The species-rich arborescent assemblages of humid tropical forests encompass much of the known range of the leaf economics spectrum, often including > 20-fold variation in leaf lifespan. This suite of traits underpins a life-history continuum from fast-growing pioneers to slow-growing shade-tolerant species. Less is known about the range of leaf traits in humid temperate forests, and there are conflicting reports about relationships of these traits with the light requirements of temperate evergreen angiosperms. Here I quantify the range of leaf functional traits in a New Zealand temperate evergreen forest, and relationships of these traits with light requirements of juvenile trees and shrubs. Foliage turnover of saplings of 19 evergreen angiosperms growing beneath gaps (12 – 29 % canopy openness) and in understories (1.2 - 2.9 %) was measured over 12 months. Dry mass per area (LMA), dry matter content, thickness, density and nitrogen content (N) of leaves were also measured. Species minimum light requirements were indexed as the 10th percentile of the distribution of saplings in relation to canopy openness. Interspecific variation of leaf lifespan was ~6-fold in gaps (0.6 to 3.8 yrs) , and ~11-fold in the understorey (0.7 to 7.7 yrs). Six small tree and shrub species are effectively leaf-exchangers, with leaf lifespans of c.1 year in gaps—albeit usually longer in the shade. Interspecific variation in other leaf traits was 2.5 to 4-fold. Lifespans and LMA of both sun and shade leaves were negatively correlated with species light requirements i.e. positively correlated with shade tolerance. However, light environment (gap vs shade) explained about the same amount of variation in LMA as species' identity did. Species light requirements were not significantly correlated with leaf N, dry matter content, density or thickness—except for a marginally significant correlation with dry matter content of shade leaves. Species light requirements were thus less consistently related to leaf structural traits than appears to be the case in humid tropical forests. Whereas the wide interspecific variation in leaf economic traits of tropical rainforest species outweighs plastic response to light availability, temperate evergreen woody angiosperms appear to occupy a narrower

range of the leaf economic spectrum. Standardization of the light environments in which LMA is measured is vital in comparative studies of humid temperate forest evergreens, because of countergradient responses of this trait to light, and because of the relative magnitudes of plastic and interspecific variation in LMA in these forests.

7 ## Abstract

8 The species-rich arborescent assemblages of humid tropical forests encompass much of the known

9 range of the leaf economics spectrum, often including > 20-fold variation in leaf lifespan. This suite of

10 traits underpins a life-history continuum from fast-growing pioneers to slow-growing shade-tolerant

11 species. Less can be said with certainty about the range of leaf traits in humid temperate forests, and

12 there are conflicting reports about relationships of these traits with the light requirements of temperate

13 evergreen angiosperms. Here I quantify the range of leaf functional traits in a New Zealand temperate

14 evergreen forest, and relationships of these traits with light requirements of juvenile trees and shrubs.

15 Foliage turnover of saplings of 19 evergreen angiosperms growing beneath gaps (12 – 29 % canopy

16 openness) and in understories (1.2 - 2.9 %) was measured over 12 months. Dry mass per area (LMA), dry

17 matter content, thickness, density and nitrogen content (N) of leaves were also measured. Species

18 minimum light requirements were indexed as the 10th percentile of the distribution of saplings in

19 relation to canopy openness. Interspecific variation of leaf lifespan was ~6-fold in gaps (0.6 to 3.8 yrs) ,

20 and ~11-fold in the understorey (0.7 to 7.7 yrs). Six small tree and shrub species are effectively leaf-

21 exchangers, with leaf lifespans of ~1 year in gaps—albeit usually longer in the shade. Interspecific

22   variation in other leaf traits was 2.5 to 4-fold. Lifespans and LMA of both sun and shade leaves were

23   negatively correlated with species light requirements i.e. positively correlated with shade tolerance.

24   However, light environment (gap vs shade) explained about the same amount of variation in LMA as

25   species' identity did. Species light requirements were not significantly correlated with leaf N, dry matter

26   content, density or thickness—except for a marginally significant correlation with dry matter content of

27   shade leaves. Species light requirements were thus less consistently related to leaf structural traits than

28   appears to be the case in humid tropical forests. Whereas the wide interspecific variation in leaf

29   economic traits of tropical rainforest species outweighs plastic response to light availability, temperate

30   evergreen woody angiosperms appear to occupy a narrower range of the leaf economic spectrum.

