## ABSTRACT

*Hypericum perforatum* L. is a widely known medicinal herb used mostly as a remedy for depression because it contains high levels of naphthodianthrones, phloroglucinols, alkaloids, and some other secondary metabolites. Quantitative real-time PCR (qRT-PCR) is an optimized method for the efficient and reliable quantification of gene expression studies. In general, reference genes are used in qRT-PCR analysis because of their known or suspected housekeeping roles. However, their expression level cannot be assumed to remain stable under all possible experimental conditions. Thus, the identification of high quality reference genes is essential for the interpretation of qRT-PCR data. In this study, we investigated the expression of 14 candidate genes, including nine housekeeping genes (HKGs) (*ACT2*, *ACT3*, *ACT7*, *CYP1*, *EF1- $\alpha$* , *GAPDH*, *TUB- $\alpha$* , *TUB- $\beta$* , and *UBC2*) and five potential candidate genes (*GSA*, *PKS1*, *PP2A*, *RPL13*, and *SAND*). Three programs—GeNorm, NormFinder, and BestKeeper—were applied to evaluate the gene expression stability across four different plant tissues, four developmental stages and a set of abiotic stress and hormonal treatments. Integrating all of the algorithms and evaluations revealed that *ACT2* and *TUB- $\beta$*  were the most stable combination in different developmental stages samples and all of the experimental samples. *ACT2*, *TUB- $\beta$* , and *EF1- $\alpha$*  were identified as the three most applicable reference genes in different tissues and stress-treated samples. The majority of the conventional HKGs performed better than the potential reference genes. The obtained results will aid in improving the credibility of the standardization and quantification of transcription levels in future expression studies on *H. perforatum*.

## INTRODUCTION

An increasing number of studies on the gene expression levels in plants are being carried out to better understand the signaling and metabolic pathways underlying the developmental processes involved in plant development and growth, as well as plant responses to biotic and abiotic stresses ([Moreno-Risueno et al., 2010](#); [Yamaguchi et al., 2010](#); [Wang et al., 2011](#)). Methods for assessing gene expression include northern blot, gene chips, semi-PCR, RNase protection analysis, and Quantitative real-time PCR (qRT-PCR). qRT-PCR has become a very popular and effective method for detecting and quantifying gene transcription levels because of its high sensitivity, specificity, reproducibility, and accuracy ([Nolan, Hands & Bustin, 2006](#)). Reliable quantification of gene expression levels using qRT-PCR analysis requires the standardization and fine-tuning of several parameters, such as the amount of initial sample, RNA recovery and integrity, enzymatic efficiency of cDNA synthesis and PCR amplification, and the overall transcriptional activity of the tissues or cells analyzed ([Nolan, Hands & Bustin, 2006](#); [Udvardi & Scheible, 2008](#)). The expression stability of frequently used reference genes also cannot be neglected. Therefore, the normalization of the transcript levels of test genes is essential for minimizing technical differences that arise in different samples and experimental conditions ([Udvardi & Scheible, 2008](#)). More importantly, the selection of stable reference genes must be done before qRT-PCR analysis.

An appropriate reference gene is not affected by the experimental conditions and remains at an invariable level among samples ([Bustin & Mueller, 2005](#)). However, the transcription levels of the traditional reference genes and even some housekeeping genes (HKGs) can vary between different types of tissue and under different treatment conditions ([Leal et al., 2015](#)). Therefore, a growing number of studies have been published on the analysis and evaluation of the stability of internal reference genes in plant tissues under different conditions. Consequently, different reference genes should be applied for different experimental materials and conditions. In addition, the use of reference genes with lower stability may lead to an erroneous understanding of the qRT-PCR results and mask the true nature of gene expression ([Brattelid & Levy, 2011](#); [Bustin & Nolan, 2004](#)).

