddle & Lockwood,
211 1998, Gatesy & Dial; 1996). Together, body size, bill size and wing chord represent
212 morphological traits that are related to the flycatcher ecology.

213 In general, we only measured adult male specimens to homogenize the data set and to
214 avoid morphological variations associated with sexual dimorphism. In some cases, we had to
215 measure female specimens (~8% specimens) to complete the sample, and used these data based
216 on a previous test (Cortés-Ramírez, Ríos-Muñoz & Navarro-Sigüenza, 2012) that showed that
217 the variation between sexes is smaller than interspecific variation (*sensu* Claramunt, 2010). We
218 took all the measurements with digital or analog Mitutoyo calipers, with a precision of 0.01 mm.
219 For statistical analysis we used *natural log*-transformed measures in order to normalize the
220 dataset, and because all morphological measurements may scale with overall body size, we made
221 bill and wing size measurements relative to body size by dividing each measurement by body
222 mass. Relative variation of the three bill measurements was obtained by performing a principal
223 component analysis (PCA) to reduce the dimensionality of bill variation (Table S2), retaining the
224 first principal component as representative of bill variation and size. The first principal
225 component represented 86% of bill variation and overall size of the bill. Each morphological
226 variable was evaluated independently from the other variables.

227

228 ***Environmental and geographic data.***

229 *Climatic variables.* We considered the geographic location of each specimen to obtain locality-
230 specific climate data based on a set of 19 bioclimatic variables (Hijmans et al., 2005). To reduce

231 the dimensionality without eliminating bioclimatic variables, we constructed four climatic
232 indexes by applying a PCA on climatic variables following Alvarado-Cárdenas et al. (2013,
233 Table 1). These four indexes represent annual temperature variation, temperature range or
234 seasonality, variation of precipitation in the most humid season, and variation of precipitation in
235 the driest season. We decided to use the first principal component of each climatic index, as they
236 account for most of the climatic variation in the study area (Table S3). For each specimen we
237 extracted locality-specific climate index data using a geographic information system. We used
238 the climatic index data for each individual as a fixed explanatory variable in the regression
239 models.

240

241 *Topographic variables.* In order to separate the effects of the geographical setting, we used the
242 USGS Digital Elevation Model (altitude, USGS, 2015, <https://lta.cr.usgs.gov/GTOPO30>) and
243 aspect as predictor variables in all regression models. To facilitate the use of aspect as a variable
244 that describes topographic orientation, we transformed it using the cosine to express northness
245 and the sine for eastness following Kobelkowsky-Vidrio, Ríos-Muñoz, & Navarro-Sigüenza
246 (2014).

247

248 ***Historical distribution and relatedness data***

249 *Assemblages of the tyrant flycatchers.* In order to discriminate the effects of the
250 evolutionary/historical distributional of the tyrant flycatchers, we divided the data into three
251 separate sets taking into account characteristics of three constructed assemblages of tyrant
252 flycatchers distributed across Mexico. We defined an assemblage as a temporal and spatial
253 arrangement in which species potentially occur and interact; i.e., the pool of species in a

254 geographic area (Halffter & Moreno, 2005, Lessard et al., 2016). We defined three assemblages
255 on the basis of environmental factors delimited by elevation and vegetation type (Fig. 1, Table
256 S1): Type I- Assemblage of the lowland forests (species distributed only below 1500 m), Type
257 II- Assemblage of the highland forests (species present mainly above 1500 masl) and other types
258 of vegetation, and the Regional assemblage (species distributed in both assemblages, which
259 represent the species distributed in all Mexico). We assigned the species to each assemblage and
260 carried out statistical analysis independently for each data set. We focused on the type I
261 assemblage data because Mexican lowland forests are characterized by high levels of species
262 richness, endemism, and habitat specialization, and patterns of biogeographic distribution define
263 them as areas with a particular evolutionary history (Ríos-Muñoz & Navarro-Sigüenza, 2012;
264 Olguín-Monroy et al., 2013). The Type II and Regional assemblage datasets were used to
265 contrast the response of morphological variation to environmental gradients at different spatial
266 scales and community levels. It is known that the influence of different variables on the
267 morphological variation change at different scales of analysis (Lawing et al., 2017).

268

269 *Phylogenetic signal and phylogenetic structure.* We reconstructed a phylogenetic tree for the
270 species of Tyrannidae distributed in Mexico using Jetz et al.'s (2012) bird tree with the Hackett
271 et al. (2008) backbone (Fig. S1), in order to calculate the phylogenetic signal of traits and the
272 phylogenetic structure of the localities. The phylogenetic signal was calculated for each
273 morphological variable using the generalized K statistics (Adams, 2014). Phylogenetic signal
274 indicates the tendency of related species to resemble each other more than species drawn at
275 random from the same tree (Blomberg & Garland, 2002). Generalized K statistics tests a null
276 model of evolution of a trait by Brownian motion (drawn at random from the tree), $K = 1$

277 indicates that trait evolution is consistent with Brownian motion model, while $K < 1$ indicates less
278 similarity in the trait than expected under Brownian motion model, and $K > 1$ indicates greater
279 similarity in the trait than expected under Brownian motion model (Blomberg et al., 2003).
280 Phylogenetic signal tests were conducted using *geomorph* package (Adams & Otarola-Castillo,
281 2013) in R version 3.4.1 (R Core Team, 2017).

282 To determine if the species in a particular area were more closely related than expected
283 by chance, we measured the phylogenetic structure of the Tyrannidae distributed at each locality.
284 To calculate the metric, we used the Net Relatedness Index (NRI, Webb et al., 2002) in the R-
285 package *PhyloMeasures* (Tsirogianis & Sandel, 2016). Values of NRI greater than zero indicate
286 phylogenetic clustering and values lower than zero indicate phylogenetic evenness or
287 overdispersion. Phylogenetic clustering is found when the co-occurring species of an area are
288 more closely related than expected by chance. Phylogenetic evenness or overdispersion is found
289 when the coexisting species of an area are less related than expected by chance (Webb et al.,
290 2002). To calculate the NRI for each locality, we used the reconstructed phylogenetic hypothesis
291 and we established which species likely co-occur by extracting presence data from distributional
292 hypotheses for Mexican Tyrannidae, generated elsewhere using ecological niche models
293 (Navarro-Sigüenza et al., unpubl. data).

294

295 ***Statistical analyses***

296 ***The regression models***

297 We evaluated the effects of environmental gradients and phylogenetic structure on
298 morphological variation in the tyrant flycatchers of Mexico using regression models. We
299 constructed trait maps (see below) and obtained our inferences based on the fitting of linear

300 mixed-effects models predicting morphological variation in body size, bill and wing length. We
301 used linear mixed-effects modeling because our data are nested in the sense that samples derive
302 from multiple species, and from each species we have various specimens.

