Ontogenetic sequences are relatively rare among dinosaurs, with Ceratopsia being one of the better represented clades, and especially among geologically earlier forms, such as *Psittacosaurus*. *Psittacosaurus* is a small, bipedal basal ceratopsian abundant in the Lower Cretaceous deposits of Asia, whose cranial and endocranial morphology has been well studied, but only cursory details have been published on the bones surrounding the brain. Using reconstructions created from micro-computed tomography (μ CT) scans of well-preserved skulls from the Barremian–Aptian Yixian Formation, China, we document morphological changes in the braincase of *Psittacosaurus lujiatunensis* through three growth stages, hatchling, juvenile, and adult, thus providing the first detailed study of ceratopsian braincase morphology through ontogeny. Notable ontogenetic changes in the braincase of *P. lujiatunensis* include a dramatic relative reduction in size of the supraoccipital, an increase in the lateral expansion of the paroccipital processes and a decrease in the angle between the lateral semicircular canal and the palatal plane. These ontogenetic morphological changes in the braincase relate to expansion of the cranium and brain through growth, as well as reflecting the switch from quadrupedal juveniles to bipedal adults as documented in the changing orientation of the horizontal semicircular canal through ontogeny. Recognition of these patterns in a basal ceratopsian has implications for understanding key events in later ceratopsian evolution, such as the development of the parieto-squamosal frill in derived neoceratopsians.

**ONTOGENETIC BRAINCASE DEVELOPMENT IN *PSITTACOSAURUS*
LUJIATUNENSIS (DINOSAURIA: CERATOPSIA) USING MICRO-
COMPUTED TOMOGRAPHY**

Abstract

Ontogenetic sequences are relatively rare among dinosaurs, with Ceratopsia being one of the better represented clades, and especially among geologically earlier forms, such as *Psittacosaurus*. *Psittacosaurus* is a small, bipedal basal ceratopsian abundant in the Lower Cretaceous deposits of Asia, whose cranial and endocranial morphology has been well studied, but only cursory details have been published on the bones surrounding the brain. Using reconstructions created from micro-computed tomography (μ CT) scans of well-preserved skulls from the Barremian–Aptian Yixian Formation, China, we document morphological changes in the braincase of *Psittacosaurus lujiatunensis* through three growth stages, hatchling, juvenile, and adult, thus providing the first detailed study of ceratopsian braincase morphology through ontogeny. Notable ontogenetic changes in the braincase of *P. lujiatunensis* include a dramatic relative reduction in size of the supraoccipital, an increase in the lateral expansion of the paroccipital processes and a decrease in the angle between the lateral semicircular canal and the palatal plane. These ontogenetic morphological changes in the braincase relate to expansion of the cranium and brain through growth, as well as reflecting the switch from quadrupedal juveniles to bipedal adults as documented in the changing orientation of the horizontal semicircular canal through ontogeny. Recognition of these patterns in a basal ceratopsian has implications for understanding key events in later ceratopsian evolution, such as the development of the parieto-squamosal frill in derived neoceratopsians.

Introduction

Psittacosaurus is an Early Cretaceous genus of Ceratopsia, a diverse and geographically widespread suborder of ornithischian dinosaurs (Dodson et al., 2004; Chinnery-Allgeier & Kirkland, 2010; Dodson, 2013). Their position within ceratopsian phylogeny has been debated, from being basalmost (e.g., Sereno, 2000; Morschhauser, 2012; Han et al., 2017), to more derived than *Yinlong* and chaoyangsaurids (e.g., Xu et al., 2006; He et al., 2015; Zheng et al., 2015). Recent work by Han et al. (2015, 2016, 2017) has suggested a close relationship with chaoyangsaurids. Chaoyangsauridae is a family of basal ceratopsian dinosaurs, that is either sister to Neoceratopsia (e.g., Xu et al., 2002; Han et al., 2018) or its most basal member (e.g., Sereno, 2000; You & Dodson, 2003).

Ceratopsia underwent a shift from bipedalism to quadrupedalism during their evolution (Weishampel et al. 2004; Xu et al., 2006). Conversely, *Psittacosaurus* underwent a significant postural shift during ontogeny, as quadrupedal hatchlings developed into facultative bipeds during growth. Evidence for the postural shift comes from allometric studies of limb ratios and histology (Zhao et al., 2013, 2014). Skeletal evidence shows relative shortening of the forelimbs during growth, and histological evidence shows relative slowing of growth of the forelimbs and increasing growth rates for hindlimb elements (femur, tibia) when they reached maturity, at an age of approximately 4 years (Zhao et al., 2013). *P. mongoliensis*, *P. sibiricus* and *P. lujiatunensis* are the largest species of *Psittacosaurus*, all three reaching up to 2 m in length. *P. lujiatunensis* is prevalent in the Early Cretaceous Lujiatun deposits of the Yixian Formation in Liaoning Province of China. Hedrick & Dodson (2013) posited that three species of Lujiatun *Psittacosaurus* (*Hongshanosaurus houi*, *Psittacosaurus lujiatunensis* and *Psittacosaurus major*) are synonymous and represent different taphomorphotypes rather than individual species. Here,

we accept their results and follow their taxonomic assignments. Associated volcanic beds have provided radioisotopic dates for the Lujiatun volcanoclastic sediments of approximately 126 Ma (Chang et al., 2017). The fossiliferous layers exhibit evidence of rapid burial due to volcanic activity (Rogers et al., 2015) and subsequent exceptional preservation.