31   Standardization of the light environments in which LMA is measured is vital in comparative studies of

32   humid temperate forest evergreens, because of countergradient responses of this trait to light, and

33   because of the relative magnitudes of plastic and interspecific variation in LMA in these forests.

34   **Introduction**

35   The unrelenting evergreenness of humid tropical forests belies the vast range of foliage turnover rates

36   revealed by comparative studies of their arborescent assemblages, which often exceeds 20-fold

37   variation (Reich et al. 1991; Russo & Kitajima 2016). This wide variation in leaf lifespan, closely linked to

38   a suite of other leaf traits in what has become widely known as the "leaf economics spectrum",

39   underpins a life-history continuum from fast-growing pioneers to slow-growing shade-tolerant species

40   (Lohbeck et al. 2013; Poorter & Bongers 2006; Sterck et al. 2006; Walters & Reich 1999). This continuum

41   is also associated with interspecific variation in wood density (King et al. 2006; van Gelder et al. 2006).

42   The consistent picture emerging from studies of humid tropical forests is that low leaf mass per area

43   (LMA), high assimilation rates and low wood density enable pioneer trees to rapidly pre-empt gaps and

44   clearings, whereas positive long-term net carbon gain and survival under shade is made possible by

45 robust, long-lived leaves, dense wood, and low respiration rates. The fast-growing pioneers that colonize

46 gaps in humid tropical forests have "high-maintenance" foliage: their low-LMA leaves turn over rapidly

47 (2 - 6 months) and have high rates of photosynthesis and respiration.

48 Less can be said with certainty about functional diversity of leaf traits in humid temperate forests, or

49 about trait relationships with species' light requirements and life histories. Tall, fast-growing pioneers of

50 the type found in tropical and subtropical humid forests are known to be lacking from mid-latitude

51 forests (Lusk et al. 2011a). Seven-fold variation in leaf lifespans of juvenile trees has been reported from

52 the humid temperate forests of south-central Chile (Lusk et al. 2008a), but fewer data are available from

53 comparable assemblages in New Zealand and temperate Australia. In the deciduous angiosperm

54 assemblages typical of continental temperate climates, interspecific differences in leaf lifespan are

55 inevitably muted (van Ommen Kloeke et al. 2012; Walters & Reich 1999). In evergreen temperate

56 forests, leaf lifespan is once again consistently negatively correlated with species' reported light

57 requirements (i.e. positively so with shade tolerance), but there is no such agreement about

58 relationships of leaf structural traits such as LMA with light requirements (Fajardo & Siefert 2016; Hallik

59 et al. 2009; Lusk et al. 2011b; Lusk & Warton 2007).

60 A lack of standardization of the light environments in which traits are measured might underlie some of

61 the discrepancies in reporting relationships of leaf structural traits with light requirements of temperate

62 forest evergreens (Keenan & Niinemets 2016). LMA shows strong plastic responses to light availability,

63 with sun leaves being much thicker than shade leaves of the same species (Poorter et al. 2009), and

64 sometimes also denser. Plastic variation of LMA along light gradients thus runs counter to interspecific

65 variation relating to species' shade tolerance (Lusk et al. 2010; Lusk et al. 2008b), with the result that

66 sun leaves of light-demanding evergreens can have similar LMA to shade leaves of shade-tolerant

67 species. If juvenile trees are sampled randomly or haphazardly without controlling for light environment,

68 interspecific differences in traits such as LMA may be masked by plastic variation (Laughlin et al. 2017),

69   as differential survival along light gradients results in light-demanding species being found on average in

70   better-lit environments than their more shade-tolerant associates (Kobe 1999; Lusk et al. 2006; Poorter

71   & Arets 2003). The same biases may be present in databases compiled from reviews of the literature

72   (see Keenan & Niinemets 2016).

73   Here I document the range of leaf traits in a humid temperate forest arborescent assemblage in New

74   Zealand, and relationships of these traits with species' light requirements. Leaf traits were measured in

75   two distinct light environments (understorey shade and treefall gaps), using hemispherical photography

76   to quantify canopy openness. It has recently been shown that the microclimates of clearings at the same

77   site favour very different traits from those of species that regenerate primarily in treefall gaps (Lusk &

78   Laughlin 2017). The present study focuses mainly on species sorting along gap to understorey gradients,

79   rather than the more open environments of clearings.