303 To find the best fitting models for each morphological variable (and assemblage dataset),
304 we followed the protocol recommended by Zuur et al. (2009). In the first step, we started with a
305 model for each morphological variable that contained all the predictor variables and their
306 interaction in the fixed part of the model. There are seven fixed predictor variables (temperature
307 variation index, temperature range or seasonality index, variation of precipitation in humid
308 season, variation of precipitation in the dry season, topographic setting, altitude, and
309 phylogenetic structure) and four interactions (relationships between altitude and the temperature
310 and precipitation indexes, Table 2, Table S4 model 1). After obtaining the more complex linear
311 model, we made a new model allowing random intercepts for the nested structure of individuals
312 of a species within a subfamily (Table 2, Table S4 model 2). The random intercept implies that
313 the basal value of the response is influenced by the nested structure of the data, so measures
314 within a species are more likely to be correlated just because they belong to the same
315 phylogenetic group (Militino et al., 2010). Next, we allowed random slopes and intercepts for
316 individuals of a species within a subfamily (random intercept), influenced by the phylogenetic
317 structure of the communities (random slope, Table 2, Table S4 model 3). Letting the slope to
318 change implies that morphological traits can change between communities in function of how
319 closely related are the species distributed on it. Then, we included the optimal variance structure
320 to the optimal model for the random terms (Table 2, Table S4 model 4). We considered that
321 different variance exist for the observations that have distinct phylogenetic membership. Next,
322 we selected the best fitting model structure for the fixed terms by sequentially adding each

323 predictor variable and their interactions (Table 2) to the optimal random and variance structure
324 model (Table S4 models 5-16). We tested if phylogenetic structure influenced morphological
325 variation (Evidence for hypothesis 2, Table S4 model 12) by including it to the best fitting model
326 for the fixed terms. Finally, we included the interaction term between phylogenetic structure and
327 the climatic variables that best explained the morphological variation (temperature seasonality,
328 model 17). The interaction between phylogenetic structure and temperature seasonality implies
329 that phylogenetic structure modifies the effect of temperature seasonality on the morphological
330 variation within assemblages. The final products of the procedure described were nine best
331 fitting models predicting each morphological variable, at each assemblage, in relation to climatic
332 variables, phylogenetic structure and phylogenetic membership (Table S4, Table 3). We
333 considered the best-fitting model for each variable the one with the highest maximum likelihood
334 (ML), the Akaike information criterion (AIC), and Bayesian informative criterion (BIC,
335 Burnham & Anderson, 2002). We performed all statistical analyses using the *nlme* (Pinheiro et
336 al., 2013) package in R version 3.4.1 (R Core Team, 2017).

337

338 ***Mapping the spatial variation of morphological traits***

339 To map the spatial variation of the morphological traits, we extrapolated the best-fitting models
340 into GIS layers. First, we extracted the value of the predictor climatic variable in each pixel (30
341 seconds per side) of Mexico within each assemblage. Then, we translated the best-fitting model
342 formula for the climatic index value at each pixel. For instance, if the model was: “*Size expected*
343 *at pixel X = slope*value of climatic index at pixel X + intercept*”, we obtained a different value
344 for the morphological variable at each pixel according to the model and the variation of the
345 predictor variable, generating a map of the measurements of the functional traits (Moles et al.,

346 2011). We performed all analyses using the Maptools (Lewin et al., 2011) package in R version
347 3.4.1 (R Core Team, 2017). Trait maps were visualized using ArcGIS 10 (ESRI, 2011).

348

349 **RESULTS**

350 *Relationship between climatic gradients and morphological variation*

351 Climatic gradients were associated positively with morphological variation of the three measured
352 traits in all three assemblages (Table 3). All best fitting models included at least one climate
353 variable among the fixed terms, specifically, temperature seasonality (temperature range) or
354 mean variation. Temperature appears to explain variation in morphology at all levels analyzed.
355 At the regional assemblage, for body size, bill and wing length, temperature is related positively
356 and significantly to morphological change, and reflects increase in the morphological variables
357 values as temperature seasonality increases. The magnitude of the response is higher for body
358 and bill sizes (slopes 0.42 and 0.65, respectively), whereas for wing is close to zero
359 (slope=0.091); that means that although it is positive and reflects an increase in the
360 morphological variable values, this change is small. In other words, while the climatic
361 seasonality increases, wing length will not tend to increase as much as body and bill size, it
362 reflects a poor association between wing and temperature range index.

363 For type I and type II assemblages, the relationship between morphological variables and
364 temperature range is also positive but not significant for some variables ($p\text{-value}>0.05$). For
365 instance, the regression model for bill size and temperature range, and wing length and
366 temperature range, in the highland forests and other types of vegetation assemblage indicates that
367 the relationship is not significantly different from 0 (there is no relationship between the
368 morphological variable and temperature range). Also, for the lowland forests assemblage,
369 regression model for wing and temperature range is not significant either. Only the relationship

370 between body size and temperature range is significantly positive in all assemblages. The
371 relationship between bill variation and temperature range is significant in lowland forests
372 assemblage but the magnitude of the response is less steep (slope=0.43).

373

374 *Influence of phylogenetic structure on morphological variation*

375 Linear mixed-effects models results indicated that phylogenetic relatedness also helped to
376 explain morphological variation in type I and type II assemblages, for body size, bill and wing
377 variables (Table 3). At highland forests and other types of vegetation assemblage, models for bill
378 and wing were not significant ($p\text{-value}>0.05$), whereas the model for body size is significant and
379 positively related to phylogenetic structure (slope= 0.60). A positive correlation between body
380 size and phylogenetic structure means that body size values increase at areas with more
381 phylogenetically related species occurring at the community (phylogenetic clustering), and
382 decreases in areas with less phylogenetically related species (phylogenetic overdispersion). For
383 lowland forests, phylogenetic structure was positively correlated to bill variation, and negatively
384 correlated to body size. The relationship between wing and phylogenetic structure was not
385 significant. The results indicate that there is a tendency of decrease in body size while
386 communities became more phylogenetically clustered.

387 Our results indicate that phylogenetic structure exhibits a geographical pattern (Fig. 2).

388 Both highland and lowland forests assemblages presented areas with phylogenetic overdispersion
389 and phylogenetic clustering (Table S5). Areas of higher phylogenetic clustering appeared to be
390 distributed along the lowland areas of the Balsas Depression, and the highlands of Sierra Madre
391 del Sur (mountain range in the southern Mexico) and Sierra Madre Oriental (mountain range in

392 eastern Mexico). Areas with high phylogenetic overdispersion are mainly distributed in
393 southeastern Mexico (i.e. southeastern Yucatan Peninsula, Tehuantepec Isthmus).

