

The relative importance of DNA methylation and Dnmt2-mediated epigenetic regulation on *Wolbachia* densities and cytoplasmic incompatibility

Wolbachia pipientis is a worldwide bacterial parasite of arthropods that infects host germline cells and manipulates host reproduction to increase the ratio of infected females, the transmitting sex of the bacteria. The most common reproductive manipulation, cytoplasmic incompatibility (CI), is expressed as embryonic death in crosses between infected males and uninfected females. Specifically, *Wolbachia* modify developing sperm in the testes by unknown means to cause a post-fertilization disruption of the sperm chromatin that incapacitates the first mitosis of the embryo. As these *Wolbachia*-induced changes are stable, reversible, and affect the host cell cycle machinery including DNA replication and chromosome segregation, we hypothesized that the host methylation pathway is targeted for modulation during cytoplasmic incompatibility because it accounts for all of these traits. Here we show that infection of the testes is associated with a 55% increase of host DNA methylation in *Drosophila melanogaster*, but methylation of the paternal genome does not correlate with penetrance of CI. Overexpression and knock out of the *Drosophila* DNA methyltransferase Dnmt2 neither induces nor increases cytoplasmic incompatibility. Instead, overexpression decreases *Wolbachia* titers in host testes by approximately 17%, leading to a similar reduction in CI levels. Finally, strength of CI induced by several different strains of *Wolbachia* does not correlate with levels of DNA methylation in the host testes. We conclude that DNA methylation mediated by *Drosophila*'s only known methyltransferase is not required for the transgenerational sperm modification that causes CI.

8 Introduction

9 *Wolbachia pipientis*, an obligate intracellular bacteria, is estimated to infect
10 approximately 40% of all arthropod species (Zug & Hammerstein, 2012). This widespread
11 prevalence can be attributed to efficient maternal transmission of the infection, intermediate rates
12 of horizontal transmission to new hosts, and strong manipulations of the host reproductive system
13 to enhance its maternal transmission (Stouthamer, Breeuwer & Hurst, 1999; Serbus et al., 2008).
14 These sexual alterations all act to increase the number of infected females within a population
15 and include male-killing, feminization, parthenogenesis, and cytoplasmic incompatibility (CI). CI
16 is the most common defect observed in *Wolbachia*-infected hosts and has been documented in
17 numerous species (Serbus et al., 2008).

18 CI acts as a post-fertilization mating barrier by preventing the development of embryos
19 from uninfected females that are mated with *Wolbachia*-infected males. This zygotic defect can
20 be rescued, however, by females infected with the same strain of *Wolbachia* present in the male.
21 This rescue capability gives a strong fitness advantage to *Wolbachia*-infected females and can
22 lead to rapid sweeps of the infection through host populations. For instance, CI-inducing
23 *Wolbachia* have been able to spread across most of the *Drosophila simulans* population in eastern
24 Australia in less than a decade (Kriesner et al., 2013). Cytoplasmic incompatibility is also a major
25 isolation barrier between young sibling species (Bordenstein, O'Hara & Werren, 2001; Jaenike et
26 al., 2006; Miller, Ehrman & Schneider, 2010) and is currently being used as a genetic drive
27 mechanism to eliminate dengue virus in *Aedes aegypti* populations (Moreira et al., 2009; Bian et
28 al., 2010; Walker et al., 2011) and to generally reduce mosquito population sizes (Laven, 1967;
29 O'Connor et al., 2012).