Materials and methods

80

Study site

81

82   The study was carried out in a humid temperate forest in the Lake Okataina Scenic Reserve (38.08° S,

83   176.42° E), in the North Island of New Zealand. Sampling was carried out in a 300 ha basin lying at about

84   400m a.s.l. within the reserve, infilled with tephras (mainly rhyolitic) derived from the Okataina Volcanic

85   Centre (Pullar et al. 1973). Climate data from GIS layers indicate a mean annual temperature of 11.7 °C,

86   a frost-free period of 195 days, and mean annual precipitation of 1659 mm (IIASA/FAO 2012; Landcare

87   Research 2011). Rainfall is evenly-distributed throughout the year. Although juvenile trees growing in

88   clearings are exposed to large vapour pressure deficits (> 1.5 kPa) during dry spells, deficits of that

89   magnitude have not been recorded in the understorey and tree-fall gap environments where traits were

90   measured in the present study (Lusk & Laughlin 2017). A research permit to work at the site (66760-RES)

91   was obtained from Department of Conservation.

92   The disturbance history of the basin has created a complex vegetation mosaic, including a wide range of

93   light environments (Lusk & Laughlin 2017). Most of the basin remains in tall forest with a canopy

94   dominated by *Beilschmiedia tawa* (Lauraceae) up to 30m tall and scattered emergent conifers up to

95   45m, mainly *Dacrydium cupressinum* and *Dacrycarpus dacrydioides* (Podocarpaceae). Conifers occurred

96   at higher densities before selective logging during the mid-20th century (Nicholls 1991); this history of

97   logging has left behind several clearings and a network of skidder tracks, some of which have been

98   converted to walking tracks. At the north end of the basin is a stand of < 2ha with a canopy dominated

99   by *Weinmannia racemosa* (*Cunoniaceae*), which admits more light to the understorey than the deep-

100   crowned *B. tawa* that predominates elsewhere (Beveridge 1973). As a result, seedlings and saplings of a

101   wide range of species can be found in the understorey of this stand, which presumably owes its origin to

102   a small fire or wind damage. All native tree and shrub species present in the basin are evergreen, except

103   for *Fuchsia excorticata* (Onagraceae) and very occasional *Plagianthus regius* (Malvaceae)— McGlone et

104   al. (2004) describe both as deciduous, but report that some northern populations of the former retain

105   some leaves during winter.

106   **Measurements of leaf traits**

107   I measured a range of leaf traits that have variously been shown to correlate with species' light

108   requirements in other evergreen forests (Kitajima & Poorter 2010; Lusk et al. 2010; Poorter & Bongers

109   2006). Although leaf mass per area (LMA) is the structural trait included in the original leaf economic

110   spectrum concept (Reich et al. 1991; Wright et al. 2004), it can be informative to partition this trait into

111   leaf thickness and density—it has been reported that density correlates strongly with species' shade

112   tolerance in tropical humid tropical forests, whereas thickness does not (Kitajima & Poorter 2010).

113   Accordingly, leaf density and thickness were measured in addition to LMA. Leaf dry matter content is a

114   widely used alternative to LMA, and has also been found to correlate with species' light requirements in

115   some humid forests (Lusk et al. 2010; Poorter 2009).

116   Two ranges of light environments were defined as sources of sun- and shade-leaf traits (Tables 1, 2).

117   Sun-leaf traits were measured on plants growing beneath tree-fall gaps, or besides roads or walking

118   tracks. Shade-leaf traits were measured on juvenile trees growing mostly in the understorey of the *W.*

119   *racemosa*-dominant stand at the north end of the basin. In each of these two light environments, five to

120   six juveniles (50 – 200 cm tall) were selected haphazardly for leaf trait measurements. A Nikon Coolpix

121   4500 digital camera (Nikon, Tokyo, Japan) and an EC-08 fisheye adaptor were used to take a photo

122   immediately above the apex of each of these selected juveniles (as described above), and Gap Light

123   Analyzer (Frazer et al. 1999) was used to estimate % canopy openness from each photo. Light

124   environments above plants sampled in gaps ranged from 12.0 to 27.8 % canopy openness, compared to

125   1.2 to 3.0 % in the understorey. There was no significant interspecific variation in mean canopy

126   openness above plants sampled in either gaps (ANOVA, P = 0.97) or shade (P = 0.76). Juveniles of

127   *Coprosma robusta* could not be found in understorey environments comparable with those of the other

128   species, so *C. robusta* was sampled only in gap environments.