394 We also measured the phylogenetic signal of the morphological traits, in order to explore
395 the tendency of the traits to resemble each other taking into account phylogenetic relatedness.
396 Phylogenetic signal analysis returned a value of $K= 0.85$ for body size, $K= 0.88$ for bill variation,
397 and $K= 0.87$ wing chord. All values were statistically significant at $\alpha= 0.05$. These values
398 indicate that although the phylogenetic signal for each morphological variable at the species
399 level is lower than 1, values are close to Brownian motion model (no tendency of traits to
400 resemble each other due to phylogenetic relatedness), which means that they are slightly less
401 similar than expected due to phylogenetic relatedness.

402

403 *Spatial variation of morphological traits in relation to environmental gradients*

404 Overall, trait variation was explained by temperature gradients and phylogenetic structure at
405 assemblages other than regional. Mapping the predictions of the best fitting models (Table 3)
406 yielded different patterns of spatial distribution for morphological variation (Figures 3-5), across
407 the geography at different scales. Maps represent the gradient of change of the morphological
408 traits with respect to the environmental variable that better explain their variation. We only
409 mapped the statistically significant models. At the regional assemblage (Fig. 3), for the three
410 morphological variables, morphological trait values increase with increasing latitude.
411 Phylogenetic structure does not help to explain morphological variation in the regional
412 assemblage. Lowland forests assemblage showed a morphological trait variation from northeast
413 to southwest (Fig. 4), in which body size and bill size increases towards the southwest. In the
414 lowland forests assemblage, bill size increases with increasing phylogenetic structure.

415 Conversely, body size increases in areas with low phylogenetic structure (overdispersion) and
416 decreases in areas phylogenetically clustered (Fig. 2A). Geographically, that means that
417 phylogenetic structure decreases size in areas where temperature gradients predict increase in
418 size, and increase in size where temperature gradients predict decrease. For the type II
419 assemblage (Fig. 5), we mapped body size and bill variation, which are explained by temperature
420 seasonality. Increases in body size and bill variation were predicted in areas of higher
421 phylogenetic clustering and in southwestern Mexico (Fig. 2B).

422

423 **DISCUSSION**

424 Our results suggest that both climatic variables and phylogenetic structure influence the
425 morphological variation of Mexican tyrants, but the influence of the phylogenetic structure
426 varies between different assemblages and morphological traits. When we focused on how
427 climatic gradients explain the variation in morphology, our results suggest that temperature
428 seasonality is the most influential climatic variable, but the magnitude of the influence varies
429 across different assemblages. This variable assumedly represents tolerance limits of species to
430 variation in temperature, likely influencing morphological variation through maintaining habitat
431 use through time (Wiens & Graham, 2005). Our results showed a latitudinal pattern that is
432 consistent with the Bergmann's rule for birds: as temperature increases, body mass is likely to
433 decrease (McNab, 1971). This is a common finding in many studies, because the total surface
434 area of an animal is a proxy for heat dissipation, and predicts that a larger size can be reached in
435 colder climates than in warmer ones, which is linked to the temperature economy of the animal
436 (Salewski and Watt, 2017). Due to the distribution of temperature at the regional assemblage,

437 latitudinal pattern is likely to show an increase in body size from south to north (Fig. 3), but
438 some studies found exceptions at another regions (e.g. James, 1970).

439 Patterns of morphological variation in western Mexico type I and II assemblages showed
440 a pattern in which the tendency to increase in size was predicted in direction to both highlands
441 and lowlands of western Mexico (Fig. 4 and Fig. 5), which also contain areas with the highest
442 values of phylogenetic structure. A larger body size in less vegetated or highly seasonal areas
443 may be an adaptation to live in these types of isolated environments, and higher phylogenetic
444 structuring agrees with the fact that western areas have been identified as a complex
445 biogeographical and ecological setting in which a highly endemic and phylogeographically
446 structured bird fauna occurs (e.g. García-Trejo & Navarro-Sigüenza, 2004; Navarro-Sigüenza et
447 al., 2004; Ríos-Muñoz & Navarro-Sigüenza, 2012; Arbeláez-Cortés et al., 2014). For patterns of
448 morphological variation in eastern lowlands, like the phylogenetically overdispersed Yucatan
449 Peninsula or the Tehuantepec Isthmus, relatively constant (i.e., less seasonal) temperatures in the
450 east, may have influenced the distribution of lineages and the variation of its morphological
451 traits, and consequently the particular phylogenetic community structure in those regions (Martin
452 et al., 2018).

453 The results of several studies support the idea that environmental gradients influence the
454 phylogenetic structure of the communities and therefore, phylogenetic clustering increases with
455 decreasing temperature, meaning that closely related species tend to have a strong phylogenetic
456 signal, and more similar traits and geographic distributions than expected by chance (Helmus et
457 al., 2007; Donoghue, 2008; Graham et al., 2009; Flynn et al., 2011; Tedersoo et al., 2012; Miller
458 et al., 2013). For instance, Miller et al. (2013) found that the tendency of species to remain in an
459 environmental space similar to that of their ancestors (niche conservatism, Wiens & Graham,

460 2005) constrains honeyeater assemblages in arid regions, along a gradient of decreasing
461 precipitation. Instead, we found that tyrant's assemblages became more phylogenetically
462 clustered along a gradient of increasing temperature seasonality, but with low phylogenetic
463 signal. Our findings might reflect that variation in morphological traits of phylogenetically
464 clustered assemblages is more restricted in their climatic ranges. Moreover, on another study,
465 Graham et al. (2009) found that phylogenetic diversity of hummingbird communities of the
466 Andean region tend to be phylogenetically clustered at higher elevations and colder areas, and be
467 overdispersed at lower elevations, whereas in the transition zone between lowlands and
468 highlands there is a species turnover of relatively distant related species that can be associated to
469 the environmental gradient. We found similar results in which phylogenetically clustered
470 communities are found in the western areas (Fig. 2) which includes mountainous ranges above
471 1500 masl (southern Sierra Madre Oriental, and the Sierra Madre del Sur), although lowland
472 areas like the Balsas Depression also show high values of phylogenetic clustering.

473 Phylogenetic clustering at higher elevations supports the idea of environmental filtering,
474 a pattern where similar traits are selected above other variations because they have an advantage
475 within the community and the environment, also allowing the coexistence of close relatives
476 (Webb et al., 2002). Phylogenetic clustering in lowlands like the Balsas Depression supports the
477 idea of the effect of dispersal barriers over community structuring, where communities are
478 phylogenetically similar despite their large differences in species composition, a pattern
479 reflecting the influence biogeographic barriers (Graham et al., 2009) that promote regions with a
480 set of related species with a common and isolated history, like areas of endemism (Harold &
481 Mooi, 1994).

482 The phylogenetic overdispersion patterns we found could be more related to the
483 expectation that competition influences the local trait composition of a community by promoting
484 the filling of the morphological and ecological space exploited (Wainwright & Reilly, 1994); but
485 it can also be associated with the distribution of a lineage along a transition zone, that is, an area
486 where a mixed set of distinct biotic elements overlap (Morrone 2004). Areas found with higher
487 phylogenetic overdispersion have been recognized by other authors as areas where different
488 biotic elements overlap, e.g parts of the Mexican Transition Zone (Sierra Madre Oriental),
489 Yucatan Peninsula and the limits of the Tehuantepec Isthmus (Morrone, 2006, 2014).