The integration of advanced computed tomography (CT) techniques into palaeontological studies has enabled extensive, in-depth morphological reviews and non-destructive investigations into both extinct and extant taxa (e.g., Chapelle & Choiniere, 2018; Hoffman et al., 2018; Neenan & Scheyer, 2012; Walsh & Knoll, 2018). While several studies have touched upon the braincase of *Psittacosaurus* (Coombs, 1982; Zhou et al., 2007; Dodson et al., 2010; Sereno, 2010), few have used CT data to explore internal structures (Zhou et al., 2007).

Here we describe three braincases, each belonging to individuals of *P. lujiatunensis* at different ontogenetic stages. Using the methodology of Zhao et al. (2014), we determined the approximate ages of these specimens from their base skull lengths. Using sutural fusion as a proxy for age is ambiguous at best and varies in different taxa and skeletal location (Brown & Schlaikjer, 1940; Scannella & Horner, 2011; Longrich & Field, 2012; Bailleul et al., 2016). When used in conjunction with other techniques, however, sutural fusion has been accepted as a rough proxy for determining age in some vertebrates (Brochu, 1996; Sampson et al., 1997), and we follow this principle of using combined evidence.

Materials and Methods

The smallest skull (IVPP V15451) belongs to a hatchling under one year old, as determined by its size, lack of fusion, and partial disarticulation within the braincase (Fig. 1). The second specimen (IVPP V22647) is fully articulated and well fused (Fig. 1). The level of fusion present

and the size of the specimen indicates an age of approximately two years. The largest skull (IVPP V12617) is a fully fused mature *Psittacosaurus*, determined to be 10 years old at the time of death, based on the lines of arrested growth (Zhao et al., 2013) (Fig. 1).

Specimens were scanned using the CAS (Chinese Academy of Sciences) μ CT scanner at the Institute of Vertebrate Palaeontology and Palaeoanthropology (IVPP), Beijing. Avizo 8 (Visualization Science Group) was used to virtually reconstruct and segment the braincase into 3D models. The hatchling skull was partially disarticulated, and so segmentation was relatively quick and straightforward, but both older specimens were well fused in comparison. Using structures such as semicircular canals, cranial nerve pathways, arteries, and undulations on the bone surface, we were able to divide both braincases into their constituent elements. Measurements of individual bones were taken in Avizo and the angles between the plane of the lateral semicircular canal and the palatal plane were calculated following the method in Schellhorn (2018).

Hatchling braincase description

The relatively undeformed skull of the hatchling *Psittacosaurus* (IVPP V15451) is compact and rounded in comparison to the older specimens (Fig. 1). It is complete except for the nasals,

prefrontals and orbitosphenoids. It measures 23.6 mm long (rostral to occipital condyle (OC)) by 15.5 mm tall (basipterygoid processes to frontal-parietal contact).

The **foramen magnum** (FM) is circular (Fig. 2D). Approximately 70% of the wall of the FM is made up by the exoccipitals (lateral walls), the rest is an equal measure of supraoccipital dorsally and basioccipital ventrally.

The **basioccipital** (BO) contacts the basisphenoid anteriorly and the exoccipitals laterodorsally (Fig. 3D). It measures 5.4 mm anteroposteriorly by 5.8 mm transversely across its widest point. It forms the posterior floor of the braincase and contributes to the majority of the basal tubera (Fig. 2A: bo) with the basisphenoid contributing to the anteroventral-most regions. The basal tubera hang 1.2 mm below the occipital condyle and are separated by a pronounced medial groove (Fig. 3C, 3E and 3F). Their apices are rounded, blunt and the orientation of the long axis of the tubera is in the sagittal plane (Fig. 3C: bt).

The occipital condyle is anteroposteriorly compressed resulting in an oval appearance in dorsal and ventral views (Fig. 3C), with a shallow dorsal depression for the entry of the spinal cord (Fig. 3E). It measures 3 mm wide by 2 mm high. The basioccipital makes up the entirety of the occipital condyle with the exoccipitals resting on either side of the FM depression (Fig. 2D: eoas). There is no dorsal restriction of the condylar neck and little lateral constriction. The condylar neck is ventrally constricted, with its maximum constriction occurring proximal to the condyle making it dorsoventrally compressed and relatively thin in lateral view (Figs. 2B and 3A).

The flat dorsal surface of the basioccipital is anteriorly inclined and slopes away from the notch formed by its contribution to the foramen magnum. Two ridges extend anterolaterally from the

opening of the FM to a plateau that lies on the dorsal surface of the basal tubera. The exoccipital articular surfaces are lateral to these ridges (Fig. 3D: eoas). The basioccipital of the hatchling specimen only contributes to approximately 15% of the foramen magnum, but comprises the entire occipital condyle (Fig. 2D).