129   Leaf lifetimes were estimated by following survival of leaves over a 12-month period. The height of the

130   principal axis of each juvenile was measured to the apex, and all fully-expanded leaves on this axis were

131   counted. Twelve months later, each plant was revisited, its height remeasured, and survival of leaves

132   recorded. Abscission scars were counted to determine mortality of new leaves initiated after the start of

133   the study period; this was important for species that turn over most or all of their foliage in a single

134   year, such as *Aristotelia serrata*.

135   Leaf lifetime (years) was estimated as:

136
$$\frac{n^i}{(n^i - n^f) + m^n}$$

ﾟ

137 where n_i = initial number of leaves, n_f = final number surviving from n_i, and m_n = mortality of new leaves

138 initiated since the first census (King 1994; Lusk et al. 2008a). A few of the marked plants either suffered

139 major damage by herbivores or disturbance during the study, or could not be relocated, and leaf

140 lifespan estimates were eventually obtained from four to five plants of each species in each light

141 environment.

142 After leaf lifespan measurements, leaves were taken from each of the same plants, for measurement of

143 sun- and shade-leaf structural traits. Depending on leaf size, one to 10 of the youngest fully-expanded

144 intact leaves were taken from each plant, avoiding leaves damaged by herbivores. Leaves were placed

145 immediately in re-sealable plastic bags with moist tissue paper, and fresh weight determined within six

146 hours of removal. Fresh leaves were photographed, and area calculated using ImageJ software

147 (Schneider et al. 2012). Leaf volume was estimated using Archimedes' principle. The leaf was immersed

148 in a small container of water placed on an electronic balance, and displaced volume determined from

149 the change in apparent weight. A small amount of detergent was added to the water to reduce

150 hydrophobicity of leaf surfaces, and reduce bubble formation. Leaf thickness was later estimated

151 dividing volume by area. Leaves were oven-dried at 60 °C for three days before measuring dry weight;

152 drying was initiated within eight hours of leaf excision in all cases, minimizing the effect of dark

153 respiration on non-structural carbohydrates, which can contribute up to 25% of leaf dry mass (Lusk &

154 Piper 2007). Leaf density was then calculated as dry mass / fresh volume. Leaf samples were pooled to

155 obtain one estimate of total nitrogen content of each species in each light environment, using the

156 Dumas combustion method.

157 **Quantifying species light requirements**

158 Distributions of juvenile trees 50 – 200 cm tall were quantified in relation to canopy openness

159 determined from hemispherical photographs. Sampling was carried out on a series of transects run

160   through old-growth stands, including tree-fall gaps of varied sizes and forest margins. Sets of parallel

161   transects were run through forest stands, spaced at least 20 m apart, A total of 748 points were sampled

162   at random intervals (10 to 15 m apart) along transects. Presence of juvenile trees and shrubs 50-200 cm

163   tall was recorded in a circular plot of 1-m diameter, centred on the sample point. Although multiple

164   juveniles of some species were often found in the same plot, only presence or absence data are used in

165   the present analysis. A Nikon Coolpix 4500 digital camera (Nikon, Tokyo, Japan) and an EC-08 fisheye

166   adaptor were used to take a photo at 1.5m height at each sampling point. A spirit level fitted to the lens

167   cap was used to level the camera, and photos were taken mostly while the solar disc was either

168   obscured by clouds or below the horizon, to avoid errors caused by flaring and reflection. Gap Light

169   Analyzer (Frazer et al. 1999) was used to estimate % canopy openness from each photo.

170   The 10th percentile of the distribution of each species in relation to canopy openness was used as an

171   approximation of the lowest light levels tolerated by each species (Lusk et al. 2008a). This parameter is

172   referred to hereafter as minimum light requirements (MLR). MLR represents an inversion of traditional

173   shade tolerance ratings, i.e., shade-tolerant taxa have low MLRs, and light-demanders score high. Only

174   species represented on at least 15 sampling plots were considered, yielding 18 species (Table 1).