490 Contradictory to the expectations of patterns of phylogenetic structuring, our data show
491 low phylogenetic signal, so traits are less similar than expected due to phylogenetic relatedness.
492 We would have expected a strong phylogenetic signal, as closely related species of a community
493 tend to occupy similar morphological space due to common ancestry, especially in
494 phylogenetically clustered areas. Overdispersion of traits driven by competitive interactions and
495 divergent trait evolution, as well as the taxonomic and spatial scale, may have influenced the
496 results by masking phylogenetic signal patterns at different assemblages (Webb et al., 2002;
497 Cavender-Bares et al., 2006; Lawing et al., 2017). The latter seems to be the case for tyrant
498 flycatchers, as many closely related clades that supposedly have similar distribution of traits, are
499 concentrated in the same areas of high phylogenetic structure. For example, closely related and
500 morphologically similar *Empidonax* and *Contopus* are concentrated southeastward, while another
501 set of closely related *Empidonax* are found concentrated westward (i.e. *E. difficilis*, *E.*
502 *occidentalis*, *E. fulvifrons* and *C. cooperi*, *C. pertinax* and *C. sordidulus*). On the other hand, the
503 areas that have more phylogenetically diverse communities (phylogenetic overdispersion) are
504 found in southeastern tropical region, for example the Yucatan Peninsula.

505 Another contradicting pattern revealed by our analyses was defined by the discordant
506 response of variation in body size in relation to temperature seasonality and phylogenetic
507 structure (Fig. 4). Our results indicate that body size increases as temperature seasonality
508 increases, but as communities became more phylogenetically clustered, body size decreases,
509 resulting in a trade-off between the influences of temperature seasonality and phylogenetic
510 structure over variation in body size. An evolutionary trade off suggests that the functional trait
511 of size is limited by the action of another trait of evolutionary and ecological importance, like the
512 relatedness of the species occurring within the community. Trade offs can occur at different
513 hierarchical levels, and situations can even occur in which the selection on traits of individual
514 organisms is opposed to the selection on an emergent characteristic at the species level
515 (Jablonski, 2007), establishing variation patterns that cannot be fully explained by analyzing a
516 single level. Then, the variation of a characteristic of the individual like body size could be
517 opposed to the selection of a property at the species level (Diniz-Filho, 2004), like the structuring
518 of communities.

519

520 **CONCLUSIONS**

521 Our analyses demonstrate that the environment has an effect on morphological variation that is
522 mediated by the phylogenetic structure of communities across geography. The use of different
523 environmental variables to elucidate patterns of morphological change in lineages, with distinct
524 levels of phylogenetic signal, and varied patterns of lineage composition across space provides
525 greater explanatory power than only taking into account species richness or abundance, or simply
526 presence/absence distributional data (Olson et al., 2009; Maestri et al., 2016; Lawing et al.,
527 2017). Several authors have noticed that morphological variation is best explained by a varied set

528 of variables, given that the effect of a single climatic variable, most of the time explains variation
529 only at one scale (taxonomic or geographic, James 1970; Dial 2008; Olson et al. 2009; Martínez-
530 Monzón et al. 2017). Assessing the distribution of ecomorphological traits of organisms is the
531 best way to predict change over an environmental gradient (Olson et al. 2009; Santos et al. 2016)
532 and consequently, regression models representing variation of functional traits provide new
533 insights into elucidating the general mechanisms that relate biodiversity across environmental
534 and geographical changes (Violle et al. 2014). A spatial visualization of the predicted response of
535 trait variation in relation to environmental factors can integrate individual and interspecific level
536 responses to evaluate the importance of morphological adaptation in the explanation of broader
537 scale processes. Finally, our results highlight that to allow a better understanding of the spatial
538 distribution patterns of morphological traits, and the processes that promote them in different
539 assemblages, it is necessary to consider the relationship of different ecomorphological traits of
540 the species in conjunction with the phylogenetic composition of the communities.

Table 1 (on next page)

Bioclimatic variables used to construct the climatic indexes.

Temperature mean variation index	Temperature range index (seasonality)	Variation of precipitation in humid season	Variation of precipitation in the dry season
BIO1 = Annual Mean Temperature	BIO4 = Temperature Seasonality (standard deviation * 100)	BIO13 = Precipitation of Wettest Month	BIO14 = Precipitation of Driest Month
BIO5 = Max Temperature of Warmest Month	BIO7 = Temperature Annual Range (BIO5-BIO6)	BIO16 = Precipitation of Wettest Quarter	BIO15 = Precipitation Seasonality (Coefficient of Variation)
BIO6 = Min Temperature of Coldest Month	BIO2 = Mean Diurnal Range (Mean of monthly (max temp - min temp))	BIO12 = Annual Precipitation	BIO17 = Precipitation of Driest Quarter
BIO8 = Mean Temperature of Wettest Quarter	BIO3 = Isothermality (BIO2/BIO7) (* 100)	BIO18 = Precipitation of Warmest Quarter	BIO19 = Precipitation of Coldest Quarter
BIO9 = Mean Temperature of Driest Quarter			
BIO10 = Mean Temperature of Warmest Quarter			
BIO11 = Mean Temperature of Coldest Quarter			

1 All bioclimatic variables taken from Worldclim 1.4 project (<http://www.worldclim.org>, Hijmans et al. 2005)
2

Table 2 (on next page)

Variables used as fixed terms, interactions and random effects in the regression models for the Mexican tyrant flycatcher.