*Hypericum perforatum* L. (commonly known as St. John's wort) is a widely known medicinal herb used mostly as a remedy for depression ([Veronika, 2003](#)). Pure essential compounds isolated from *H. perforatum*, namely naphthodianthrones and phloroglucinols, have been shown to possess anti-depressive, anti-cancer, anti-viral, anti-inflammatory, and other activities ([Birt et al., 2009](#); [Filippo et al., 2011](#)). Xanthonenes and flavonoids have also been identified in extracts from this plant ([Schröder, 1997](#)). To date, a limited number of qRT-PCR studies focusing on *H. perforatum* have been published. [Velada et al. \(2014\)](#) studied the stability of 11 candidate reference genes analyzed in *H. perforatum* plants subjected to only cold and heat stresses, and *TUB* was found to be the most stable gene under both experimental conditions. Therefore, it is essential to screen suitable reference genes in different tissues of *H. perforatum* under different experimental conditions. Ribosomal RNA and some HKGs are usually used as reference genes, such as actin (*ACT*), tubulin

(*TUB*), glyceraldehyde-3-phosphate dehydrogenase (*GAPDH*), and polyubiquitin (*UBQ*) (Costa et al., 2015; Goulao, Fortunato & Ramalho, 2012; Llanos, François & Parrou, 2015; Willems, Leyns & Vandesompele, 2008), whereas many studies have revealed that the most commonly used HKGs are not always reliable among different experimental samples. Thus, an evaluation to screen the optimal HKGs in different species is urgently needed (Ohl et al., 2005; Selvey et al., 2001; Thellin et al., 1999).

This study aimed to assess the expression stabilities of 14 reference genes in 15 experimental samples using qRT-PCR, including nine traditional HKGs and five potential reference genes: *GAPDH*, actin (*ACT2*, *ACT3*, and *ACT7*), ubiquitin-conjugating (*UBC2*), elongation factor (*EF1-a*), tubulin (*TUB- $\alpha$*  and *TUB- $\beta$* ), cyclophilin (*CYP1*), polyketide synthase (*PKS1*), glutamate semialdehyde aminomutase (*GSA*), SAND family protein (*SAND*), ribosomal protein L (*RPL13*) and protein phosphatase 2A (*PP2A*). These genes were selected from the *H. perforatum* genome sequencing data obtained in our lab. In this study, we evaluated the transcriptional stability of these genes in different tissues, developmental stages and under different stress conditions to determine the most stable reference genes.

## MATERIALS AND METHODS

### Plant materials

*H. perforatum* seeds ( $2n = 2 \times = 16$ ) were germinated on a seedling bed in the glasshouse ( $25 \pm 2$  °C, natural lighting, 60–80% humidity). Whole plant tissues were collected at the one-month-old (1M), two-month-old (2M), three-month-old (3M), and six-month-old (6M) stages. Samples of different tissues (leaf, flower, stem, and root) were taken from two-year-old plants ( $2n = 2 \times = 16$ ). 3M seedlings were subjected to abiotic stresses and hormonal treatments, including 10  $\mu$ M salicylic acid (SA), 200  $\mu$ M methyl jasmonate (MeJA), 100  $\mu$ M abscisic acid (ABA), one mM  $\text{AgNO}_3$  (Ag), 200  $\mu$ M  $\text{CuSO}_4$  (Cu), 100 mM NaCl (Na), low temperature (4 °C) and wounding (W). The stress-treated samples were each collected 6 h after the corresponding treatments, and the control groups were collected following non-treatment. All samples were collected in three replicates, frozen in liquid nitrogen immediately, and then stored at  $-80$  °C.

### Total RNA isolation and cDNA synthesis

Total RNA was extracted using the Polysaccharide and Polyphenols Plant Quick RNA Isolation Kit (centrifugal column type; Waryong, Beijing, China). The genomic DNA was digested with RNase-free DNase I (TaKaRa, Kusatsu, Japan). The total RNA was quantified using the absorbance at  $A_{260}/A_{280}$  and  $A_{260}/A_{230}$  nm measured with a NanoDrop 2000c spectrophotometer (Thermo Scientific, Waltham, MA, USA). A 1% (p/v) agarose gel was run to visualize the integrity of the RNA. Only RNA samples with an  $A_{260}/A_{280}$  wavelength ratio between 1.9 and 2.1 and an  $A_{260}/A_{230}$  ratio close to 2.0 were used for cDNA synthesis. Then, 1.0  $\mu$ g DNA-free total RNA was used to synthesize first-strand cDNAs with a PrimeScript RT Reagent Kit (TaKaRa, Kusatsu, China) in a 20  $\mu$ L volume. All cDNA samples were diluted (1:40) with DNase/RNase-free deionized water for qRT-PCR.