The evolutionary, ecological, and medical importance of cytoplasmic incompatibility has fueled decades of research seeking to understand its underlying mechanisms. However, apart from studies that suggest the host genes JhI-26 and HIRA are involved (Zheng et al., 2011; Liu et al., 2014), it remains unknown how *Wolbachia* in the testes encode a sperm modification that renders embryos inviable. Previous work elucidated a few post-fertilization hallmarks of CI, most of which are associated with defects in the paternal genome during embryogenesis. These changes include a failure of maternal histones to deposit correctly, prolonged or incomplete replication of the paternal DNA, and failed condensation of the paternal chromosomes (Breeuwer & Werren, 1990; Callaini, Dallai & Riparbelli, 1997; Landmann et al., 2009). The alterations of the paternal chromatin and host cell cycle lead to a failure of the first mitosis followed by embryonic death. Interestingly, *Wolbachia* are not actually present within the sperm of their hosts, indicating a semi-permanent modification of the paternal genome that is transgenerationally transmitted to the egg (Clark et al., 2008).

Several assumptions can be made about the paternal genome modification underlying cytoplasmic incompatibility including:

- (i) It targets host pathways that are highly conserved across numerous host species
- (ii) It involves a semi-permanent but reversible alteration to the paternal genome
- (iii) It must be able to affect histone recruitment, DNA replication, and chromosome condensation

Working under these assumptions, we selected the host DNA methylation pathway as a probable target for *Wolbachia*. Methylation is a stable, yet reversible, modification to DNA that could be sex-specific and easily rescued by infected females. It also has the capability to modulate many cell cycle functions including chromosome condensation and histone recruitment (Bird, 2001; Harris & Braig, 2003; Weber & Schübeler, 2007) and has previously been hypothesized to play a

role in CI (Negri, 2011; Saridaki et al., 2011; Ye et al., 2013b; Liu et al., 2014). While the role of DNA methylation in insects is not fully understood it is a highly conserved pathway that shows strong upregulation during embryogenesis (Field et al., 2004). Finally, the ability of bacteria to alter host methylation and chromatin structure is increasingly being recognized (Gómez-Díaz et al., 2012; Bierne, Hamon & Cossart, 2012) and previous work shows that *Wolbachia* infection in particular alters the host methylation profile in both leafhoppers and mosquitoes (Negri et al., 2009; Ye et al., 2013a).

Here we use the model organism *Drosophila melanogaster* infected with the *w*Mel strain of *Wolbachia* to determine the role of host DNA methylation in cytoplasmic incompatibility. *D. melanogaster* flies utilize just one canonical DNA methyltransferase, *Dnmt2* (Lyko, Ramsahoye & Jaenisch, 2000), which enables easy genetic manipulation of the host methylation pathway without the confounding influence of other DNA methyltransferases (*Dnmt1* and *Dnmt3*) present in most other insect species (Group et al., 2010). While the role of *Dnmt2*-dependent methylation is debated and multifaceted (Schaefer & Lyko, 2010; Raddatz et al., 2013; Takayama et al., 2014), evidence demonstrates that the methylation machinery in *D. melanogaster* is not only present but also functional (Lyko, Ramsahoye & Jaenisch, 2000; Kunert et al., 2003; Schaefer, Steringer & Lyko, 2008; Gou et al., 2010). Moreover, overexpression of the mouse *Dnmt3a* in *D. melanogaster* induces CI-like defects such as reduced rates of cell cycle progression and altered chromosome condensation (Weissmann et al., 2003).

