A substantial body of work has depicted a positive association between physical exercise and cognition, although the key factors driving that link are still a matter of scientific debate. Here, we aimed to contribute further to that topic by pooling the data from seven studies (N=361) conducted by our research group to examine whether cardiovascular fitness (VO_2), sport type participation (externally-paced [e.g., football or basketball] and self-paced [e.g., triathlon or track and field athletes] vs. sedentary), or both, are crucial factors to explain the association between the regular practice of exercise and vigilance capacity. We controlled for relevant variables such as age and the method of VO_2 estimation. The Psychomotor Vigilance Task was used to measure vigilance performance by means of reaction time (RT). The results showed that externally-paced sport practice (e.g., football) resulted in significantly shorter RT compared to self-paced sport (e.g., triathlon) and sedentary condition, depicting larger effects in children and adolescents than in adults. Further analyses revealed no significant effect of cardiovascular fitness and self-paced sport practice, in comparison to the sedentary condition, on RT. Our data point to the relevance of considering the type of sport practice over and above the level of cardiovascular fitness as crucial factor to explain the positive association between the regular practice of exercise and vigilance capacity

20 Abstract

21 A substantial body of work has depicted a positive association between physical exercise
22 and cognition, although the key factors driving that link are still a matter of scientific debate.
23 Here, we aimed to contribute further to that topic by pooling the data from seven studies
24 (N=361) conducted by our research group to examine whether cardiovascular fitness (VO₂),
25 sport type participation (externally-paced [e.g., football or basketball] and self-paced [e.g.,
26 triathlon or track and field athletes] vs. sedentary), or both, are crucial factors to explain the
27 association between the regular practice of exercise and vigilance capacity. We controlled for
28 relevant variables such as age and the method of VO₂ estimation. The Psychomotor Vigilance
29 Task was used to measure vigilance performance by means of reaction time (RT). The results
30 showed that externally-paced sport practice (e.g., football) resulted in significantly shorter RT
31 compared to self-paced sport (e.g., triathlon) and sedentary condition, depicting larger effects in
32 children and adolescents than in adults. Further analyses revealed no significant effect of
33 cardiovascular fitness and self-paced sport practice, in comparison to the sedentary condition, on
34 RT. Our data point to the relevance of considering the type of sport practice over and above the
35 level of cardiovascular fitness as crucial factor to explain the positive association between the
36 regular practice of exercise and vigilance capacity.

37 **Introduction**

38 The current trend towards a sedentary lifestyle in modern societies clashes with the
39 human natural tendency to be physically active^{1,2}. This pervasive lack of regular physical activity
40 has been related to numerous chronic physical and mental diseases and, relevant to this article, to
41 suboptimal cognitive functioning³. Indeed, there is a substantial body of work depicting a
42 positive association between regular practice of physical activity and cognition^{4,5}. The key
43 factors driving that link, however, are still a matter of scientific debate⁶. The aim of this brief
44 report was to further contribute to that topic by testing the role of two critical variables,
45 cardiovascular fitness and sport type participation, on the association between the regular
46 practice of exercise and the level of vigilance (i.e., the ability to stay focused, and to detect and
47 respond efficiently to target stimuli in order to attain the goals of the task). The interest in the
48 study of vigilance (or sustained attention) was motivated by its crucial role in general cognitive
49 capacities and to achieve optimal performance in many daylife activities (e.g., driving, attending
50 to an academic lesson, etc.)⁷. To accomplish the objective of the present study, we performed a
51 mixed-effects analysis including data from seven studies conducted by our research group (total
52 N=361) that used the same reaction time (RT) measure from the Psychomotor Vigilance Task
53 (PVT)⁸.

54 Exercise is typically defined as physical activity performed in a structured, planned and
55 repetitive manner⁹. Enhanced physical or cardiovascular fitness is one of the main consequences
56 of the regular practice of physical exercise that has been related to cognitive performance^{4,10-12}.
57 In the particular case of vigilance, our studies showed that higher-fit individuals outperformed
58 lower-fit individuals in the PVT^{8,13,14}. The evidence comes from both behavioural (RT) and
59 electrophysiological measures (event related brain and cardiac potentials). The outcome of this

60 research appears to support the cardiovascular fitness hypothesis, by virtue of which,
61 physiological adaptations (e.g., increased VO_2 , increased BDNF, etc.) induced by regular
62 exercise are assumed to be responsible for observed cognitive improvements^{15,16}.