## Selection of reference genes and primer design

We performed genomic sequencing of *H. perforatum* using Illumina paired-end, 10× Genomics linked reads and PacBio SMART (GenBank accession numbers: [MK054303](#), [MK106356](#)–[MK106365](#)). The transcriptome sequencing of *H. perforatum* for the roots, stems, leaves, and flowers assisted annotation. The 14 candidate genes, including nine traditional HKGs (*ACT2*, *ACT3*, *ACT7*, *CYP1*, *EF1-α*, *GAPDH*, *TUB-α*, *TUB-β*, and *UBC2*) and five potential reference genes (*PKS1*, *GSA*, *RPL13*, *SAND*, and *PP2A*) which have been used as candidate genes in other studies ([He et al., 2016](#); [Li et al., 2017](#); [Velada et al., 2014](#)), were selected for the assessment of the most stably expressed reference genes ([Table S1](#)). To ensure the accuracy of the reference gene predictions, we first screened the candidate genes according to the genome annotation of each, which was assigned based on the best match of the alignments using Blastp to SwissProt, KEGG, NR, and TrEMBL databases. Then the coding sequences of the 14 selected genes were used as queries for BLAST orderly through the TAIR database (<http://www.arabidopsis.org/>) to further ensuring accuracy. The sequences with the highest homology with Arabidopsis are shown in [Table 1](#). The primers of all the genes were designed using GenScript (<https://www.genscript.com>) with a melting temperature between 59 and 61 °C, a primer length of 20–25 bp, and an amplicon length of 70–180 bp. The descriptions of the candidate reference genes, primer sequences, and qRT-PCR amplification efficiencies are presented in [Table 1](#).

## qRT-PCR conditions and analysis

PCR reactions were performed on the Roche LightCycler 96 system using SYBR<sup>®</sup> Master Mix. Reactions were performed in triplicate in 20 μL volumes containing five μL 30-fold diluted synthesized cDNA, 10 μL SYBR<sup>®</sup> Master Mix, 0.4 μL 10 mM forward primer, 0.4 μL 10 mM reverse primer and 4.2 μL DNase/RNase-free deionized water. The cycling conditions were 95 °C for 30 s, 45 cycles of 95 °C for 5 s, and 60 °C for 30 s, and a final melting curve analysis. Each reaction was set up with a negative control group and triple technical replicates were performed in each of three biological samples. To calculate the amplification efficiency from 10-fold continuous dilutions of the cDNA ( $10^0$ ,  $10^{-1}$ ,  $10^{-2}$ , and  $10^{-3}$ ) for each gene, standard curves were constructed to obtain the correlation coefficients ( $R^2$ ) and slope values. Using these standard curves, the corresponding PCR amplification efficiencies ( $E$ ) were calculated ( $E = (10^{-1/\text{slope}} - 1) \times 100$ ) ([Aleksandar et al., 2004](#)).

## Assessment of expression stability

The expression stability of the genes was analyzed using three different Visual Basic applets, GeNorm ([Schlotter et al., 2009](#)), NormFinder ([Obrero et al., 2011](#); [Zhang et al., 2016](#)), and BestKeeper ([Rhinn et al., 2008](#); [Rotenberg et al., 2006](#)). GeNorm derives a stability measure ( $M$ -value) via the stepwise exclusion of the least stable gene, and creates a stability ranking ([Hu et al., 2009](#)). Genes with  $M < 1.5$  are generally considered stable reference genes ([Tong et al., 2009](#)). This measure is based on the principle that the expression ratio of two ideal control genes should be identical in all samples; thus, genes with the lowest  $M$ -value are the most stably expressed ([Dekkers et al., 2012](#)). The GeNorm