The basisphenoid contacts the prootic dorsally and the basioccipital posteriorly, but is indistinguishable from the parasphenoid even at this early stage of ontogeny. This **basisphenoid-parasphenoid complex** (BPC) is complete and well preserved comprising the anterior floor of the braincase (Fig. 2B: bs). It measures 10.3 mm long (without the contribution to the basal tubera). The most prominent features of the complex are the four processes that radiate from the corners of the cuboid basisphenoid body, the basal tubera and the basipterygoid processes. The basipterygoid processes project anterolaterally, diverge at an angle of approximately 81° and measure approximately 3 mm in length. The anterior tips of the basipterygoid processes are flared and flattened to articulate with the pterygoids (Fig. 4F: ptas). The ventral surface of the basisphenoid is concave. The troughed cultriform process of the parasphenoid extends anteriorly from the basisphenoid, passing beyond the distal-most surface of the basipterygoid processes (Fig. 4: cp, bpp). It measures 7 mm, approximately $2/3$ of the total length of the parabasisphenoid. Note that for the purposes of these descriptions, the “troughs” that separate the cultriform process from the basipterygoid processes will be called the paracultriform troughs (Fig. 4D: pct). The paracultriform troughs in the juvenile specimen are gentle and rounded. The furrow that separates the basal tubera continues anteriorly and separates the basipterygoid processes.

The sella turcica (pituitary fossa) is a deep depression in the anterodorsal surface of the basisphenoid which would have held the pituitary gland (Fig. 4D: st). It is triangular when

viewed dorsally. This fossa continues to the cerebral carotid artery canal which then divides into two circular carotid foramen which exit the basisphenoid laterally, ventral to the prootics. The ridges on either side of the trough of the cultriform process meet anterior to the sella turcica which is separated from the former by a large laterally compressed midline blade extending down the cultriform process. The basisphenoid meets the basioccipital posterodorsally at the basal tubera (Fig. 2B). The contribution of the basisphenoid to the basal tubera consists of thin, posteriorly projecting, plate-like extensions ventral to the main bulk of the tubera (approximately 20% of the tubera). A well pronounced, smooth, flattened ridge dominates the posterodorsal surface of the basisphenoid and forms the contact surface for the prootic (Figs. 4A, 4B, 4D and 4E: pras). This slightly anteriorly inclined platform extends laterally and anteriorly bordering the posterolateral edges of the sella turcica.

The sub-oval, plate-like **supraoccipital** dominates the occipital surface and tapers dorsally in thickness (Fig. 2D: so). It measures 8.7 mm wide by 3.6 mm tall. The dorsal margin of the supraoccipital articulates with the posterior most edge of the parietals, whilst the ventral border contacts the paroccipital processes. The boundaries with the paroccipital processes are poorly defined; however, the thin (<1 mm) supraoccipital flares lateroventrally to 2.4 mm to meet them (Fig. 5C: eoas). The supraoccipital contributes approximately 20% of the dorsal wall of the foramen magnum. In caudal view, a V-shaped notch approximately one-fifth the depth of the supraoccipital is present at the mid-point of the dorsal margin. (Fig. 5E). A low midline ridge extends from the base of the notch to the ventral margin (Fig. 5E: somr). The anterior surface is concave where the hindbrain would have sat (Figs 5C, 5D and 5F). The posterior semicircular canal traverses through the lateral wings of the supraoccipital (Fig. 5F: sccp).

The **paroccipital processes** make up most of the lateroposterior surface of the braincase (Fig. 2D: pp) and are composed of exoccipitals and opisthotics which are so well fused that their suture is obliterated. The processes contact the supraoccipital dorsally, the prootic anteriorly and the basioccipital ventrally; there is also a small area of contact with the parietal lateral to the supraoccipital contact. The anterior boundary of the paroccipital processes can only be inferred due to high levels of fusion in this region. The paroccipital processes of the hatchling specimen are stunted and subrectangular. A single paroccipital process has a length of 6.2 mm and a height of 2.8 mm giving a height/length ratio of almost 1:2. Cranial nerve pathways X-XII pass through the exoccipitals, exiting posterolaterally underneath the processes. They are visible when the braincase is viewed posteriorly. The exoccipital-opisthotic complex of the hatchling does not contribute to the occipital condyle, but does contribute approximately 70% of the wall of the FM (Figs. 2D and 6E). A trunk of the exoccipital extends medioventrally from the FM to contact the basioccipital at the top of the occipital condyle (Fig. 6D). The exoccipitals house a section of the semicircular canals. Dorsal to the paroccipital processes are unpaired foramina which most likely allowed for the passage of the *vena capitis dorsalis* (Fig. 6D: vcd?).