63 Given the variety of exercise-related contexts available, however, exercise practice is far
64 more than just a way for enhancing cardiovascular fitness¹⁷. In fact, given its inherent and
65 varying perceptual and cognitive demands, it is expected that cognitive enhancement would
66 follow sustained practice¹⁸. For instance, optimal performance in football or basketball requires,
67 together with a sufficiently good level of fitness, rapid adaptation and response to the constantly
68 varying exercise environment (i.e., they are instances of externally-paced activities). In contrast,
69 endurance cycling or long distance running involve self-regulation of the effort in a relatively
70 consistent and predictable environment (i.e., they are instances of self-paced exercise). It is
71 therefore reasonable to expect that any cognitive improvement related to the regular practice of
72 exercise would depend on the particular activity and the associated cognitive demands. Our
73 research on vigilance¹⁹ has taken that possibility into consideration, reporting that individuals
74 (children) who practice externally-paced exercise regularly outperform those who practice self-
75 paced exercise (i.e., they show shorter RTs in absence of differences in cardiovascular fitness
76 between the two groups of athletes). These findings are consistent with the “cognitive skill”
77 hypothesis^{20,21}, whereby the learning of basic cognitive abilities through practice of one
78 particular activity can be transferred to other domains. This result may in turn jeopardize the
79 notion that cardiovascular fitness is critical for differences in vigilance performance to occur as a
80 function of exercise practice.

81 At this point, our research has not hitherto provided a clear answer to the issue of whether
82 cardiovascular fitness, sport type participation, or both, are among the key factors determining

83 the relationship between regular practice of exercise and vigilance performance. For this reason,
84 we have decided to perform a mixed-effects multistudy analysis on data from seven studies (6
85 published and 1 non-published) that our research group has conducted so far on this topic (Table
86 1) involving a total of 361 participants.

87 The use of the same task (the PVT) in all studies enabled us to incorporate the raw RT
88 data, which we believe represents an advantage over the use of standardized effect sizes that are
89 included in typical meta-analytical reports. To maintain homogeneity between studies, we only
90 analyse RT from the first 5 minutes of the task, that corresponds to the shortest version of the
91 PVT we have used so far. Note that the 5 minutes version of the task has been reported to be a
92 reliable tool to assess vigilance performance²². Importantly, apart from including cardiovascular
93 fitness and sport type participation as main variables of interest in the analysis, we controlled for
94 age, sex and the method of cardiovascular fitness estimation (that differed between studies).

95 In brief, this report aims to advance our current understanding of the research linking
96 physical exercise and cognition, with a focus on vigilance. The details of the analysis are
97 reported below and the raw data and the R scripts can be downloaded here
98 (https://osf.io/wcbev/?view_only=b308817398c3477092d2ee267fa3ed08).

99

100 **Method**

101 *Types of studies and sample characteristics*

102 The seven studies included in the present manuscript were carried out by our research
103 group and employed cross-sectional quasi-experimental designs. To the best of our knowledge,
104 there are no other studies so far comparing groups as a function of physical fitness and/or type of
105 sport practice, that used the same task (i.e., PVT) as a vigilance measure and reported VO₂ as an

106 index of cardiovascular fitness, both essential requirements to be included in the analysis. A total
107 sample of 361 participants (114 females) of an age range between 10 and 50 years old, different
108 levels of cardiovascular fitness (i.e., high-fit vs. low-fit) and sport type participation (i.e., self-
109 paced vs. externally-paced exercise) were included in the present multi-study analysis (Table 1).
110 All participants reported normal or corrected-to-normal vision, had no history of neurological
111 problems or cardiovascular diseases, and were not taking any medications that may affect
112 cognitive functions.

113

114 ***Sport type characteristics and VO₂ estimation method***

115 Participants included in the externally-paced group practiced sport modalities such as
116 football, basketball, volleyball, tennis or martial arts, while participants included in the self-
117 paced group practiced sport modalities such as track & field, running, swimming, triathlon or
118 cycling. Importantly, all participants included in sedentary groups (i.e. low-fit groups) reported
119 no historical participation in any sport and were not physically active (less than 2 hours per
120 week).

121 Across studies, VO₂ consumption (ml•kg⁻¹•min⁻¹) during exercise was employed as the main
122 index of cardiovascular fitness and was estimated and reported using three different methods: A
123 = estimation of the VO_{2max} (ml•kg⁻¹•min⁻¹) from the maximum power output measured in watts
124 in a maximal incremental cycle-ergometer test²⁵ (Studies 1 and 7; see Luque-Casado et al.⁸ and
125 Ballester et al.²⁴ for details); B = estimation of the VO_{2max} (ml•kg⁻¹•min⁻¹) from the Léger Multi-
126 stage fitness test²⁷ (Studies 2 and 6; see Ballester et al.^{19,23} for details); C = direct measure of
127 oxygen uptake (ml•kg⁻¹•min⁻¹) at the ventilatory anaerobic threshold (VAT; VO_{2 at VAT}) in a

128 submaximal incremental cycle-ergometer test (Studies 3-5; see Ciria et al.¹³ and Luque-Casado
129 et al.¹⁴ for details).