**Table 1** Candidate genes, primers, and different parameters derived from the qRT-PCR analysis in *H. perforatum*.

pairwise variation ( $V$ ) values between ranked genes ( $V_n/V_{n+1}$ ) were determined for the optimal number of reference genes to be used in the quantitative analysis experiments. A cut-off of 0.15 ( $V_n$  value) is usually applied ([Vandesompele et al., 2002](#)). NormFinder uses an ANOVA-based model to estimate intra- and intergroup variation within tissues or treatments (“groups” in NormFinder terminology) to assess the expression stability ([Marchal et al., 2013](#)). For GeNorm and NormFinder, the raw Ct values need to be converted to relative quantities ( $Q$ ) using the formula  $Q = 2^{-\Delta Ct}$ , in which  $\Delta Ct =$  each average Ct value–minimum Ct value ([Yang et al., 2015](#)). In BestKeeper, the coefficient of variance (CV) and the standard deviation (SD) were calculated using the Ct values, with lower CV and SD values indicating higher stability ([Migocka & Papierniak, 2011](#)). The mean standard error and level of statistical significance were calculated using GraphPad Prism 6.0, and the level of statistical significance was assessed using  $^*P < 0.05$ ,  $^{**}P < 0.01$ , and  $^{***}P < 0.001$ .

## Validation of reference gene stability

The relative expression of the *HpHYP1* gene in different tissues was measured and standardized by using the most stable and unstable candidate genes as internal references to verify the reliability of the selected genes according to the  $2^{-\Delta\Delta C_t}$  method (Kumar *et al.*, 2011). Three technical replicates were performed for each biological sample.