175   **Statistical analyses**

176   One-way ANOVA was used to test for interspecific variation in the light environments in which leaf traits

177   were measured. All trait data except leaf dry matter content were $\log_{10}$-transformed before analysis, in

178   order to meet the assumption of additivity of effects (Quinn & Keough 2002). The field sampling

179   procedure meant light environments were effectively nested within species, as species were not all

180   compared in common plots using a full factorial design. Nested ANOVA were therefore used to test for

181   leaf trait differences between sun and shade leaves, and among species. In addition to cross-species

182   correlations, relationships among leaf traits and species light requirements were also measured using

183   phylogenetic least squares regression (PGLS: Symonds & Blomberg 2014), to take into account the

184   influence of phylogeny on trait relationships. COMPARE 4.6 (Martins 2004) was used to carry out PGLS

185   contrasts. A fully-resolved tree of the 19 species was obtained from the Angiosperm Phylogeny Group

186   website (Stevens 2001), although the lack of *Coprosma robusta* in the understorey meant only 18

187   species were included in the analysis of shade leaf traits. All other analyses were carried out in Statistica

188   (Stat Soft. Inc., Tulsa, OK 74104, USA)

189   **Results**

190   **Inter- and intraspecific variation in leaf traits**

191   ANOVA showed highly significant interspecific variation in all traits, as well as highly significant effects of

192   light environment on all traits except for leaf density, which was only marginally affected by light (Table

193   3). ANOVA of leaf N data was not possible, due to the lack of replication resulting from pooling of leaf

194   samples.

195   Interspecific variation of most traits was more marked in shade leaves than in sun leaves. This was

196   especially true of leaf lifespan, which ranged 0.6 to 3.8 years in gaps, and 0.7 to 7.7 years in the

197   understorey (Table 2). Other traits showed narrower ranges of values, spanning 2.4- to 3-fold variation

198   in gaps, and 2.5- to 3.9-fold variation in the understorey.

199   Leaf lifespan was the trait that responded mostly strongly to light, shade leaves on average living about

200   70% longer than sun leaves of the same species (Table 2). LMA also responded strongly to light, leaves

201   from plants growing in gaps on average having 58% more dry mass per area than shade leaves of the

202   same species (Table 2); light environment explained just as much variation in LMA as species identity did

203   (Table 3). Light environment had least effect on leaf density and leaf dry matter content, which

204   respectively averaged only 10 and 11 % higher in gap plants than in understorey conspecifics; variation

205 in these two traits was therefore dominated by the effect of species (Table 3). Leaf N of most species

206 was similar in the two light environments (Table 2).

Trait correlations with species' minimum light requirements

208 The three traits included in the original leaf economic spectrum (LMA, leaf N, and leaf lifetimes) were

209 tightly coordinated in both sun and shade leaves (Kendall's coefficient of concordance = 0.78 and 0.76

210 respectively, P<.0001; Fig. 1a. They showed varied correlations with the other traits making up the

211 dataset (Table 4).

212 Species' minimum light requirements ranged from 0.8% (*Beilschmiedia tawa*) to 4.2% (*Coprosma*

213 *robust*a) (Table 1). Species light requirements were strongly negatively correlated with leaf lifespans,

214 especially those of shade leaves (Table 4; Fig. 1c); leaf lifespan was thus positively correlated with

215 species' shade tolerance. Light requirements were also negatively correlated with LMA (Fig. 1b),

216 although this relationship was only marginally significant in gaps (P = 0.048) and non-significant

217 according to PGLS (Table 4). Light requirements were not significantly correlated with any other

218 structural trait or with leaf N, except for a marginally significant correlation with dry matter content of

219 shade leaves under PGLS (Table 4).

Discussion

221 Leaf lifespans in the arborescent assemblage at Okataina spanned ~6-fold interspecific variation in gaps,

222 and ~11-fold in the understorey (Table 2). The absence from this temperate assemblage of the fast end

223 of the leaf trait spectrum found in humid tropical forests results in an approximate halving of the log-

224 scaled range of leaf lifespans found in the tropics. Some tropical pioneer trees turn over their foliage in

225 as little as two months (Poorter & Bongers 2006; Reich et al. 1991; Williams et al. 1989), whereas the

226 shortest-lived leaves found in the assemblage at Okataina were those of *Aristotelia serrata*, which lived

227   about 7 months on average in gaps, and about 8 months in the shade (Table 2). *A. serrata* is a small,

228   fast-growing tree associated mainly with treefall gaps and the edges of tracks at Okataina (Lusk &