The **laterosphenoid** articulates with the prootic posteriorly, the parietal posterodorsally and the frontal anterodorsally. It measures 5.2 mm by 4.2 mm and is blocky and triangular in lateral view. It has a flared ‘wishbone’ shape in cross section (Fig. 7C). The laterosphenoid sits anterodorsally to the prootic and contributes to the anterolateral wall of the braincase (Fig. 2A: ls). The laterosphenoid at this stage in growth appears very fragile and thin. The medial surface of the laterosphenoid is concave and flares posteriorly resulting in a triangular appearance. The lateral surface of the laterosphenoid is convex and comes to a central point called the

laterosphenoid head (Figs. 7A and 7B: lsh). The laterosphenoid makes up the dorsal boundary of the foramina for cranial nerve V (trigeminal nerve).

The **prootic** of *Psittacosaurus* is a complex element that forms much of the lateral braincase wall and houses the majority of the inner ear. The prootic contacts the paroccipital processes posteriorly, the laterosphenoid anteriorly, and the basisphenoid ventrally (Fig. 2A: pr). It measures 7.1 mm dorsoventrally and 3.9 mm mediolaterally. It is sub-triangular when viewed dorsally. It is morphologically similar to the prootic of the perinatal *Alligator mississippiensis* reconstructed in Dufeu & Witmer (2015). A large notch for cranial nerve V can be seen on the anterior surface of the prootic, but it is not entirely enclosed by the prootic (Figs. 8A-8D: cranial nerve, CN V). A prominent median ridge extends down the medial surface of the prootic (Fig. 8D: prmr). Anterior to this ridge lies a concavity spanning the entire height of the prootic. Within this anterior concavity and posterior to the trigeminal foramen lies the foramen for CN VII (facial nerve) (Figs. 8A-8D). Posterior to this median ridge lies the space for the cochlear duct and vestibule of the inner ear. The pathway of the anterior semicircular canal can be seen extending anteroposteriorly across the dorsal edge of the prootic when viewed dorsally (Fig. 8F: sccp). This section of the canals is loosely held within the prootic and is not entirely enclosed within the bone.

The **parietal** is contacted by the frontal anteriorly, the laterosphenoid anteroventrally, the supraoccipital posteroventrally and the squamosals posterolaterally. It is located on the posterodorsal surface of the braincase and comprises approximately half of the dorsal surface of the braincase (Fig. 2C: pa). It measures 7.4 mm anteroposteriorly and 14.1 mm across its widest point. The posterior edge of the parietal is an inverted 'V' shape in cross section, whilst the anterior is convex (Fig. 9). The ventral surface of the parietal is deeply concave which is

mirrored in the convex dorsal surface continuing the rounded dome-like skull roof that originates from the frontal. The hatchling parietal lacks a sagittal ridge. The upper temporal fenestra forms rounded indentations in the lateral margins of the parietal and a process extends posteroventrally to contact the squamosals.

Frontal contacts include the parietal posteriorly, the nasal anteriorly, the laterosphenoid posteroventrally and the postorbital posterolaterally (Fig. 10: paas, nas, lsas, poas). The prefrontals would also have contacted the frontal, but there is no indication of where this contact lies. The frontals measure 11.2 mm anteroposteriorly and 15.8 mm transversely across their widest point. The frontals of the hatchling exhibit extreme dorsal doming which contributes greatly to the overall roundness of the skull (Fig. 2). Two deep rounded concavities are present on the ventral side of these elements, which is the location of the cerebral hemispheres (Fig. 10C: cc). They measure 11.1 mm across their widest point. The hourglass indentation that marks the anterior regions of the brain is anterior to these bulbous depressions. The interfrontal suture cannot be discerned and there is no crest present on the dorsal surface of the frontal. The frontal is anteriorly transversely thin and widens posteriorly, the widest point being posterior to the orbits. Dorsally, two small (0.6 mm) epiossifications lie symmetrically either side of the midline – this is the first time these structures have been observed in Ceratopsia. The frontal contributes to the dorsal edge of the large eye socket. The eye socket creates a rounded concave border on the anterolateral edges of the frontal where a ventral lip is present (Figs. 10A and 10B: om). The supra-orbital wall is orientated in a sagittal plane, meaning that the wall is fully visible laterally. In dorsal and ventral views, the orbits cut concavities into the anterolateral sides of the frontals.

Juvenile (2-year old) braincase description

237 The juvenile specimen (IVPP V22647) proved difficult to segment due to poor preservation and
238 obliterated sutures.

239 The skull has undergone uniaxial dorsoventral compression giving it a blocky appearance with
240 an extremely flattened skull roof (Fig. 1C). The lack of a rostral also means that it appears
241 rectangular in lateral view. Unlike the other specimens, the occipital surface of the juvenile is
242 orientated posteriorly with no ventral inclination. It measures 76 mm (rostral - OC) by 30 mm
243 (basipterygoid processes – frontal).

244 The **foramen magnum** is oval, with a flattened dorsal margin (Fig. 11D). Whether this is due to
245 the taphonomic deformation is unclear. The foramen magnum is made up of 50% exoccipitals
246 (laterally), approximately 35% supraoccipital (dorsally) and 15% basioccipital (ventrally).