## RESULTS

### Primer specificity and expression level analysis of candidate reference genes

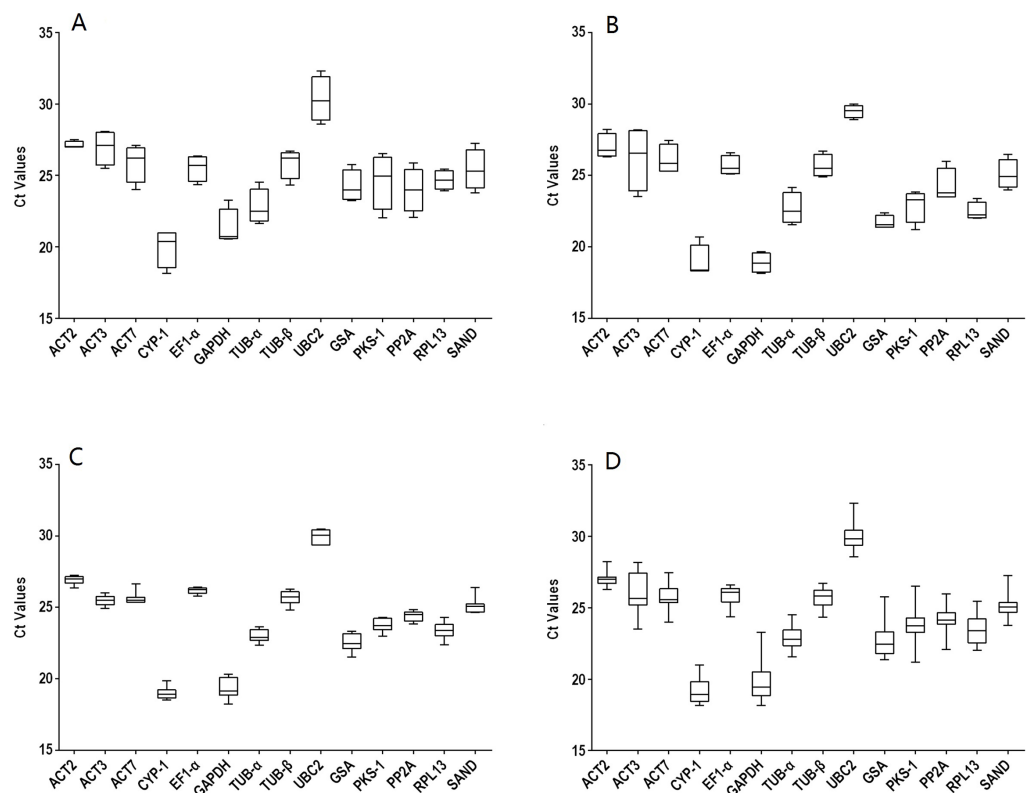

The gene names and abbreviations, accession numbers, primer sequences, amplification efficiencies, amplicon sizes,  $T_m$  values, and molecular functions are listed in Table 1 and Table S1. The amplification efficiencies listed in Table S2 ranged from 92.5% (*RPL13*) to 109.5% (*TUB- $\alpha$* ), the  $T_m$  values varied from 81.2 °C (*PP2A*) to 87.8 °C (*CYP1*), and the amplicon sizes were between 76 (*GAPDH* and *PKS1*) and 170 bp (*TUB- $\beta$* ). Furthermore, primer specificities were determined using melting curves (Fig. S1) and triple technical replicates were performed for each of the three biological samples. A single band indicated the correct size of each pair. The average raw  $CT$  values of different genes ranged from 18.15 to 32.32 (Table S3). Data were analyzed within experiments and divided into four groups: tissues from two-year-old plants (TS: R, S, L, and F), seedling developmental stages (SG: 1M, 2M, 3M, and 6M), 3M seedlings exposed to abiotic stresses (ST: SA, MeJA, ABA, Cu, Ag, Na, 4 °C and W) and a combination of all experimental conditions (TT). The expression levels of the 14 selected genes in the four groups are shown in Fig. 1. Among them, *UBC2* (TS) had the highest  $C_t$  value, but *GAPDH* (SG) had the lowest, indicating their levels of expression.

### Stability of candidate reference genes

GeNorm was used to calculate the normalization factor from the geometric mean of the genes to identify the most stably expressed gene. The  $M$ -value is defined as the average pairwise variation of a particular gene with all other potential reference genes. The expression stability ranking of the 14 reference genes in the TT samples was arranged as follows: *TUB- $\beta$*  > *ACT2* > *CYP1* > *EF1- $\alpha$*  > *TUB- $\alpha$*  > *SAND* > *UBC2* > *ACT7* > *PP2A* > *GSA* > *PKS1* > *RPL13* > *GAPDH* > *ACT3*. Except for in the TT group, *ACT2* and *ACT3* were the genes with the lowest and highest  $M$ -values, respectively, (Fig. 2; Table S4). The  $V_{2/3}$  values for almost all of the experimental sets in *H. perforatum* were lower than the cut-off threshold of 0.15 (Fig. 3), which indicated that the combination of two reference genes (*ACT2* and *TUB- $\beta$* , or *ACT2* and *EF1- $\alpha$* ) can accurately standardize these samples. For the TT group,  $V_{2/3}$  was 0.2039, which indicated that the top three reference genes (*ACT2*, *TUB- $\beta$* , and *CYP1*) were required for accurate normalization.

NormFinder with lower values indicating higher stability is another Excel application that ranks the candidate genes based on their minimal combined inter- and intragroup variation of expression. The results (Table 2) indicated that *ACT2* was the most stable gene in the SG and ST groups. *EF1- $\alpha$*  and *TUB- $\beta$*  ranked first in the TS and TT groups respectively. *ACT3* was at the end of the rankings in all groups calculated using

**Figure 1** Distribution overview of the expression profiles of 14 candidate genes. The box indicates the 25th and 75th percentiles; whisker caps indicate the maximum and minimum values; and dots indicate outliers.