130 In order to obtain a single measure of cardiovascular fitness across studies, we
131 standardized the VO_{2max} (or $VO_{2 at VAT}$) data for each participant using the corresponding
132 sedentary group as reference (i.e., the participant's VO_2 minus the mean VO_2 of the sedentary
133 group (in the same study) divided by the unbiased -populational- VO_2 standard deviation
134 estimated from the same sedentary group). Henceforth, we will refer to this standardized
135 measure as simply VO_2 , which is interpreted as a measure of individual (higher or lower)
136 cardiovascular fitness, relative to same age range and similar sociodemographic extraction peers
137 who do not exercise regularly. Extra measures to prevent different VO_2 estimation methods to
138 bias results will be described in the statistical analysis and results sections.

139

140 ***Psychomotor Vigilance Task***

141 A modified version of the PVT developed by Wilkinson & Houghton²⁸ was used in all
142 studies included in the multi-study analysis. This task was designed to measure sustained
143 attention by recording participants' RT to visual stimuli that occur at random inter-stimulus
144 intervals^{22,29}. The PVT is a simple and reliable task to measure vigilance given the monotonous,
145 repetitive, and unpredictable nature of the target onset³⁰. In the standard procedure, a black circle
146 with a red edge ($6.68^\circ \times 7.82^\circ$) is displayed at the center of the screen in a black background.
147 Later, in a random time interval (from 2000 to 10000 ms), the circumference begins to be filled
148 in a red color and in a counter-clockwise direction with an angular velocity of 0.094 degrees per
149 second. The participants are instructed to respond as fast as they can to stop it. They must
150 respond with their dominant hand by pressing the space bar on the PC. Feedback of the response

151 time is displayed on the screen on each trial for 300 ms. The next trial begins after 1500 ms.
152 Response anticipations are considered as errors. Participants are allowed 3750 ms to respond. If a
153 response is not made during this time, the message “You did not answer” appears on the screen.
154 Different task durations (5, 9, 10, 12 and 60 minutes) and characteristics of the stimuli (gabor
155 patch or red circumference) were used according to the necessary adaptation to the aims of each
156 study (Table 1). In any case, the original paradigm of the PVT task was always maintained
157 making possible the comparison between studies. In extended task durations (i.e., 60 minutes),
158 we observed a differentiated pattern of RT performance between groups of participants as a
159 function of the time-on-task¹⁴. Therefore, in order to maintain homogeneity between studies, we
160 only analysed the RT from the first 5’ of the task based on three main reasons: 1) this duration
161 corresponds to the shortest version of the PVT we have used in all studies; 2) given that the
162 Group and Time-on-task factors seem to interact in extended task durations, the selection of the
163 first 5 minutes (when the effects of greater magnitude were observed and these do not depend on
164 the time-on-task) reduces the complexity of the statistical model; 3) five minutes are sufficient
165 for a reliable measure of vigilance²². As a common premise for the studies included in the
166 analysis, the experimental session was administered alternatively between morning or afternoon
167 hours among participants of each group except for studies including children (i.e., study 2 and 6),
168 which were carried out during the afternoon due to hourly restrictions of the participants.

169

170 ***Design and statistical analyses***

171 RTs from the seven studies conducted in our laboratory were collapsed into a single
172 dataset to estimate the effects of sport type (i.e., self-paced, externally-paced, and sedentary
173 conditions) on them. In face of the diversity of samples’ characteristics and study features, we

174 fitted RTs using multilevel linear mixed-effects modelling, as implemented in the *lme4* R
175 package³¹.

176 In order to take into account the dependencies potentially generated by any procedural
177 differences between studies, we treated RTs as obeying to a multilevel data structure (Figure 1),
178 with participant (level 3), nested into study (level 2), and study nested into estimation method
179 (level 1). Thus, the random part of the model consisted of intercepts for participant (nested in),
180 study (nested in), VO₂ estimation method. This random part was common to all models. The
181 fixed part in a first, *baseline model* (H₀) consisted of VO₂, age, and trial number (to facilitate
182 model convergence, gender was not included as a fixed factor, as it is mostly controlled for by
183 participant and VO₂, and not included in any further interactions). Additionally, the effect of age
184 consisted of a linear and a quadratic component, to allow for non-linearity in the age-reaction
185 time association. This baseline model was pitched against a second, *H₁ model* with the same
186 random and fixed parts as H₀, plus sport type (self-paced, externally-paced, sedentary) as an
187 added fixed-effects factor. A third, *saturated* model further included the sport type x age, the
188 VO₂ x age, and the sport type x trial interactions (please, note that interactions involving age
189 actually refer to two different interaction effects, one involving the linear component and the
190 other involving the quadratic component of the age effect, that were always jointly
191 included/excluded for model comparisons). Interactions were later removed one-by-one
192 (*Interaction 1*, *Interaction 2*, and *Interaction 3* models; see Table 2). If any of the three
193 interactions contributed to the model fit, it was kept in the final, *best-fitting* model. This last,
194 best-fitting model thus consisted of the same random and fixed parts as the H₁ model plus the
195 interactions identified as substantially contributing to model fit. This model was used to estimate
196 effects.