1

	Significance	References
Morphological variables	Response variables	
Body mass (as size proxy)	Body size is a major influential variable that explains most of the morphological and trait variation within an individual and a species. It is strongly related to their ecology, and also imposes physical constraints to other morphological traits of birds. Body size can predict from the proportion of body parts to the distribution patterns of a species. Its variation has been related to variation in climate and other environmental and phylogenetic factors.	Schmidt-Nielsen (1984); Peters & Peters (1986); Olson et al. (2009); Bonner (2011); Salewski & Watt (2016)
Wing length	Wing is considered a major eco-evolutionary module of the birds, that is, a body part identified as an anatomical subregion of the musculoskeletal system that is highly integrated and act as functional unit during locomotion. Wing is related to habitat exploitation and locomotion (bird flight), because of that, wing variation is very physically constrained. For tyrant flycatchers, wing is usually related to the type of habitat that the individual lives in and exploits, as they use a special flights called sallies to catch their prey. Wing shape directly influences evasive movements against predators. Also, the shape and length of the wing are important factors as they directly influence the dispersal ability of birds. Several species of tyrant flycatchers are migratory, so wing length is an important aspect that is directly related to migratory movements.	Hamilton (1961); Fitzpatrick (1980); Fitzpatrick (1981); Fitzpatrick (1985); Miles & Ricklefs (1984); Winkler & Leisler (1992), Gatesy & Dial (1996), Swaddle & Lockwood (1998); Bowlin & Wikelski (2008); Dawideit et al. 2009; Förschler & Barlein 2011
Bill variation	Bill is another major module of the birds, that is, a body part identified as an anatomical subregion of the head that is highly integrated and acts as functional unit during specific processes of the individual, like feeding or communication. For this reason, bill is related to many features of the ecology of the bird, and varies and responds to environmental and evolutionary factors semi-autonomously from other body parts. For tyrant flycatchers, it is most related to their diet breadth and insectivorous feeding habits.	Fitzpatrick (1980); Fitzpatrick (1985); Symonds & Tattersall (2010); Greenberg et al. (2012); Felice & Goswami (2017)
	Predictor variables	
	Fixed terms	
Climatic variables Temperature means Temperature range Variation of precipitation in humid season Variation of precipitation in the dry season	Climatic gradients are part of the environment in which a species occurs. Variables of temperature and precipitation have been related to many functions of organisms and species, as they affect the variation of many morphological traits. For instance body size, distribution range, habitat and diet breadth (niche breadth), reproductive traits, trophic level, and others. In particular, for tyrant flycatchers, temperature means and range variation could define the suitable areas for occupation and habitat distribution. They also are supposedly major drivers of morphological trait variation. Precipitation seasonality may be related to the distribution of food, as insect abundance within forests and other habitats is correlated with the humid season. Body size and appendage size may be related to climate gradients following the Bergmann's and Allen's rules, respectively, as temperature decrease, body size increases but appendage sizes decrease.	Diniz-Filho (2004); Zellweger et al. (2006); O'Donnel & Ignizio (2012), Symonds & Tattersall (2010); Salewski & Watt (2016)

Altitude Topographic setting (northness and eastness)	There is evidence that climatic patterns of precipitation and temperature are affected by altitude. For instance, temperature drops with altitude and precipitation patterns differs with the topographic orientation within a mountainous area (hillshade effect).	Seoane et al. (2004) Kobelkowsky-Vidrio et al. (2014)
Phylogenetic structure	Communities are assembled at the local level from regional pools of species, by means of competition and other biotic interactions, and also by the local dispersion or clustering of functional traits. But at the regional scale, the sorting of species, in relation to functional traits can be related to large-scale environmental and climatic gradients. The sorting of individuals at both scales is the result of the combination of the patterns and processes occurring at different scales, and includes a historical component by which the community (or assemblage) is constructed, that is the phylogenetic relatedness of the members of the community. Closely related species can coexist based on the distribution of their functional traits, so the trait composition of the community is predictable because of the sorting of individuals and the history of the community. Then, the phylogenetic structure of a community can potentially explain the distribution of the trait at the community or assemblage scale.	MacArthur & Levins (1967); Webb et al. (2002); Cavender-Bares et al. (2009); Lawing et al. (2017)
Interaction terms		
Altitude x Climatic variables (one interaction with altitude per each climatic index)	As there is clear evidence of the relationship between climate and altitude, we considered that the interaction between the two types of variables) must be considered in the model as a term that might explain morphological variation.	Seoane et al. (2004)
Predictor variables Random effect		
Species of a subfamily at an assemblage influenced by the phylogenetic structure of the communities	Individual's morphological traits are likely to resemble the morphology of another individual of the same species more closely, simply because they belong to the same phylogenetic group (their shared common ancestry). Measures from individuals of the same species are expected to be correlated; this nested structure potentially violates the statistical assumptions of independence among data, so it has to be considered in the analysis.	Blomberg & Garland (2002); Blomberg et al. (2003); Zuur et al. (2009)
Variance structure		
Phylogenetic membership of species	Different species groups may have different responses to the fixed terms, thus morphological variables show different dispersion of the data simply because they belong to different groups.	Blomberg & Garland (2002); Blomberg et al. (2003); Zuur et al. (2009)

1 * Assemblages explanation. Type I: Lowland tropical forests. Type II: Highlands above 1500 masl and other types of vegetation. Regional the
2 combination of assemblages type I and II.

3

Figure 1

Geographical limits of the three delimited tyrant flycatchers datasets on the basis of the species distributed within Mexico.

Areas in green represent the distribution of the lowland tropical dry and humid forests (type I assemblage) and in brown the forests above 1500m (highland forests) or other types of vegetation (type II assemblage), the combination of both represent the regional assemblage. Modified from Ríos-Muñoz & Navarro-Sigüenza (2012) and Olguín-Monroy et al. (2013).