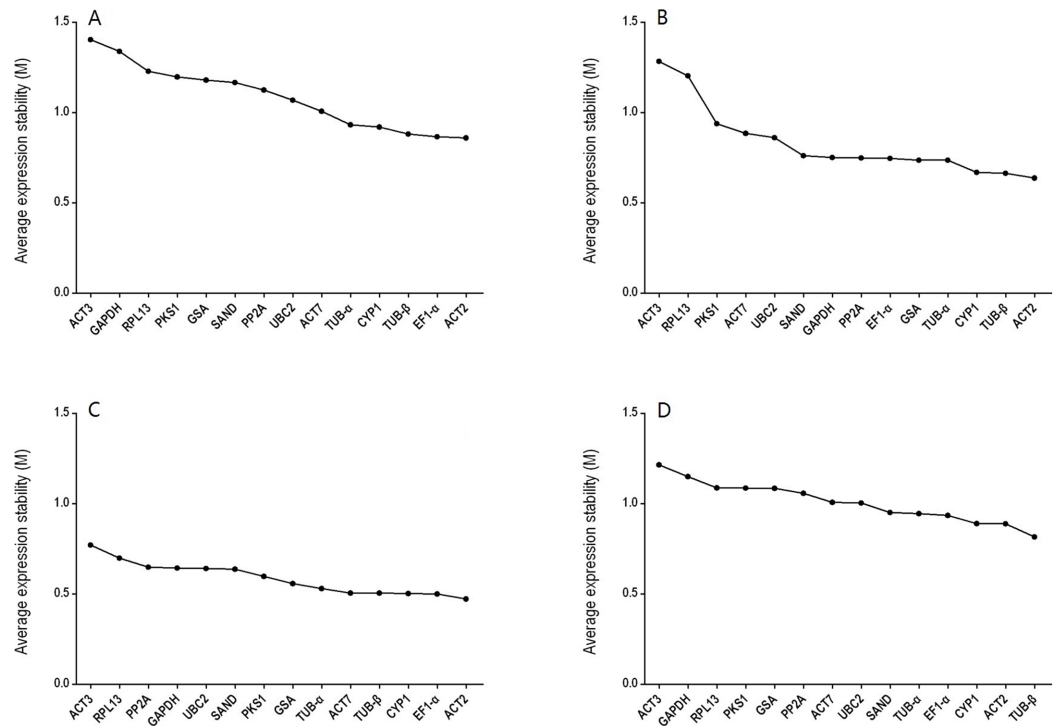

Full-size [DOI: 10.7717/peerj.7133/fig-1](https://doi.org/10.7717/peerj.7133/fig-1)

NormFinder. The stability order of the candidate genes calculated using NormFinder was nearly the same as that calculated using GeNorm, although there was a small difference. For example, *ACT2* was identified as the most stable reference gene in the TS group with the GeNorm analysis, while its stability rankings placed it third within the NormFinder analysis.

BestKeeper is another Excel-based program and is able to compare the expression levels of up to 10 target genes, each in up to 100 biological samples. The CV and SD values of the 14 candidate genes computed using BestKeeper are represented in Table 3. The smaller the SD and the CV values are, the better the stability of the internal reference genes. The expression of the reference gene was unstable when SD value is greater than one. The results revealed that *ACT2* was the most stable genes for the ST and TT samples, while *TUB-β* ranked first in the TS and SG samples.

### Reference gene validation

To test the reliability of the results, the relative expression patterns of the target gene *HpHYP1*, which belongs to the PR-10 family and is associated with stress control, were evaluated using different internal control genes in the roots, stems, leaves, and flowers. Based on the results of the present study, the top two stable genes (*ACT2* and *TUB-β*) and

**Figure 2** Average expression stability ( $M$ -value) of the 14 candidate reference genes calculated using GeNorm. (A) different tissues, (B) developmental stage seedlings, (C) stress-treated seedlings, and (D) data from all experimental groups combined. Lower average expression stability ( $M$ -value) indicates more stable expression. the most unstable gene (*ACT3*) were chosen as internal controls. As shown in Fig. 4, when normalized using *ACT2* as the reference genes, the transcript abundance of *HpHYP1* was upregulated compared with the results in the root samples. When *ACT2* and *TUB- $\beta$*  (as identified using GeNorm) were used as the internal references, the expression patterns

**Figure 4** Relative expression levels of *HpHYPI* in (R) root, (S) stem, (L) leaf, and (F) flower used for normalization using the most stable reference genes or a combination and the least stable genes. Error bars indicate the mean standard error calculated from three biological replicates. The statistical level was according to \* $P < 0.05$ , \*\* $P < 0.01$ , and \*\*\* $P < 0.001$ . [Full-size !\[\]\(1663bb69f307a960345edb0e712f8c02\_img.jpg\) DOI: 10.7717/peerj.7133/fig-4](https://doi.org/10.7717/peerj.7133/fig-4)

were similar to those obtain with *ACT2*. When normalization was based on *TUB-β* alone, the expression level of *HpHYPI* was still up-regulated. The only difference was that the expression level in stems was lower than that in leaves, although the difference was not significant. In general, when stable reference genes, including *ACT2*, *TUB-β*, and their combination, were used as internal parameters, *HpHYPI* had the highest expression level in flowers. When normalized using the less stable gene *ACT3*, the target genes in all tissues were expressed at lower levels but showed significantly up-regulation ( $P < 0.001$ ). Thus, the selection of inappropriate reference genes can lead to over- or under-estimation of the relative transcript level, which might lead to a biased result.