Materials and Methods

Fly rearing and dissections

All flies were reared on a cornmeal and molasses-based media at 25°C. The *Dnmt2* loss-of-function mutant has been previously described (Goll et al., 2006). Briefly, the mutant contains a 28bp insertion with multiple stop codons as well as a frameshift within the coding region of *Dnmt2*. Overexpressing flies were created through the Gal4-UAS system. Crosses were performed between virgin *nos*-Gal4 driver females (y^1w^* ; P{w[+mC]=GAL4-nos.NGT}40 (either *Wolbachia*-infected or uninfected) and 5-6 uninfected UAS-*Dnmt2* (Kunert et al., 2003), UAS-GFP or *W¹¹¹⁸* males. Crosses for Supplemental Figure 1 were conducted between virgin Act5c-Gal4 driver females (y^1w^* ; P{w[+mC]=Act5C-GAL4}25FO1/CyO, y^+ , *Wolbachia* infected or uninfected depending on desired progeny) and UAS-*Dnmt2* males. For Act5c-Gal4 crosses, straight-winged progeny were assumed to be overexpressing *Dnmt2* while CyO expressing lines were used as the wild-type expressing lines. *Wolbachia*-uninfected lines were created through tetracycline treatment (20ug/mL for 3 generations) and infection status was confirmed through PCR using the following primers: WolbF (GAAGATAATGACGGTACTCAC) and WolbR3 (GTCAGTATCCCACTTTAAATAAC) which target the 16S rRNA gene of *Wolbachia*. These lines were further reared for at least three generations on undrugged media before experimentation to avoid detrimental paternal effects seen in other systems (Zeh et al., 2012).

wAu, *wNo*, and *wRi* (also known as *wRi* Agadir) strains of *Drosophila simulans* were kindly provided by Charlat Sylvain (University Lyon, France). All testes and ovary dissections were performed in cold phosphate buffered saline (PBS). Males were dissected within 24 hours of emergence while females were aged 3-4 days before dissections. Testes samples consisted of tissue obtained from a minimum of 20 males while ovary samples were pooled from 10 females each. Tissues were frozen and stored at -80°C before analysis.

97 *Hatch rate assays*

98 Assays were performed using a grape juice/agar media in 30mm plates for egg laying. For
99 each cross 32-48 individual crosses of one male and one female were set up in separate mating
100 chambers with individual grape juice plates. A minimal amount of a 1:2 dry yeast and water mix
101 was added to each plate and the parents were allowed to mate for 16 hours before the grape juice
102 plates were discarded. Fresh plates were then used for 24 hours, removed, and the number of eggs
103 laid was counted for each cross. The number of unhatched eggs was counted again at 36 hours
104 after the plates had been removed to determine hatch rates.

105 *MethylFlash quantification of DNA methylation*

106 Genomic levels of cytosine methylation (5-mC) were measured using the MethylFlash kit
107 (Epigentek; Farmingdale, NY, USA). 8-10 replicate sets of testes (20-40 testes pairs each
108 replicate) were dissected and DNA was isolated using the Puregene Tissue kit (Qiagen, Venlo,
109 Netherlands). 100ng of genomic DNA from each sample was used and each sample was analyzed
110 in duplicate on a BMG LabTech FLOUstar OPTIMA plate reader (Ortenberg, Germany)
111 according to manufacturer instructions.

112 *Wolbachia density*

113 Eight replicates each of whole animals (pools of 3), testes (pools of 20 pairs), and ovaries
114 (pools of 10 pairs) were collected and DNA was isolated. All males were less than 24 hours old
115 while females had been aged 3-4 days. Quantitative PCR was performed on a Bio-Rad CFX96
116 Real-Time System using iTaq Universal SYBR Green Supermix (Bio-Rad; Hercules, CA, USA).
117 *groEL* copy number, determined against a standard curve, was compared to counts for the host

118 gene *Actin*, also determined against a standard curve. It was assumed that one copy of *groEL* was
 119 present in each *Wolbachia* genome and 1 or 2 copies of Act5c (for males and females,
 120 respectively, as the gene is on the X chromosome) in each *Drosophila* genome. Primers: Act5c
 121 (231bp product, Forward: ATGTGTGACGAAGAAGTTGCT Reverse:
 122 GTCCCGTTGGTCACGATACC), groEL (97bp product, Forward:
 123 CTAAAGTGCTTAATGCTTCACCTTC Reverse: CAACCTTTACTTCCTATTCTTG). qPCR
 124 conditions: 50° 10 min, 95° 5 min, 40x (95° 10 sec, 55° 30 sec), 95° 30 sec. Followed by melt
 125 curve analysis (0.5° steps from 65-95° for 5 sec each).