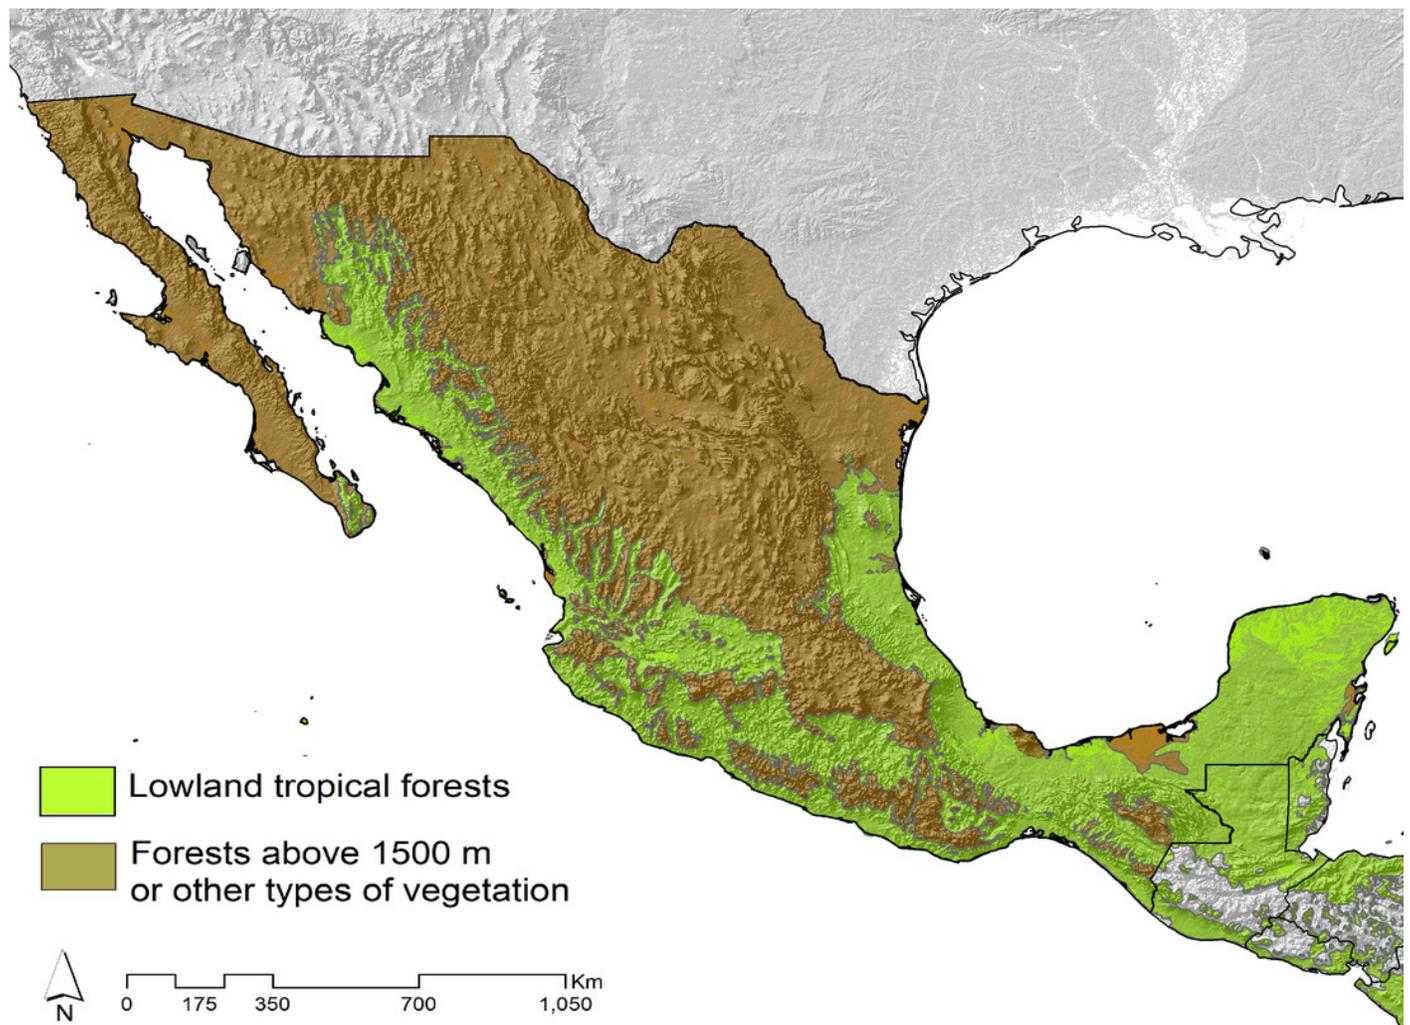

Figure 2

Geographical patterns of phylogenetic structure.

(A) Phylogenetic structure at localities of the lowland forests. (B) Phylogenetic structure at localities of the highland forests or other types of vegetation.