197 Prior to fitting, RTs larger than 1000 ms (i.e., omission errors; 0,5% trials) were removed
198 from further analyses, and the remaining ones (16,239) were log-transformed. To enable model
199 convergence and facilitate interpretation of regression coefficients, trial number and log-
200 transformed RTs, were scaled and zero-centered. Models were compared using the Akaike
201 Information Criterion (AIC), and a Likelihood ratio test. For model comparisons performed to
202 identify the best-fitting model, a relatively lenient 0.010 p-value criterion was adopted.
203 Inferences were subsequently made based on the results of the best-fitting model.

204

205 **Results**

206 Table 2 shows the fitting indices for all the models included in the relevant comparisons
207 described above (baseline, H1, saturated, interaction 1-3, and best-fitting models). Table 3
208 (columns 1-5) displays unstandardized regression coefficients (B), their standard errors (SE) and
209 significance levels (according to t-tests), for each fixed component in the best-fitting model. The
210 best-fitting model included the effects of sport type, and the sport type x age interaction.

211 In the best-fitting model, the contrast corresponding to the comparison between
212 externally paced sports and the other two conditions (sedentary and self-paced sports, pooled
213 together) yielded a significant t-test (contrast 1); whereas self-paced sports did not differ from
214 the sedentary condition (contrast 2). Neither C1 nor C2 interacted with either the linear or the
215 quadratic effect of age.

216 The absence of a significant effect of VO_2 in the best-fitting model ($p = 0.247$) was also
217 confirmed by an approximated Bayes Factor³². In order to compute it, we built a third model
218 ($H1_b$), equivalent to the best-fitting model, but with VO_2 removed from the fixed part. The AIC
219 value for this model was 34861.02. The Bayes Factor approximation for this comparison

220 between the best-fitting model and $H1_b$ was $BF_{10} = 0.016$, which supports $H0_b$ relative to the
221 best-fitting model, and suggests the absence of any substantial influence of VO_2 on RTs if sport
222 type is controlled for.

223 The upper panel of Figure 2 displays predicted (standardized) RTs across age for the
224 three sport types. Although the age x sport type interactions were not significant, the effect of
225 sport type seems to vanish for intermediate ages. Additionally, given there were virtually no
226 practitioners of externally paced sport among 40-50 years-old participants, predictions for that
227 age group mostly resulted from fitting the effect of age on RT for younger participants. In order
228 to ensure the effect of sport type was not inflated in the previous analysis, we run the best-fitting
229 model with a dataset restricted to the studies in which there were participants in the three sport
230 types (study 6 and 7). As shown in columns 6-9 in Table 3, the effect of sport type remained
231 largely significant, but there also was an interaction between the sport type C1 contrast and the
232 linear component of age. The lower panel of Figure 2 shows the shape of this interaction.
233 Importantly, qualitative predictions for these studies were virtually identical to the ones made
234 from the full dataset for the 10-35 age range.

235 **Discussion**

236 Sedentarism has been related to numerous health issues and, according to a wealth of
237 literature, to poorer cognitive function (with respect to active individuals)⁴. The aim of this
238 paper was to contribute to that body of work by pooling the data from seven studies (N=361) to
239 examine whether VO_2 (index of cardiovascular fitness), type of sport participation (externally-
240 paced and self-paced), or both (controlling for sex, age and the method of VO_2 estimation), are
241 crucial factors to explain the association between the regular practice of exercise and vigilance
242 capacity (measured by means of the PVT).

243 The results were straightforward. Sport type was significantly related to RT, although
244 only externally-paced sport differed from the sedentary condition (and also from the self-paced
245 sport condition). Sport type and age interacted, showing that the (same) pattern of differences
246 between sport types was more evident in children and adolescents than in older participants.
247 Both the multilevel linear mixed-effects modelling and Bayesian analysis confirmed the absence
248 of effect of VO_2 and self-paced sport practice (with respect to the sedentary condition) on RT.