247 The **basioccipital** contacts of the juvenile include the basisphenoid anteriorly and the
248 paroccipital processes posterodorsally. As in the hatchling, the basioccipital forms the posterior
249 half of the braincase floor. It measures 14 mm anteroposteriorly and 16.6 mm across its widest
250 point. The basal tubera are poorly preserved compared to those of the hatchling and adult
251 specimens. The tubera are approximately 5 mm long and are separated by what appears to be a
252 very shallow medial groove (Fig. 12E: btg), but the depth of this feature may be the product of
253 the taphonomic deformation and compression. Ventrally, the tubera have a loose, rounded L
254 shape and no strong orientation (Fig. 12C: bt). Posteriorly, they are dorsoventrally compressed
255 and ventrally extend no further than the OC (Figs. 11D, 12A, 12B and 12E).

256 The occipital condyle of the juvenile *Psittacosaurus* specimen is dorsoventrally flattened and,
257 like the hatchling, is made up entirely of the basioccipital (Fig. 11D: bo). Whether this
258 compression is due to post-mortem deformation or was present in vivo is not clear. As both the

FM and OC are oval in the juvenile specimen and round in the other two specimens, the former is most probable. The OC measures 7.7 mm wide by 5.4 mm tall. There is a well pronounced condylar neck which exhibits ventral constriction. Similar to the OC of the hatchling, the neck restricts proximal to the condyle making it anterodorsally compressed and relatively thin in lateral view (Fig. 12: cdn).

A shallow groove on the dorsal surface of the basioccipital marks the ventral-most margin of the foramen magnum (Fig. 11D). Because the braincase is fused, the dorsal surface of the basioccipital is hard to distinguish. However, it is clear that the majority of the dorsal surface of the basioccipital is taken up by contact points for the two exoccipitals (Fig 12D: eoas). The basioccipital seems to taper ventrolaterally at these surfaces, meaning it appears triangular when viewed posteriorly or anteriorly (Figs. 12E and 12F). The basioccipital constitutes 60% of the basal tubera, with the basisphenoid contributing approximately 20% more than it did in the hatchling.

The **basisphenoid** contacts the prootic dorsally and the basioccipital posteriorly. The pterygoid articular surface sits on the anterior-most surface of the basipterygoid processes (Fig. 13F: ptas). The basisphenoid-parasphenoid complex measures 30.8 mm anteroposteriorly by 20 mm across the widest point of the basipterygoid processes. As with the hatchling, the boundary between the basisphenoid and parasphenoid of the juvenile is completely obscured by extreme sutural fusion. The basipterygoid processes project anterolaterally from the main body of the basisphenoid and diverge at an angle of approximately 70°. They measure approximately 8.7 mm in length and expand distally. The juvenile parasphenoid is complete and the cultriform process exhibits minimal deformation (Fig. 13: cp). The cultriform process is long, thin and troughed. It measures 23 mm in length and, as in the hatchling, it contributes to approximately two-thirds of the total

parabasisphenoid length. The paracultriform troughs are more angled and abrupt than the curving troughs of the hatchling (Fig. 13: pct). The sella turcica sits on the dorsal surface of the parabasisphenoid, posterior to the cultriform process (Fig. 13D: st). It is oval when viewed dorsally. The carotid foramina lie lateroventrally to the sella turcica (Figs. 13A and 13B: cfo). The basisphenoid contributes to a larger proportion of the basal tubera (approximately 45%) than in the hatchling specimen, although the location of the boundary remains the same.

The **supraoccipital** of the juvenile contacts the exoccipitals dorsolaterally and the parietal dorsally. It measures 9.8 mm at its widest point (ventral margin). The boundaries of the supraoccipital are inferred as they were unclear, making it hard to segment. It is anteroposteriorly triangular in shape (Fig. 14). The supraoccipital contributes to the dorsal portion (approximately 25%) of the foramen magnum (Fig 11D: so). The supraoccipital lies at the midpoint between the adult's thin, rod-like supraoccipital and the relatively large, plate-like supraoccipital that contributes to much of the posterior surface of the hatchling's skull. The posterior semicircular canals are situated in the paroccipital processes rather than the supraoccipital as in the hatchling.

The **paroccipital process** contacts the basioccipital ventrally, the supraoccipital medially, the parietal dorsally and the prootic anteriorly. Most of the paroccipital processes are missing and fractured. Only the medial-most section of paroccipitals remains (Fig. 15: pop). A length to width ratio for the processes cannot be calculated as they are so incomplete. The exoccipitals make up approximately two thirds of the foramen magnum (Fig. 11D). Cranial nerve exits X-XII are located high up just below the lateral expansion of the exoccipitals which is similar to the hatchling. The location of the exit of the *vena capitis dorsalis* from the paroccipital processes is unclear due to poor preservation. A section of the posterior semicircular canal sits within the paroccipital.