126 *Gene expression*

127 Quantitative PCR was performed on a Bio-Rad CFX96 Real-Time System using iTaq
 128 Universal SYBR Green Supermix (Bio-Rad; Hercules, CA, USA). RNA was isolated from 8 sets
 129 of testes (20 pairs each) using the RNeasy Mini kit (Qiagen; Venlo, Netherlands) and DNA was
 130 removed with the TURBO DNA-free DNase kit (Ambion; Grand Island, NY, USA). cDNA was
 131 synthesized using a SuperScript III First-Strand kit (Invitrogen; Grand Island, NY, USA) and
 132 diluted 1:20. All calculations were done using delta delta Ct with Rp49 expression used for
 133 normalization of results. Primers: *Dnmt2* (150bp product, Forward:
 134 CCGTGGCGTGAAATAGCG Reverse: ACACCGCTTTCGGAGGACG), Rp49 (154bp product,
 135 Forward: CGGTTACGGATCGAACAAGC Reverse: CTTGCGCTTCTTGGAGGAGA). qRT-
 136 PCR conditions are the same as used in qPCR for *Wolbachia* densities.

137 *Bisulfite sequencing*

100 testes were dissected in PBS from *Wolbachia* infected (y^1w^*) and uninfected males and flash frozen. gDNA was then isolated using the Puregene kit (Qiagen; Venlo, Netherlands) and fragmented by Covaris shearing. gDNA was submitted to Vanderbilt Technologies for Advanced genomics (VANTAGE) where the PE-75 bp library was generated using the TruSeq sample preparation kit (with methylated adapters), bisulfite treated, PCR amplified (EpiMark and ZymoTaq) and sequenced (Illumina HiSeq 2000, 86bp PE read). Sequences with $\geq 10\times$ coverage were analyzed using Bismark (Krueger & Andrews, 2011) and cytosines which were methylated in at least one read were counted.

Results and Discussion

Wolbachia wMel increases levels of testes DNA methylation

MethylFlash analysis of host DNA from testes revealed that infection with the *Wolbachia* strain wMel in *Drosophila melanogaster* increases levels of genome-wide cytosine methylation (Figure 1a). More importantly, this methylation is specific to the host testes (55% increase, $P = 0.0015$, Mann Whitney U test) and is not observed in the ovaries, consistent with the prediction that only the paternal genome is modified during cytoplasmic incompatibility. The overall levels of methylation are extremely low, which is consistent with previously reported levels of methylation in *Drosophila melanogaster* (Lyko, Ramsahoye & Jaenisch, 2000; Kunert et al., 2003). Conflicting reports over the strength and prevalence of DNA methylation in *D. melanogaster* (Lyko et al., 2000; Raddatz et al., 2013; Schaefer and Lyko, 2010) led us to test the validity of our initial results with genome-wide bisulfite sequencing. Results indicate that, contrary to most other species, DNA methylation in *Drosophila melanogaster* is not CpG specific and is evenly distributed over cytosine residues (Figure 1b, Table S1). Sequencing results also

mirror those of MethylFlash and show that infection with *w*Mel increases testes DNA methylation 46% across all cytosine residues with a range of 43-54% depending upon the type of cytosine residue (CpG, CHG, or CHH) (Figure 1b, Table S1). The minor discrepancies between MethylFlash and bisulfite sequencing (55% and 46% increase in methylation, respectively) are likely due to the sensitivity of the MethylFlash system on such low quantities of methylation. A more thorough investigation of the bisulfite sequencing, including changes in promoter and gene body methylation, is ongoing.