## DISCUSSION

The reliability of qRT-PCR data will be greatly improved by the inclusion of a reference gene with a transcription level that is invariable across different experimental conditions. Numerous published studies have verified some common reference genes, especially the HKGs, in many species, such as in *Arabidopsis thaliana* (Dekkers et al., 2012), *Salvia miltiorrhiza* (Espinosa et al., 2015), *Cucumis sativus* (Yi et al., 2004), *Gentiana macrophylla* (Aleksandar et al., 2004), and *Isatis indigotica* (Li et al., 2017). In *G. macrophylla* (He et al., 2016), *SAND1* and *EF1-α4* were found to be the most suitable overall; *GAPC2* and *SAND1* were identified as the best reference genes for the roots under abiotic stresses, while *SAND1* and *EF1-α4* were found to be the best for stressed leaves. For the tung tree, *ACT7*, *UBQ*, *GAPDH*, and *EF1-α* were the four optimal reference genes in all samples and developing seeds. *ACT7*, *EF1-β*, *GAPDH*, and *TEF1* were the top four candidate genes for different tissues. However, the appropriate reference genes for *H. perforatum* under different experimental conditions had not yet been identified, possibly because there is very limited genomic information for *H. perforatum* in the NCBI database. With the rapid development of whole-genome sequencing technology, deciphering the genomes of medicinal herbs is a vital step in understanding and improving their medicinal value. For that reason, we assembled the first high-quality sequence of the *H. perforatum* genome. Therefore, the reported literature on *H. perforatum* (Velada et al., 2014; Yao, 2011) combined with the obtained genomic data provided the foundation for selecting reference

genes. Additionally, the *HpHYP1* gene, belonging to the PR-10 family associated with stress control, was used for validation of the candidate reference genes.

Housekeeping genes like those that participated in cell structure maintenance (*ACT* and *TUB*) or basic cellular processes (*UBC* and *CYP*) remain widely applied, but their expression can vary between different types of tissue (normal and pathological samples) and under different treatment conditions (drugs and chemicals) (Thorrez et al., 2008; Robinson, Sutherland & Sutherland, 2007). Thus, normalization with multiple reference genes is becoming a popular and standard practice in plant research (Pfaffl et al., 2004). In this work, 14 reference genes were chosen, including nine traditional HKGs and five potential reference genes. We assessed the expression patterns of these genes in different tissues, in different developmental stages, and under various abiotic stress treatments to identify the most stable HKGs for qRT-PCR analyses. As shown in Fig. 2, no one gene had a constant CT value, demonstrating how important it is to identify the most suitable reference gene for normalizing expression under all detection conditions in *H. perforatum*.

The analytical procedures applied in our research based on statistical algorithms to assess the stability of reference genes are commonly used by researchers to select the best reference genes (Haller et al., 2004; Jarošová & Kundu, 2010; De Kok et al., 2005; Szabo et al., 2004; Vandesompele et al., 2002). The three algorithms produced different results for the ranking of the 14 candidate reference genes, indicating the importance of using multiple types of software to obtain the best results. Furthermore, a comparison of the results of different algorithms used to assess reference genes results in a better evaluation and reduces the risk of the artificial selection of co-regulated transcripts (Ayers et al., 2007). NormFinder and GeNorm use almost the same arithmetic, but GeNorm is used to determine not only the most stable reference genes but also the optimal number of gene combinations. In the present study, when the data were combined to determine the optimal number of reference genes, the pairwise variation of  $V_{2/3}$  values for all of the experimental sets was lower than the cut-off threshold of 0.15 except for the TT group (Fig. 4). Thus, these results indicate that the best combination (*ACT2* and *TUB-β*, or *ACT2* and *EF1-a*) should be used to improve the accuracy of the quantitative expression analysis of *H. perforatum*. For the TT group,  $V_{2/3}$  was higher than 0.15, which indicated that the top three reference genes (*ACT2*, *TUB-β*, and *CYP1*) were required for accurate normalization.