249 Maximum oxygen consumption (VO_{2max}) has been the primary index of cardiovascular
250 fitness to associate with cognitive and brain functioning (and anatomy) over the last years. The
251 positive findings to date establish that the greater the VO_{2max} , the higher the cardiovascular
252 fitness and the better the cognitive and brain functioning^{4,10-12}. Together with the outcome of
253 randomized controlled trials (RCT; where increased VO_{2max} after exercise intervention was
254 accompanied by enhanced cognition)³⁵ this evidence has fueled the cardiovascular (selective)
255 hypothesis, i.e., the regular practice of cardiovascular exercise (not other forms of physical
256 activity such as stretching; cf. Kramer et al.³⁶) positively affect cognition (with a selective
257 influence on executive function) by means of its physiological effects at neural level. The null
258 effect of VO_2 and the non-significant RT difference between self-paced exercise and the
259 sedentary condition (well differentiated in terms of cardiovascular fitness) in our study appear to
260 challenge that hypothesis (cf. Etnier et al.³⁷).

261 A simple explanation of our null result is that VO_{2max} is a measure of cardiovascular
262 fitness that is not sensitive enough to variations in cognitive performance (RT in the PVT here),
263 even though, as we said above, it is the main index used to date. Proponents of the cardiovascular
264 selective hypothesis could also argue that our null finding was due to the low executive demands
265 of the PVT. The evidence from neuroimaging data speaks against that account. There is indeed

266 work reporting that PVT performance involves selective activation of brain areas related to
267 sustained attention and cognitive control^{30,38}, presumably driven by the (large) temporal
268 uncertainty of the target appearance, the repetitive and monotonous nature of the task and the
269 need of generating temporal expectations. Of course, in defense of the cardiovascular selective
270 hypothesis, it could still be claimed that the executive demands of the PVT are much lower than
271 those of the conflict or working memory tasks used in previous research on this topic. This is a
272 matter open to opinion and debate as no study to date has addressed this issue directly.

273 The fact that self-paced exercise was not related to improved RT with respect to the
274 sedentary condition is not surprising if one considers that only half of the studies in which we
275 compared a group of self-paced sport athletes with a group of sedentary individuals revealed
276 statistically significant RT differences. Assuming that the large N in the present analysis ensures
277 sufficient statistical power, one could argue that those reported significant group RT differences
278 were false positives (at least considering the first 5' of the task). However, those RT group
279 differences from the single studies might still be meaningful but explained by the influence of an
280 unknown (uncontrolled) variable. Moreover, in the studies showing positive results, group
281 differences were not only seen in terms of RT but also in accuracy performance in an oddball
282 task (with much lower RT demands than the PVT; see Ciria et al.¹³), and, more importantly, in
283 task-related cardiac and electroencephalographic measures^{8,14,39}. If those group differences were
284 to be true, the result of the present analysis suggests that they were not due to mere differences in
285 cardiovascular fitness.

286 Even if it involves executive functioning, the PVT is clearly a task demanding
287 visuomotor coordination to react as rapidly as possible to the target appearance. This could
288 explain that only externally-paced sport practice associates to (enhanced) RT performance in our

289 study, supporting the cognitive skills hypothesis whereby sport practice is just another medium
290 for cognitive training²¹, over and above its effect due to cardiovascular physiological adaptations.
291 Obviously, this result cannot be taken as evidence of the *effect* of externally-paced sport practice
292 on the vigilance capacity of our participants for other variables not related to the sport practice
293 itself could well account for the reported positive relationship. For instance, pre-existing
294 individual differences that biased the choice of the particular sport practice (Belsky et al.⁴⁰ for a
295 related argument) might explain the sport-type effect in our multi-study analysis, and also the
296 interaction between sport type and age. In fact, most of the younger participants in the
297 externally-paced sport type groups were football players from (two) Spanish 1st Division League
298 junior teams (with strict selection criteria and talent identification programs) while older
299 participants were amateur/recreational athletes. However, the above and any other alternative
300 explanation are speculative, for only well-designed RCTs would establish cause-effect
301 relationships between exercise practice and cognitive performance. Also, future research should
302 clarify whether indexes of response accuracy (beyond psychomotor response speed typical of the
303 PVT) from other cognitive tasks measuring sustained attention (e.g., oddball task) discriminate
304 between the type of sport practice and cardiovascular fitness in relation to the ability to maintain
305 attention over time.

306 In the absence of that RCT, one could still argue that the extant evidence on the effect of
307 chronic exercise on cognition supports the hypothesis that practicing exercise and sport regularly
308 would have a positive effect on vigilance capacity. However, that evidence is not as conclusive
309 as it may appear, with some systematic reviews and meta-analysis reporting positive results^{41,42}
310 and other showing null effects⁴³⁻⁴⁶.