Overexpression of *Dnmt2* neither induces nor strengthens CI

Drosophila melanogaster possess just one canonical DNA methyltransferase, *Dnmt2*, and overexpression of this enzyme in fruit flies has previously been shown to increase levels of DNA methylation (Kunert et al., 2003; Schaefer, Steringer & Lyko, 2008). Utilizing the Gal4-UAS expression system, we overexpressed *Dnmt2* in uninfected males to test if an increase in host methylation alone could induce the CI defect of reduced embryo hatching rates. Figure 2 shows that there was no discernable difference in hatching rates with uninfected males expressing increased or wild type levels of *Dnmt2* ($P = 0.91$, MWU). The result was confirmed using an Actin-based driver that again yielded no discernable differences in hatch rates compared to wild type flies (Figure S1, $P = 0.83$, MWU). These findings specify that amplified levels of *Dnmt2*-mediated epigenetic regulation are not sufficient to recapitulate cytoplasmic incompatibility.

If multiple factors are responsible for CI, it is possible that overexpression of *Dnmt2*, while unable to induce CI in uninfected flies, may be able to strengthen the modification in the presence of *Wolbachia*. To test this hypothesis, we overexpressed *Dnmt2* in *Wolbachia*-infected males that were then mated to uninfected virgin females. Surprisingly, *Dnmt2* overexpression in

males decreased the level of cytoplasmic incompatibility by an average of 17.4% (Figure 3). This effect is not dependent on the *Dnmt2* expression status of the female and suggests that increased methylation of host DNA can diminish the penetrance of cytoplasmic incompatibility.

Overexpression of *Dnmt2* reduces *Wolbachia* titers in host testes

Previous work suggested that *Dnmt2* is detrimental to *Wolbachia* proliferation in mosquitoes. In fact, *Wolbachia* strain wMelPop-CLA utilizes a host miRNA to downregulate *Dnmt2* expression when infecting *Aedes aegypti* (Zhang et al., 2013). We observed no differences in *Dnmt2* expression between wMel infected and uninfected *D. melanogaster* testes (data not shown) but hypothesized that overexpression of *Dnmt2* in the host may adversely affect *Wolbachia* titers. In support of this prediction, we found that *Wolbachia* density (as measured by the ratio of *Wolbachia groEL* gene copy number / *Drosophila Actin* gene copy number) decreased by 17.3% in adult testes overexpressing *Dnmt2* transcripts by 9.6% (Figure 4 and Figure S2, respectively). The low level of transcript overexpression could be specific to the developmental stage of the experimental sample or due to usage of a pUAST vector for germline expression instead of the more efficient pUASP (Kunert et al., 2003). While the upregulation of *Dnmt2* in infected males is not statistically significant, it remains possible that actual protein levels are much higher than those represented by RNA transcripts. Strong protein expression, as measured by Western blot, was seen in uninfected ovaries (data not shown) Nevertheless, the 17.3% decrease in *Wolbachia* titers compares well with the 17.4% reduction in CI penetrance reported above. Expression of the negative control green fluorescent protein (GFP) did not reduce *Wolbachia* titers, as expected (Figure S3). As the bacterial and phage density models of CI specify that *Wolbachia* titers in the testes are linked to the strength of CI (Breeuwer & Werren,

1993; Bordenstein et al., 2006), we conclude that the reduction of CI observed in *Dnmt2*-overexpressing males is likely due to reduced *Wolbachia* density.

Even though we do not observe any change in *Dnmt2* mRNA levels after *Wolbachia* infection, we cannot rule out that *Wolbachia* may be affecting intracellular *Dnmt2* localization rather than levels of gene expression. An increase in localization of *Dnmt2* to the nucleus would not only protect the cytosolic *Wolbachia* but also explain the additional genomic methylation associated with infection. In this scenario, the testes-specific increase in host methylation initially observed would simply be a by-product of high *Wolbachia* activity. Additionally, an immunomodulatory role for *Dnmt2* in *Drosophila* has already been documented in protection against RNA viruses (Durdevic et al., 2013) though we believe the findings in this report are the first evidence for a putative antibacterial role for *Dnmt2* in fruit flies.