In our research, GeNorm and NormFinder produced similar rankings for stability values, while BestKeeper always produced different rankings. Specifically, *ACT2* was identified as the most stable gene for the SG and ST groups, and *TUB-β* was the most stable gene in the TT group according to NormFinder and GeNorm. The difference was that *TUB-β* was ranked first in the TS and SG groups and that *ACT2* was ranked first in the ST and TT groups by BestKeeper. *RPL13* was given a relative top ranking in all groups. In contrast, the expression stability value of *RPL13* according to GeNorm and NormFinder was very low. Other previous studies have also reported similar differences between BestKeeper and other methods (Rapacz, Stępień & Skorupa, 2012). This variation in the results may be explained by the difference in the algorithms implemented by the three software packages. Homologous genes are widely used as reference genes for gene

expression analysis. For example, *ACT6*, *ACT8*, and *ACT7* were selected as internal controls for stress treatments in *Fortunella crassifolia* (Pfaffl et al., 2004); *UBC19*, *UBC22*, and *UBC29* were selected as reference genes in the context of the relevant experimental conditions in *I. indigotica* (Li et al., 2017); and *EF1A2a*, *EF1A2b*, and *EF1A1a1* were identified as the best reference genes under all tested conditions in *Glycine max* (Raman et al., 2015). Nevertheless, as can be seen in our results, the three homologous genes (*ACT2*, *ACT3*, and *ACT7*) exhibited totally different expression levels when used for the normalization of qRT-PCR, especially *ACT2* and *ACT3* (Tables 2–3; Fig. 3). Therefore, although the paralogous genes have similar structures, their expression levels are entirely different in terms of gene expression quantification.

In summary, our results indicate that the selection of reference genes has a significant impact on the normalized gene expression data in qRT-PCR experiments. We investigated the expression of 14 candidate reference genes across a large number of *H. perforatum* samples to identify the most stable genes for normalizing gene expression. The results of this study will provide useful information for future genomics and transcriptomics studies on this valuable medicinal plant.

## CONCLUSION

Based on the gene stability analysis, we identified that *ACT2* and *TUB-β* were the most stable combination in different developmental stages samples and all of the experimental samples. *ACT2*, *TUB-β*, and *EF1-α* were considered to be the three most applicable reference genes in different tissues and stress-treated samples. In conclusion, the reference genes identified in this study provides basic background information for qRT-PCR studies in *H. perforatum*. It will contribute to accurate and consistent expression analysis for functional genomic research.

## ACKNOWLEDGEMENTS

We thank Prof. Eva Čellárová (Department of Genetics, Pavol Jozef Šafárik University in Košice) for donating the seeds of the diploid *H. perforatum*.

## ADDITIONAL INFORMATION AND DECLARATIONS

### Funding

This work was supported by the National Natural Science Foundation of China (31670299) and the Fundamental Research Funds for the Central Universities (1301031470, GK201806006). The funders had no role in study design, data collection and analysis, decision to publish, or preparation of the manuscript.

### Grant Disclosures

The following grant information was disclosed by the authors:

National Natural Science Foundation of China: 31670299.

Fundamental Research Funds for the Central Universities: 1301031470, GK201806006.

## Competing Interests

The authors declare that they have no competing interests.

## Author Contributions

- Wen Zhou conceived and designed the experiments, performed the experiments, analyzed the data, authored or reviewed drafts of the paper, approved the final draft.
- Shiqiang Wang conceived and designed the experiments, analyzed the data.
- Lei Yang performed the experiments, contributed reagents/materials/analysis tools.
- Yan Sun performed the experiments, contributed reagents/materials/analysis tools.
- Qian Zhang performed the experiments, contributed reagents/materials/analysis tools.
- Bin Li analyzed the data, authored or reviewed drafts of the paper.
- Bin Wang analyzed the data.
- Lin Li contributed reagents/materials/analysis tools, prepared figures and/or tables.
- Donghao Wang prepared figures and/or tables.
- Zhezhi Wang conceived and designed the experiments, authored or reviewed drafts of the paper, approved the final draft.

## DNA Deposition

The following information was supplied regarding the deposition of DNA sequences:

The reference genes of *Hypericum perforatum* sequences described here are accessible via GenBank accession numbers [MK054303](#), [MK106356–MK106365](#).

## Data Availability

The following information was supplied regarding data availability:

The raw data are available in [Tables S3](#) and [S4](#). The raw data shows the average Ct values,  $2^{(-\Delta Ct)}$  values, and *M*-values of 14 candidate reference genes of *Hypericum perforatum* in all samples.

## Supplemental Information

Supplemental information for this article can be found online at <http://dx.doi.org/10.7717/peerj.7133#supplemental-information>.