311

312 Conclusions

313 The results of the multistudy analysis reported here point to the type of sport practice as a
314 major factor to explain differences in vigilance performance as a function of regular exercise
315 over and above the level of aerobic fitness, which in turn challenges the cardiovascular
316 hypothesis. In any case, this topic warrants further well-designed research (RCTs) to unveil
317 whether chronic exercise (and sport practice) has a true effect on cognition in general, and
318 vigilance in particular. Interested researchers are facing a challenging task, as they would have to
319 take into account the cognitive demands of the sport (exercise) activity as we highlighted here,
320 the many other factors related to exercising (such as the intensity and duration of each exercise
321 session or the periodization of the exercise program) and all potential mediators (BDNF, sleep,
322 motivation, etc.)⁶. Only after solid evidence is acquired, researchers would be ready to pave the
323 road for prescription of exercise as a potential tool to enhance cognition and prevent cognitive
324 decline.

454 **Acknowledgements**

455 We thank to all the participants who took part in the experiment.

Figure 1

Schematic representation of the multilevel data structure

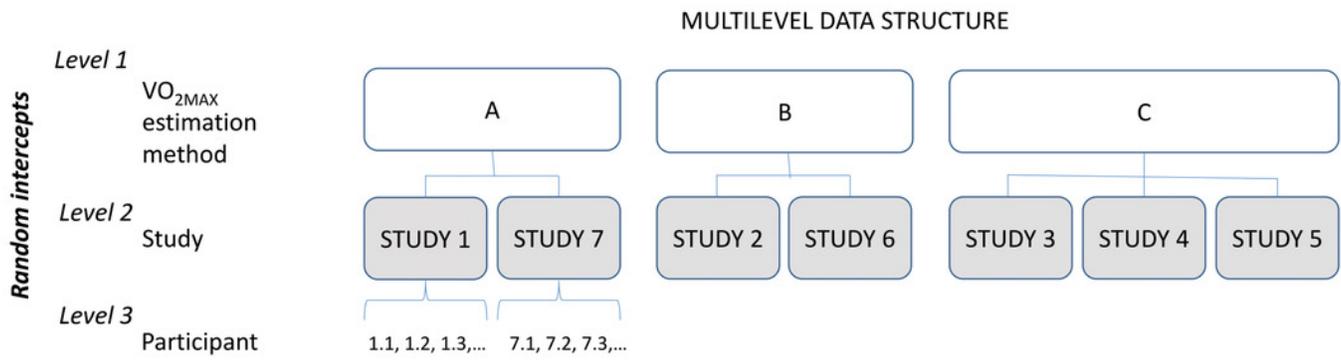

Figure 2

Predicted effect of sport type across age.

(A) predicted (standardized) reaction times (RTs) across age for the three sport types including the full dataset; (B) predicted (standardized) RTs across age for the three sport types including only dataset restricted to the studies in which there were participants in the three sport types (study 6 and 7). Figure shows that externally-paced sport practice (e.g., football) entail significantly shorter RT compared to self-paced sport (e.g., triathlon) and sedentary condition irrespective of the cardiovascular fitness level, depicting larger effects in children and adolescents.