229   Laughlin 2017). Woody assemblages in temperate South America appear to span a similar range of leaf

230   economics to that found at Okataina, with no species reported as having a leaf lifespan of < 6 months

231   (Damascos & Prado 2001; Lusk & Corcuera 2011; Lusk et al. 2011b). However, the few deciduous trees

232   present in both regions probably have slightly shorter leaf lifespans (e.g. Dungan et al. 2003). The

233   assemblage at Okataina did not include any species with the very high leaf nitrogen levels found in some

234   tropical pioneers (Poorter & Bongers 2006; Reich et al. 1991), although comparable levels (c. 4%) have

235   been reported from some New Zealand native leguminous trees not sampled at Okataina (McGlone et

236   al. 2004).

237   Species light requirements were less consistently related to leaf structural traits than appears to be the

238   case in humid tropical forests, despite strong relationships with leaf lifespan in both gaps and shade (Fig.

239   1). Although shade-tolerant evergreens in tropical and subtropical rainforests often have dense leaves

240   (Kitajima & Poorter 2010; Lusk et al. 2010), light requirements of New Zealand temperate evergreens at

241   Okataina were only weakly (and non-significantly) correlated with density of shade leaves (Table 4), and

242   showed little relationship with that of sun leaves (Table 4). Notably, leaf densities of two relatively

243   shade-tolerant species (*Laurelia novae-zelandiae* and *Hedycarya arborea*) were among the lowest found

244   at Okataina (≤ 0.20 g cm^{-3} in both gaps and shade: Table 2). Species' light requirements were

245   significantly correlated with LMA, especially in the shade (Fig. 1a), in part reflecting the thickness of the

246   leaves of the two aforementioned shade-tolerant species (Table 2). However, the correlation with LMA

247   of sun leaves was weaker when phylogenetic relationships were taken into account by PGLS (Table 4).

248   The long leaf lifespans of *L. novae-zelandiae* and *H. arborea* probably depend to a high degree on

249   chemical (rather than physical) deterrence of herbivores, as both genera are known to be rich in

250   alkaloids and essential oils (Brophy et al. 2005; Leitão et al. 1999; Urzua & Cassels 1978).

251   Standardization of the light environments in which LMA is measured may be especially important in

252   comparative studies of temperate evergreen assemblages. Not only does interspecific variation of LMA

253   in relation to light requirements run counter to plastic responses to light (as in other evergreen forests:

254   Lusk et al. 2008b), but the effect of light on LMA at Okataina was of similar size to that of species

255   identity (Table 3), reflecting a narrower range of the leaf economic spectrum than that present in the

256   arborescent assemblages of humid tropical forests. If this reduced range of leaf traits is typical of humid

257   temperate forest evergreen assemblages, lack of standardization of light environments in some studies

258   may thus explain the variety of reported relationships of LMA with light requirements of temperate

259   evergreen angiosperms, including relationships that are diametrically opposed to that reported here

260   (Fajardo & Siefert 2016; Hallik et al. 2009). Leaf dry matter content and leaf density were less sensitive

261   than LMA to light environment, species' identity greatly exceeding the effect of light in explaining

262   variation in these traits (Table 3). However, leaf dry matter content and especially leaf density were less

263   useful indicators of shade tolerance than LMA, as they were only weakly related with species' light

264   requirements in the arborescent assemblage at Okataina (Table 4).

265   The ample representation of small trees with leaf lifetimes of about one year at Okataina (Table 2)

266   suggests the scarcity of the deciduous habit in the New Zealand flora is more a reflection of weak

267   seasonality than of soil fertility (cf. McGlone et al. 2004). Deciduous or semi-deciduous species account

268   for < 5% of New Zealand's woody flora (McGlone et al. 2004); this figure is very low in comparison with

269   temperate floras from continental climates of the northern hemisphere, but falls within the range of

270   values found in other oceanic temperate climates of the southern hemisphere—the proportion of (semi-

271   ) deciduous woody species in southern Chile is somewhat higher (c.8 %), but only a single deciduous tree

272   is native to Tasmania (Duretto 2009+). Although nutrient conservation is considered one of the

273   advantages of evergreenness (Aerts 1995), those evergreens that replace their entire canopies annually

274   (sometimes termed "leaf-exchangers") will be almost as nutrient-demanding as deciduous trees. Despite