The **laterosphenoid** of the juvenile contacts the prootic posteriorly, the parietal posterodorsally and the frontal anterodorsally. It measures 15.4 mm anteroposteriorly and has a width of 6.8 mm. It is morphologically very similar to the hatchling, differing only in being anteroposteriorly elongated. It is flared and triangular in cross section near the posterior boundary (Fig. 16). The laterosphenoid head is located anteriorly and is dorsoventrally flattened in comparison to the blocky central head of the hatchling (Fig. 16A: lsh). A process extends down from the laterosphenoid creating the anterodorsal corner of the exit for CN V.

The **prootic** contacts the paroccipital process posteriorly, the parietal posterodorsally, the laterosphenoid anteriorly, and the basisphenoid ventrally. The boundaries between the prootics, paroccipital processes and the parietal were difficult to infer. They measure 12.8 mm in height, assuming that the parietal-prootic contact is roughly correct. The prootics create the posterior and ventral walls of CN V with the preprootic strut making up the anterior margin (Fig. 17: pps). Posterior to the notch for CN V the prootic thickens and a series of anteroposterior ridges extend across the medial surface. The median ridge seen in the hatchling specimen does not appear to be so prominent in the juvenile. CN VII exits through the prootic posterior to this thickened strut (Figs. 17C and 17D). There is also a second opening next to CN VII which extends into the inner ear. On the lateral surface of the prootic there is a ‘V’ shaped ridge extending anteroposteriorly.

The **parietal** is contacted anteriorly by the frontals, anteroventrally by the laterosphenoids, lateroventrally by the prootics, posterolaterally by the squamosals and posteroventrally by the supraoccipital. It also contacts the parietal posteroventrally, but this cannot be seen because of damage and poor preservation. The contacts between the parietal, paroccipital processes and the prootics are inferred due to damage and deformation. It measures 16.3 mm anteroposteriorly and approximately 25 mm across the anterior-most margin. It is flattened, and a shallow sagittal crest

has formed (Fig. 18D: sc). The apparent flatness is likely due to either taphonomic deformation or the early stage in development. Although the posterior portion of the parietal is broken and damaged, a small parietal shelf can be inferred (Fig. 18: ps?). The upper temporal fenestrae create concavities in the lateral margins of the parietal. The parietal borders the posterior margin of the upper temporal fenestra where they meet the squamosal distally.

The **frontal** contacts the parietal posteriorly, the nasal anteriorly, the laterosphenoid posteroventrally, the postorbital posterolaterally and the prefrontal anterolaterally, marked by a notch (Fig. 19D: no). The frontals measure 30.6 mm anterodorsally and 36.5 mm transversely across the widest point. Unlike those of the hatchling, the juvenile's frontals are flattened, with only the anterior section of the cerebral concavities being present on the ventral surface (Fig. 18C: cc). The frontal of the juvenile is sub-triangular, flaring posteriorly, with the widest point being the contact with the postorbital (Fig. 19D: poas). The hourglass shape of the anterior region of the brain is preserved on the ventral surface of the frontal. The margin between the brain cavity and the orbits is well defined. The small frontal ossicles that were present on the hatchling specimen are no longer evident. A shallow frontal crest extends medially down the dorsal surface, where the two frontals meet in the sagittal suture. Laterally and parallel to this crest are two shallow ridges, although whether these are a product of taphonomic deformation is unclear. The orbits occupy shallow lateral concavities into the ventral surface of the frontal (Fig. 19: om).

Adult braincase description

The specimen IVPP V12617 was approximately 10 years old at the time of death (Zhao et al., 2013). It was previously referred to *Hongshanosaurus houi* but that taxon is synonymized by most with *Psittacosaurus lujiatunensis* (Serenio, 2010; Hedrick & Dodson, 2013).

The cranium has a rounded anterodorsal surface, with a domed skull roof (Fig. 1E). It measures 146 mm in length (OC- rostral) by 60 mm in height. The skull has undergone some dorsoventral compression (Hedrick & Dodson, 2013), but the occipital condyle appears to have been comparatively unaffected by dorsoventral deformation and so we take the braincase to be negligibly deformed. The occipital surface of the skull is orientated posteroventrally, as is the case in the hatchling, but this orientation may be a result of the compression.

The circular **foramen magnum** is made up of the exoccipitals laterally (60%), supraoccipital dorsally (10%) and basioccipital ventrally (30%) (Fig. 20D).

The **basioccipital** contacts the basisphenoid anteriorly and the exoccipitals laterodorsally. It is complete, with minimal to no deformation. The element measures 26.4 mm anteroposteriorly and 32 mm across its widest point. The basioccipital takes up approximately 30% of the margin of the foramen magnum, which is double that of the younger specimens. The posterior portion of the basioccipital forms the occipital condyle and the anterior section contributes to the basal tubera. The basioccipital contributes to approximately 50% of the basal tubera, with the basisphenoids making up the other half. The basal tubera are dorsoventrally and mediolaterally larger than the OC which differs from those of the hatchling which are approximately half the size of the condyle. The distinct groove separating the basal tubera is smaller and shallower relative to the main body of the basioccipital than those in the hatchling (Fig. 21E: btg). The basal tubera are anteroposteriorly flattened and are orientated mediolaterally (Fig. 21C: bt). The basioccipital is deeper than those of the younger individuals.