Hosts defective in DNA methylation still exhibit CI

As *Dnmt2* overexpression did not induce nor increase cytoplasmic incompatibility, we next tested the strength of CI in hosts defective in the methyltransferase pathway. Knockout mutants for *Dnmt2* characterized by Goll et al (Goll et al., 2006) were acquired and found by PCR and amplicon sequencing to be infected by the *w*Mel strain of *Wolbachia*. The strain is hereafter referred to as Mut and was tetracycline treated for 3 generations to create the uninfected line MutT. We show by MethylFlash that the increase in host DNA methylation induced by *Wolbachia* infection is abolished in the knockout Mut background (Figure S4) and is thus *Dnmt2*-dependent. However, loss of this crucial enzyme in the DNA methylation pathway has no effect on the penetrance of CI (Figure 5), as shown in comparisons between mutant and wild type males mated to uninfected females ($P = 0.13$, MWU). The low level of DNA methylation still present in

mutants has recently been observed by others (Boffelli, Takayama & Martin, 2014) and suggests a possible mechanism of DNA methylation in *Drosophila* that is independent of canonical DNA methyltransferases. Thus, it is possible that CI could be induced by alterations in genomic methylation but in a *Dnmt2*-independent manner.

Curiously, despite the previously observed role for *Dnmt2* in host immunity (Zhang et al., 2013; Durdevic et al., 2013), the mutants observed here exhibit no increase in *Wolbachia* titers within any of the tissues tested (Figure S5). It is interesting to note that *Dnmt2* mutant *Drosophila*, derived from the W¹¹¹⁸ background line, have titers that are, on average, half of those seen in y¹w^{*} background lines (see Figure 4). This difference has been observed several times in our experiments and suggests either a differing ability of the host lines to control *Wolbachia* titers or an as yet unclassified difference in the wMel strains infecting these flies.

Host levels of DNA methylation do not correlate with strength of CI

To substantiate the claim that DNA methylation is not involved in the induction of CI for other *Wolbachia* strains and/or host species, we tested the DNA methylation status of testes DNA from *Drosophila* species infected with various strains of *Wolbachia*. These taxa include *D. simulans* infected with strains wRi, wNo, and wAu, which express strong, moderate, and no CI, respectively. We also tested a different *D. melanogaster*-infecting strain wMel derived from the W¹¹¹⁸ background strain instead of y¹w^{*}. As previously mentioned, while the W¹¹¹⁸ line induces strong CI, *Wolbachia* titers are much lower in these animals compared to the infection found in y¹w^{*}.

Results show that methylation status of the infected host testes is random with regards to the strength of CI (Figure 6). While infection with the high CI-inducer wRi exhibits higher

methylation in infected testes as compared to uninfecteds, this effect is marginally insignificant ($P = 0.072$, MWU) and is countered by data from the *wAu* strain, which causes no CI but still significantly increases host DNA methylation in testes ($P = 0.0047$, MWU). Furthermore, infection with the *wNo* strain of *Wolbachia*, which causes moderate CI, actually has less methylation in host testes. Finally, a low-titer infection of *wMel* (W^{1118}), while still inducing CI, does not induce the same level of DNA methylation associated with a high-density infection (y^1w^*).

Conclusions

The underlying mechanism of *Wolbachia*-induced CI largely remains elusive after several decades of research. Here we show that host DNA methylation, a promising candidate pathway hypothesized to play a role (Negri, 2011; Saridaki et al., 2011; Ye et al., 2013b; Liu et al., 2014), does not seem to be involved in the induction of cytoplasmic incompatibility. While *Wolbachia* infection preferentially increases host DNA methylation in *Drosophila melanogaster* testes (Figure 1), this modification is not conserved across other CI-causing strains of *Wolbachia* (Figure 6) and overexpression of a host methyltransferase neither induces nor increases rates of CI. We have also found that *Wolbachia*-induced changes in host methylation are dependent on the DNA methyltransferase *Dnmt2* (Supplemental Figure S4) but that *Drosophila melanogaster* lacking *Dnmt2* still suffer from CI (Figure 5). Finally, we found *Dnmt2* has anti-*Wolbachia* properties, as previously reported in *Aedes aegypti* (Zhang et al., 2013), and overexpression of *Dnmt2* reduces the strength of CI.