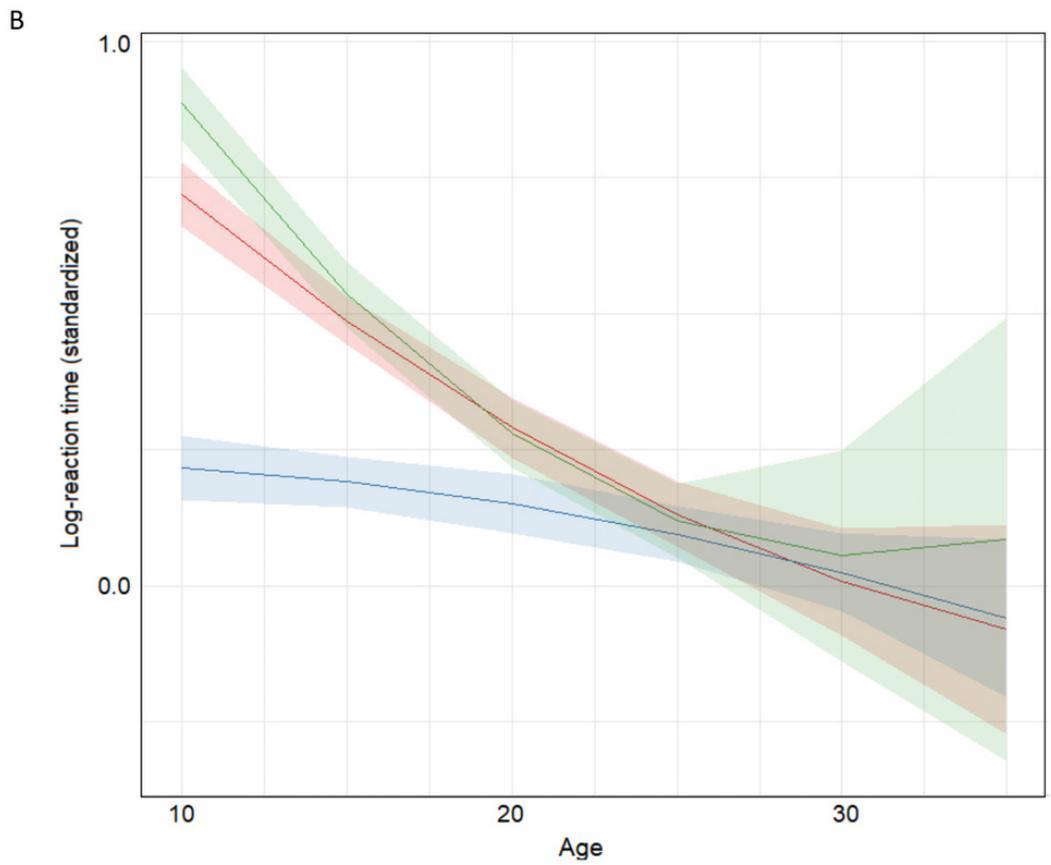

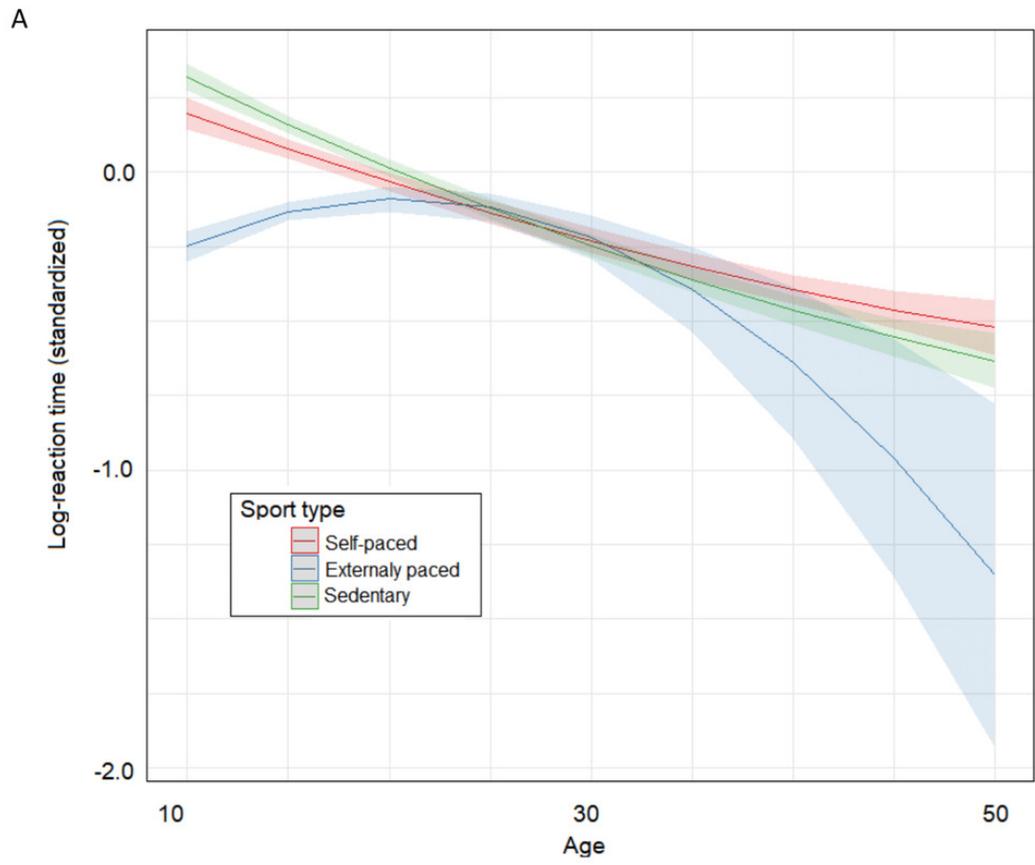

Table 1 (on next page)

Summary of sample and task characteristics, VO_2 estimation methods and results of the studies included in the analysis.