The occipital condyle is heart-shaped (Fig. 20D: boc) because the foramen magnum indents the dorsal margin. It is composed entirely of the basioccipital, as is the case with the younger specimens described here. The basioccipital-exoccipital contact was very well fused and so some sections were inferred. The basioccipital-exoccipital contact is higher up and closer to the flaring processes than in the younger specimens (Fig. 20D). This means that the basioccipital contributes to the base of the paroccipital processes, although cranial nerves X–XII still exit from the base of the exoccipitals. The occipital condyle measures approximately 14.3 mm wide by 11.9 mm deep. When viewed ventrally, the occipital condyle is triangular (Fig. 20B). Similar to the condylar neck of the hatchling and juvenile, there is some ventral constriction. This mature specimen differs from those in that the point of greatest constriction occurs closer to the basal tubera than to the occipital condyle.

The ventral margin of the foramen magnum is inscribed deeper into the dorsal surface of the basioccipital than in the younger specimens (Fig. 21D: ng) and widens anteriorly over the tubera. The dorsal surface of the basioccipital is triangular in outline. The contact separating the basioccipital and basisphenoid is visible as a transverse groove extending across the basal tubera (Figs. 20A and 20B).

The **basisphenoid-parasphenoid complex** of the adult contacts the prootic dorsally and the basioccipital posteriorly (Fig. 20). It measures approximately 24 mm anteroposteriorly and 35.9 mm across the basipterygoid processes. The basisphenoid is well preserved but, as with the other specimens, cannot be differentiated from the parasphenoid due to sutural fusion. It is a dorsoventrally deeper and more robust element than in the younger individuals. The basipterygoid processes measure approximately 14.3 mm in length and are ventrally projected compared to those of the younger individuals (Fig. 22: bpp). They diverge at an angle of

approximately 44° making the paracultriform troughs thin and angular. The distal expansion of the basiptyergoid processes is more extreme in IVPP V12617. The cultriform process is broken and incomplete, and only the tall, thin and blade-like portion, which is also present in the hatchling, is preserved (Fig. 22: cp). No prominent trough appears along the dorsal surface of the process as it does in the hatchling and juvenile specimens, but it may not be preserved due to damage. The sella turcica differs from those of the younger specimens in being more compact and sub-diamond in shape (Fig. 22D: st). This leads on to the cerebral carotid artery canal (Figs. 22A and 22B: cfo). These carotid foramina are positioned anteriorly compared to the younger specimens.

The **supraoccipital** contacts the parietal anteriorly and the paroccipitals ventrolaterally; but, it should be noted that the fused and obscured sutures make the exact points of contact difficult to determine. It measures 12.3 mm dorsoventrally and, at 6.8 mm wide, is the thinnest supraoccipital in this study. It only contributes to approximately 10% of the foramen magnum (Fig. 20D: so), a much smaller proportion than in the younger skulls. The supraoccipital appears extremely reduced, forming a small rod-like nuchal crest dorsal to the foramen magnum (Fig. 23). The dorsal extension of the supraoccipital forms a ridge that extends dorsally from the foramen magnum to the ventral edge of the parietal. Unlike the supraoccipital of younger specimens, it appears that it does not sit in contact with the hindbrain. The semicircular canals do not invade the supraoccipital.

The **paroccipitals** contact the basisphenoid ventrally, prootic anteriorly, parietal dorsally and supraoccipital mediodorsally. Distally, the paroccipital processes support the squamosals and contact the quadrate. These processes flare out from the foramen magnum in a pair of wing-like processes that expand laterally into large tabs (Fig. 20: pp). They measure 59.3 mm in length by

19.6 mm in height giving a ratio of nearly 1:3. The processes are anteroposteriorly compressed (Fig. 24). When viewed dorsally, the pair has a concave posterior surface (Fig. 24E and 24F) as the distal portions extend posterolaterally. Cranial nerves X-XII exit medioventrally through the exoccipitals and, unlike in the hatchling, are not visible posteriorly. Unfortunately, these foramina are hard to distinguish and, as a result, only two can be seen. These foramina are positioned more laterally, slightly lower, and further from the lateral expansion of the paroccipital processes than in the younger specimens. Semicircular canal foramina can be seen on the anterior surface (Fig. 24H). The exoccipitals make up approximately 60% of the foramen magnum margin.

The **laterosphenoid** contacts the prootic posteroventrally, the frontal anterodorsally and the orbitosphenoid anteromedially. The laterosphenoids of the adult are robust and nearly triangular in cross section (Fig. 25). They measure 25.9 mm anteroposteriorly and 14.5 mm wide anteriorly. Like those of the juvenile, the laterosphenoid is posteroanteriorly elongated, and the head is dorsoventrally flattened and located on the anterior surface (Figs 25A and 25B: lsh). The laterosphenoid is concave medially and convex laterally. In lateral and medial views, it appears to taper anteriorly (Figs. 25A and 25B), but when viewed anteriorly it appears to taper posteriorly (Figs. 25E and 25F). The laterosphenoid only contributes to the dorsal-most margin of the anterolaterally oriented foramen for CN V.