Taken together, we show that one of the canonical chromatin modification pathways, *Dnmt2*-dependent DNA methylation, likely has no role in *Wolbachia*-induced cytoplasmic

270 incompatibility. *Wolbachia* infection can be associated with changes in host methylation levels,
 271 but it is most likely a consequence of the bacteria modulating host immune response or the host
 272 defending itself against the infection. The possibility also remains that infection alters gene-
 273 specific, and *Dnmt2*-independent, levels of methylation that our current study of genomic
 274 methylation levels has not detected. While further investigation of the *Dnmt2* epigenetic pathway
 275 will not elucidate a CI mechanism, it may be useful in studying the complex nature of pathogen-
 276 host interactions between *Wolbachia* and the many species it infects. It remains possible that a
 277 novel methyltransferase, recently suggested to exist in *Drosophila* (Takayama et al., 2014;
 278 Boffelli, Takayama & Martin, 2014), could affect CI.

Figure 1

Wolbachia increase host levels of DNA methylation.

(a) *Wolbachia* infection (*wMel*) of *Drosophila melanogaster* increases DNA methylation in host testes by 55% ($P = 0.0015$, Mann-Whitney U (MWU) test, two-tailed), as measured by the ELISA-based MethylFlash kit. This increase is not observed in host ovaries ($P = 0.25$). Bars denote standard error of the mean (SEM) (b) Bisulfite sequencing of *Drosophila melanogaster* testes DNA shows that infection by *wMel* increases methylation of all cytosine residues including CpG (43%), CHG (54%), and CHH (50%).

a)

b)

Figure 2

Expression of DNA methyltransferase 2 does not induce CI.

Overexpression of the DNA methyltransferase *Dnmt2* in uninfected males, utilizing the Gal4-UAS system with a *nos* driver, does not reduce hatching rates. *Dnmt2* = overexpressing flies; WT = wild type flies. Bars denote standard error of the mean (SEM).

Figure 3

Overexpression of *Dnmt2* reduces levels of CI.

The overexpression of *Dnmt2* in *Wolbachia*-infected males decreases rates of CI ($P < 0.05$, Mann-Whitney U test). *Dnmt2* expression in the mother has no affect. Bars denote standard error of the mean (SEM). *Dnmt2* = overexpressing flies; WT = wild type flies.

Figure 4

Dnmt2 overexpression alters *Wolbachia* titers.

Overexpression of *Dnmt2* reduces *Wolbachia* titers within the testes ($P < 0.01$, MWU test) but has no affect on titers within ovaries or whole flies. *Wolbachia* infection is derived from the y^1w^* *Drosophila* background. Bars denote standard error of the mean (SEM). *Dnmt2* ++ = overexpressing flies; *Dnmt2* + = wild type flies. ($P = 0.007$, Mann-Whitney U test, two-tailed).

Figure 5

Dnmt2 mutants express wild-type levels of CI.

Crosses with *Dnmt2*-mutant males (“Mut”) show that *Dnmt2* expression within the father is not necessary for expression of CI. Mut = *Dnmt2* mutant flies; WT = wild type flies. Bars denote standard error of the mean (SEM).

Figure 6

Levels of host DNA methylation do not correlate with strength of CI.

Testing of several different *Wolbachia* infections, capable of inducing various levels of CI in their respective hosts, shows that levels of host DNA methylation and strength of CI are not correlated. Bars denote standard error of the mean (SEM) of testes DNA methylation, as measured by MethylFlash. White bars (-) denote uninfected flies and black bars (+) denote infected flies. # indicates levels of methylation too low for detection.