275   moderate soil C:N ratios and low total P at Okataina (Lusk et al. 2015), six of the 19 study species fit this

276   description, with leaf lifespans of 12-13 months in gaps (Table 3); these species retained their leaves

277   longer in the shade, ranging from a 27% increase in *Brachyglottis repanda* to a 100% increase in

278   *Carpodetus serratus*. Another species (*Aristotelia serrata*) turned over its foliage in well under a year in

279   both gaps and shade (Table 2). All of these seven species are small, fast-growing trees and shrubs that

280   are widespread throughout New Zealand, most of them associated with treefall gaps at Okataina (Lusk

281   & Laughlin 2017),. Elsewhere, another New Zealand *Coprosma* species has also been found to turn over

282   its foliage in about one year (Richardson et al. 2010), as has the long-lived canopy tree *Fuscospora fusca*

283   (Wardle 1984).

Conclusions

285   This study makes two main contributions to the literature. Firstly, the dataset reported here—covering

286   over half the arborescent assemblage at the site—confirms that humid temperate forests lack the fast

287   end of the leaf economics spectrum found in their tropical counterparts, reflecting the absence of the

288   fast-growing tall pioneers that exploit treefall gaps at low latitudes (Lusk et al. 2011a). Secondly, this

289   study underlines the importance of standardizing the light environments in which leaf traits (especially

290   LMA) of humid temperate evergreens are measured. Without standardization, the strong plastic

291   response of LMA to light may mask interspecific variation in LMA associated with species' light

292   requirements, which is less wide-ranging than in humid tropical forests. Insufficient standardization of

293   light environments, coupled to countergradient variation in LMA (Conover & Schultz 1995; Lusk et al.

294   2008b), may thus explain the lack of consistency in reported relationships of LMA with light

295   requirements of temperate evergreen trees.

Acknowledgments

296

297   I thank Tanja Lenz and Teruko Kaneko for technical assistance, and two anonymous reviewers for

298   comments that helped clarify some aspects of the manuscript.

Study species, and minimum light requirements of their saplings.

Species' light requirements were estimated as the 10th percentile of the natural distribution of saplings in relation to canopy openness in temperate evergreen forest, Lake Okataina Scenic Reserve, New Zealand. N indicates the number of sampling points used to compute the light requirements of each species.

1   **Table 1**. Study species and minimum light requirements of their saplings, estimated as the 10th

2   percentile of the natural distribution of saplings in relation to canopy openness in temperate evergreen

3   forest, Lake Okataina Scenic Reserve, New Zealand. N indicates the number of sampling points used to

4   compute the light requirements of each species.

Species	Code	Family	Typical final height (m)	Minimum light requirements (% canopy openness)
Beilschmiedia tawa	Beitaw	Lauraceae	30	0.8 (n = 72)

false

Summary of nested ANOVA testing the effects of light environment (gap versus shade) and species on leaf traits.

N = 4-6 of each species in each light environment. Light environment was nested within species, as species were not all compared in common plots. *Coprosma robusta* was omitted from ANOVA, as leaf traits of this species were available only from gaps.

1 **Table 3**. Summary of nested ANOVA testing the effects of light environment (gap versus shade) and

2 species on leaf traits (n = 4-6 of each species in each light environment). Light environment was nested

3 within species, as species were not all compared in common garden plots. *Coprosma robusta* was

4 omitted from ANOVA, as leaf traits of this species were available only from gaps.

Correlations among sapling light requirements (MLR) and leaf traits of 19 temperate evergreens, New Zealand.

Values to the lower left of the diagonal show Pearson cross-species correlations; results from phylogenetic least squares regression appear to the upper right. * = P < 0.05, ** = P < 0.01. Only 18 species were sampled in the shade, as not enough *Coprosma robusta* saplings could be located in the understorey.

1 **Table 4**. Correlations among sapling light requirements (MLR) and leaf traits of 19 temperate

2 evergreens, New Zealand; only 18 species were sampled in the shade. Values to the lower left of the

3 diagonal show Pearson cross-species correlations; results from phylogenetic least squares regression

4 appear to the upper right. * = P < 0.05, ** = P < 0.01.

Relationships among leaf traits and minimum light requirements of 19 temperate forest evergreens.

Gap and understorey data are shown by open and filled (black) symbols, respectively. Solid lines show relationships significant at P = 0.05; correlation coefficients appear in Table 4.