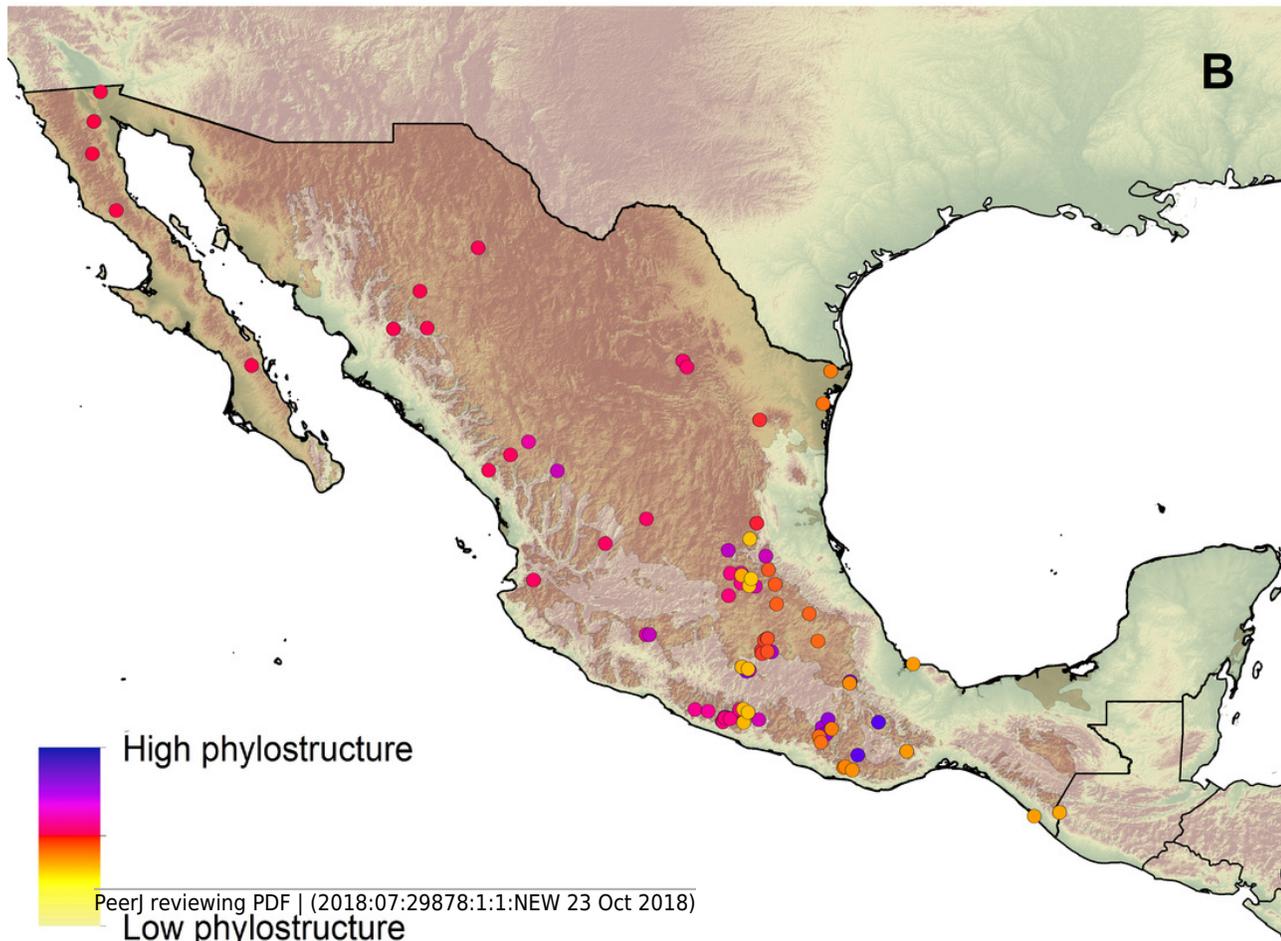

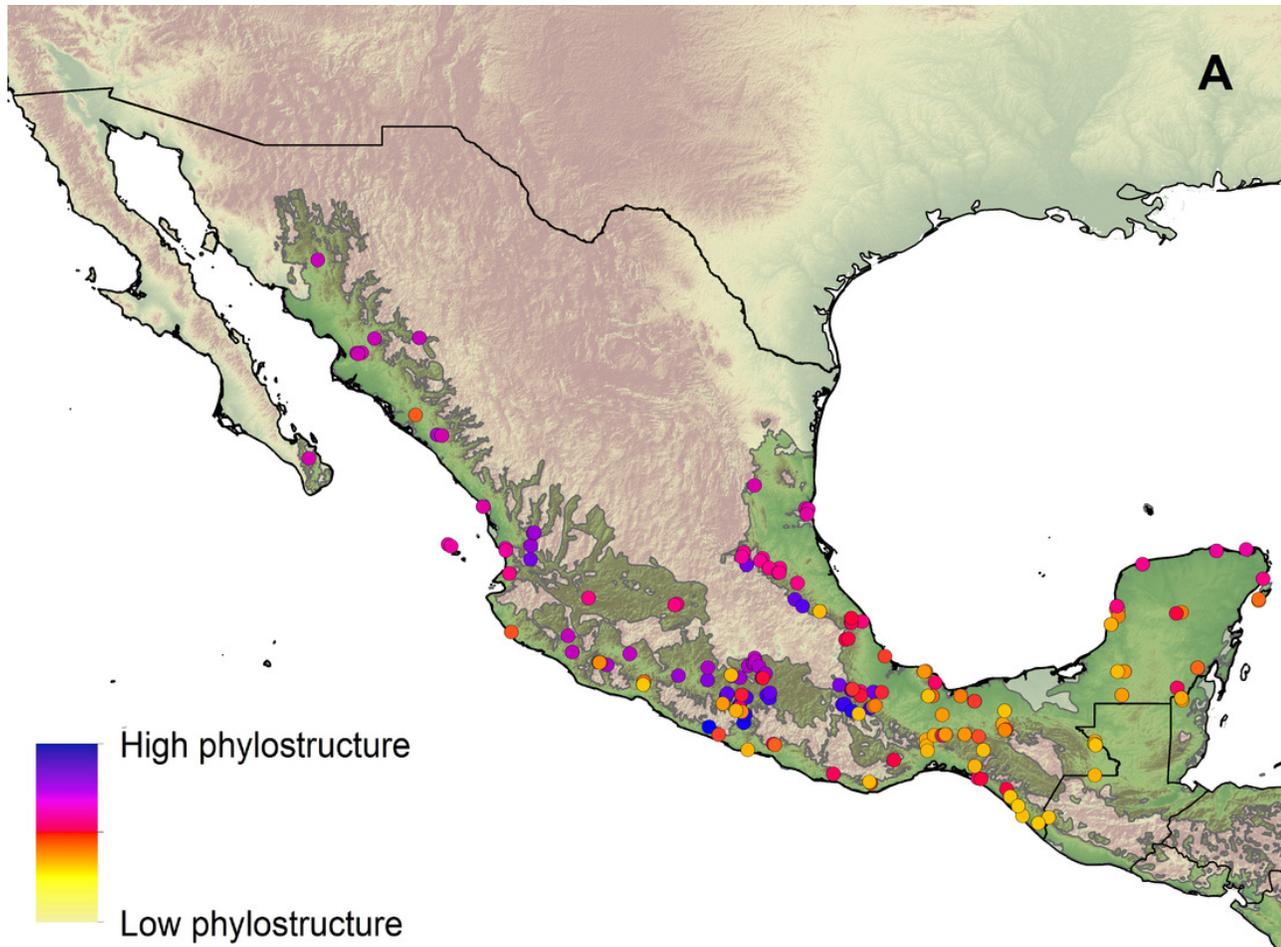

Figure 3

Spatial distribution of morphological variation of body size, bill size and wing length fitted for the regional assemblage by temperature range index.

The scatterplot diagram and the regression lines show the predicted response of body size, bill and wing to the increase in seasonality (Temp. range).