Sex: M= Male, F= Female; Sport type: SP= Self-paced, EP=Externally-paced, S= Sedentary;

Stimuli: RC = red circumference, GP = gabor patch; VO_2 ($ml \cdot kg^{-1} \cdot min^{-1}$) estimation methods:

A = estimation of the VO_{2max} from the maximum power output in a maximal incremental

cycle-ergometer test, B= estimation of the VO_{2max} from the Léger Multi-stage fitness test and

C = direct measure of oxygen uptake at the ventilatory anaerobic threshold (VAT; $VO_{2 \text{ at VAT}}$) in

a submaximal incremental cycle-ergometer test. (*) the shorter RT showed by SP group was limited to the first 36' of the task.

- 1 **Table 1.** Summary of sample and task characteristics, VO₂ estimation methods and results of the
 2 studies included in the analysis.

Study	Sample size	Age range	Sex	Groups and Sport type	PVT paradigm peculiarities	VO ₂ estimation methods	Results (RT)
Study 1 Luque-Casado et al. ⁸	N = 26	17-29	M	SP=13 S=13	Duration: 10 min Stimuli: RC	A	SP < S
Study 2 Ballester et al. ²³	N = 75	13 - 14	M & F	EP= 39 (15 females) S = 36 (18 females)	Duration: 9 min Stimuli: GP	B	EP < S
Study 3 Luque-Casado & Sanabria (unpublished)	N = 41	40 - 50	M	SP=22 S=19	Duration: 12 min Stimuli: GP	C	SP = S
Study 4 Luque-Casado et al. ¹⁴	N = 50	18-32	M	SP=25 S=25	Duration: 60 min Stimuli: RC	C	SP < S (*)
Study 5 Ciria et al. ¹³	N = 43	18 - 23	M & F	SP = 21 (10 females) S = 22 (11 females)	Duration: 5 min Stimuli: RC	C	SP < S
Study 6 Ballester et al. ¹⁹	N = 60	10 - 11	M & F	EP = 20 (8 females) SP = 20 (12 females) S = 20 (10 females)	Duration: 9 min Stimuli: GP	B	EP < S EP < SP SP = S
Study 7 Ballester et al. ²⁴	N = 66	18 – 37	M & F	EP = 22 (10 females) SP = 22 (8 females) S = 22 (12 Females)	Duration: 9 min Stimuli: GP	A	EP < S EP = SP SP = S

- 3 Sex: M= Male, F= Female; Sport type: SP= Self-paced, EP=Externally-paced, S= Sedentary; Stimuli: RC
 4 = red circumference, GP = gabor patch; VO₂ (ml•kg⁻¹•min⁻¹) estimation methods: A = estimation of the
 5 VO_{2max} from the maximum power output in a maximal incremental cycle-ergometer test, B= estimation of
 6 the VO_{2max} from the Léger Multi-stage fitness test and C = direct measure of oxygen uptake at the

- 7 ventilatory anaerobic threshold (VAT; $\text{VO}_{2\text{ at VAT}}$) in a submaximal incremental cycle-ergometer test. (*)
- 8 the shorter RT showed by SP group was limited to the first 36' of the task.

Table 2 (on next page)

Models, fitting indices, and Likelihood Ratio comparisons.

Note: All models have been adjusted with the Maximum Likelihood (ML) method. Age effects include a linear and a quadratic component, jointly included/excluded for model comparisons. The random part is common to all models (see text). “>” indicates better fit than, “<” worse fit than, and “=” not substantially worse fit than. *For factor inclusion/exclusion comparison, a relatively lenient $p < .010$ significance level has been used.

1 **Table 2.** Models, fitting indices, and Likelihood Ratio comparisons.

<i>Model</i>	<i>Fixed part</i>	<i>df</i>	<i>AIC</i>	<i>L.ratio</i>	<i>p</i>	
<i>Baseline</i>	Age + VO2 + trial	9	34881.04			
<i>H₁</i>	baseline + sport type	11	34866.47	18.569	<0.001	> baseline
<i>Interaction 1</i>	saturated - (sport type x age)	15	34865.81	8.089	0.088	< saturated*
<i>Interaction 2</i>	saturated - (VO2 x age)	17	34863.70	1.977	0.372	= saturated
<i>Interaction 3</i>	saturated - (sport type x trial)	17	34863.59	1.868	0.393	= saturated
<i>Saturated</i>	H ₁ + (sport type x age) + (VO2 x age) + (sport type x trial)	19	34865.72			
<i>Best-fitting</i>	H ₀ + sport type + (sport type x age)	15	34861.58	31.465	<0.001	> baseline

2 Note: All models have been adjusted with the Maximum Likelihood (ML) method. Age effects include a linear and a quadratic
3 component, jointly included/excluded for model comparisons. The random part is common to all models (see text). “>” indicates
4 better fit than, “<” worse fit than, and “=” not substantially worse fit than. *For factor inclusion/exclusion comparison, a relatively
5 lenient $p < .010$ significance level has been used.