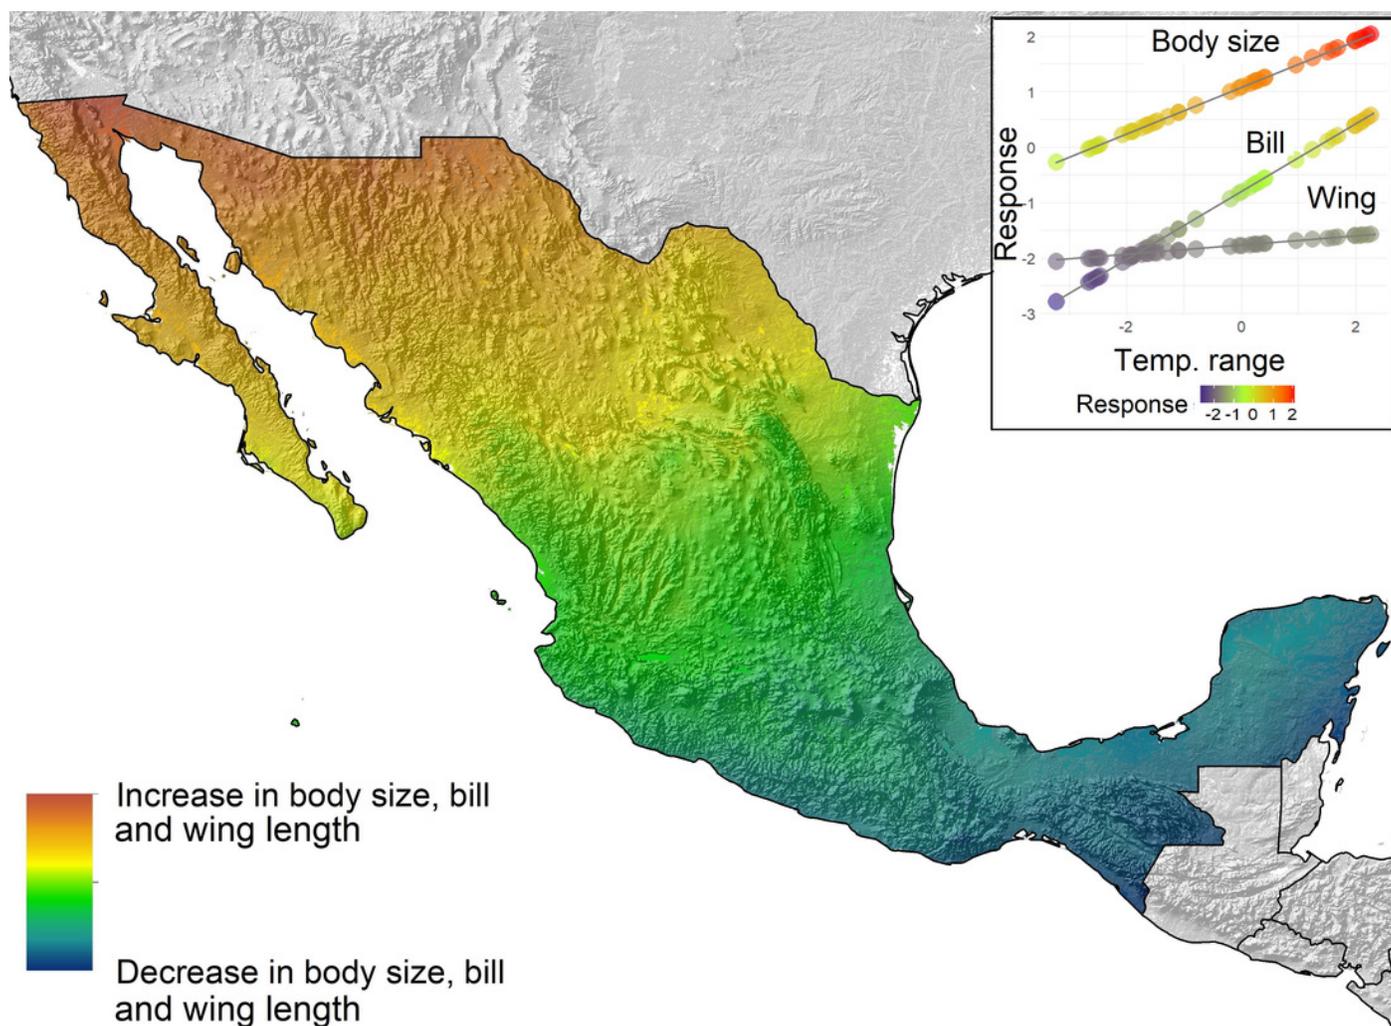

Figure 4

Spatial distribution of morphological variation of body size and bill fitted for the type I assemblage by temperature range index

The scatterplot diagrams and the regression lines show the predicted response of body size and bill to the increase in seasonality (Temp. range), and the increase in phylogenetic clustering (phylostructure).

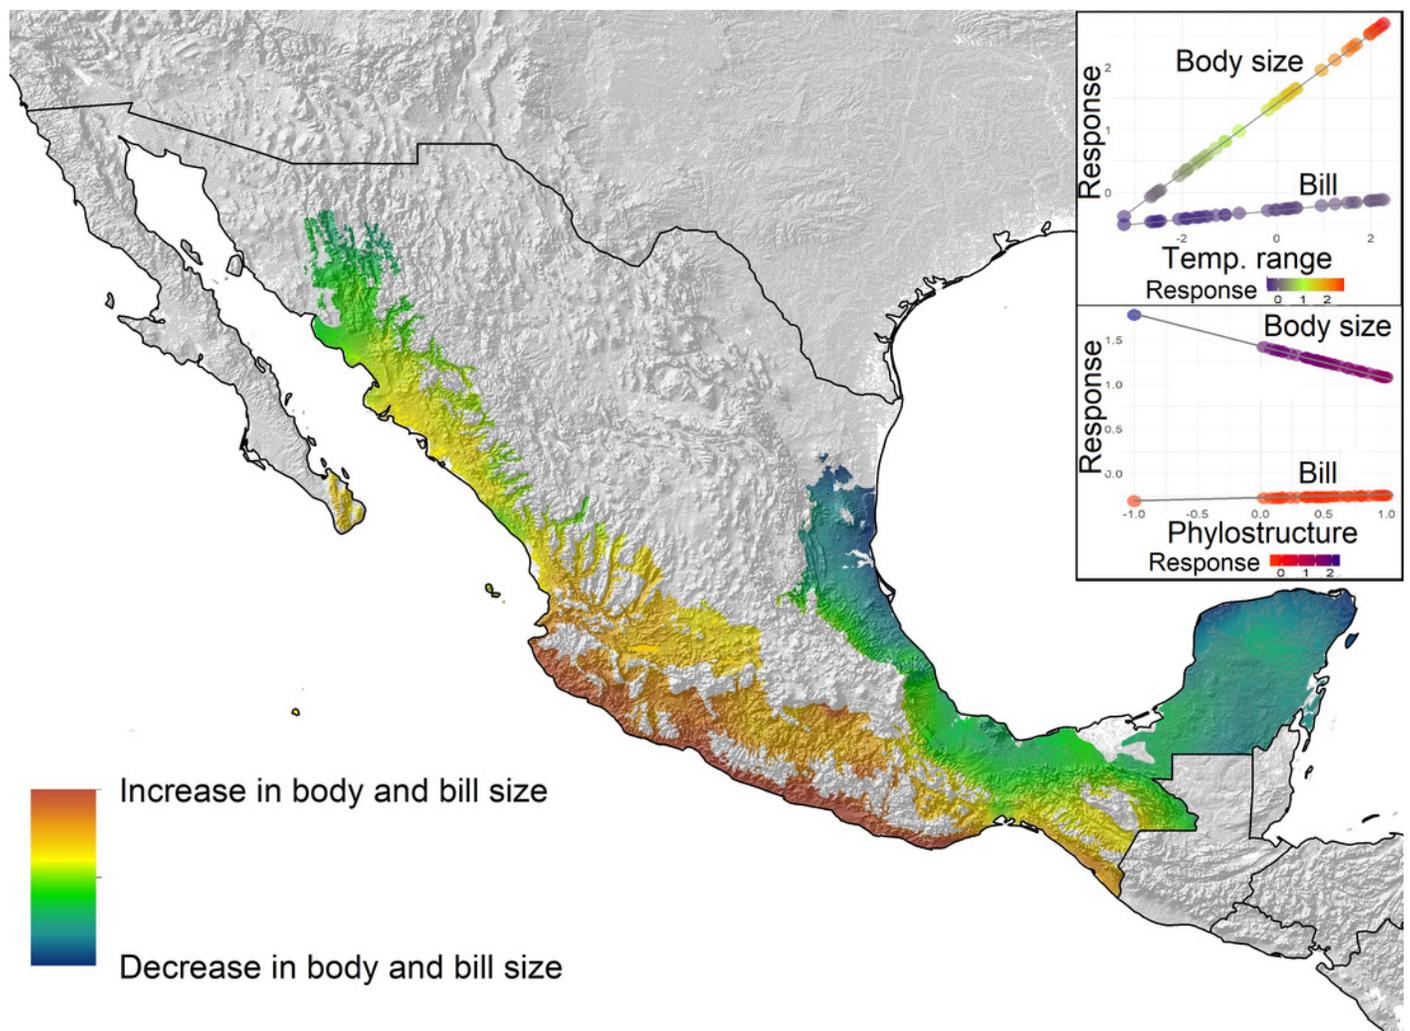

Figure 5

Spatial distribution of morphological variation of of body size fitted for the type II assemblage by temperature range index

The scatterplot diagrams and the regression lines show the predicted response of body size to the increase in seasonality (Temp. range), and the increase in phylogenetic clustering (phylostructure).