The thin posterior margin of the **orbitosphenoid** forms the articular surface for the laterosphenoid (Fig. 26: lsas). The orbitosphenoid measures approximately 27 mm dorsoventrally. This left orbitosphenoid is the only example preserved in our specimens. It is mediolaterally thin and delicate in this mature specimen making it understandable why this

element is rarely preserved in smaller individuals. The optic nerve exits medially where it inscribes a concavity in the orbitosphenoid (Fig. 26).

The boundaries of the **prootics** are difficult to distinguish, particularly the dorsal-most contacts.

Inferred contacts include the basisphenoid ventrally, laterosphenoid anterodorsally, parietal

posterodorsally and the paroccipital processes posteriorly. It is possible that it does not contact

the parietal and an anterior portion of the exoccipitals inserts between the two elements. The

prootic of the adult is a tall and relatively robust element (Fig. 27) that measures 29.2 mm in

height and 13.5 mm in width. The bone surrounding the semicircular canals is damaged, and so

boundaries between the prootic and exoccipital are obliterated. The anterior canal and parts of

the horizontal semicircular canal are well entombed in the prootic, which differs from the

hatchling (Fig. 27G: sccp). The anterior sections of the semicircular canals can be seen exiting

the posterior surface of the prootic (Fig. 27G). The medial surface of the prootic lacks both the

medial ridge of the hatchling and the transverse ridges of the juvenile. With the exception of the

cranial nerves, the medial surface is concave and smooth. CN V is almost entirely enclosed in the

prootic due to the presence of a large, robust preprootic strut (Fig. 27: pps).

The **parietal** contacts include the frontal anteriorly, prootic anteroventrally, paroccipitals

posteroventrally and the supraoccipital posteriorly. The parietal lies posteriorly on the dorsal

surface of the braincase and contributes approximately 50% of the braincase roof (Fig. 20C: pa).

The posterior position of the parietal differs from the parietal of the hatchling specimen which

sits dorsally to the brain. Although the posterior section of the parietal is missing, the preserved

parietal suggests that a small shelf projected over the occipital surface. A midline ridge spans the

height of the posterior surface of the parietal shelf (Fig. 28E: pmr) forming the supraoccipital

articular surface. A sagittal crest is a prominent feature of the adult parietals (Figs. 28A, 28B and

28D: sc) and spans the length of the dorsal surface. The mid-lateral portions of the parietal taper laterally to form the margins of the upper temporal fenestra.

Frontal contacts include the parietal posteriorly, laterosphenoids ventrally and the nasals anteriorly. It is unclear where the prefrontal contact would sit (Fig. 29D: no?). The frontal measures 54 mm anteroposteriorly and 51.5 mm across its widest point and is dorsoventrally very thin (<5 mm) along the midline. Much like the frontal of the juvenile, this element is relatively flat in the adult (Fig. 29). It appears sub-rectangular in dorsal view. Ventrally, the hourglass impression of the anterior region of the brain is present and only the anterior-most section of the cerebrum impressions is preserved. These impressions are shallower than the bulbous impressions of the hatchling specimen. A low, blunt sagittal crest is present on the dorsal surface of the frontal (Fig. 29:fc). As is the case with the juvenile frontal, the orbit wall is orientated in the coronal plane obscuring the orbit from lateral view. When viewed dorsally, the orbital margin (Fig. 29: om) inscribes anterolateral concavities into the sides of the frontal.

Discussion

Skull proportions

A comparison of the three skulls (Table 1) reveals that several elements remain relatively isometric throughout growth. The salient allometric changes that accompany growth include approximately 40% elongation of the paroccipital processes (relative to basal skull length), a dramatic reduction in supraoccipital height (approximately 50% smaller relative to basal skull length) and width (approximately 90% smaller relative to basal skull length), approximately 50% reduction in width of the laterosphenoids and the frontals (relative to basal skull length), and over 50% increase in the height of the basal tubera (relative to basal skull length). Measurements

taken from the juvenile braincase do not correspond closely to those taken from the other individuals in that the height to width ratios of the elements do not follow the same trend as in the other two specimens. This is most likely due to taphonomic deformation (mainly dorsoventral compression) or unavoidable inaccuracies during segmentation because of suture obscurity or obliteration.

The orientation and morphology of the basioccipital component of the basal tubera changes during growth. The basal tubera of the hatchling are oriented in the sagittal plane (Fig. 30A and 30B). The tubera of the juvenile are starting to develop into the anteroposteriorly compressed tubera of the adult basioccipital, but they still retain some of the mediolateral compression observed in the basioccipital of the hatchling, which creates a loose 'L' shape (Fig. 30C and 30D). The robust basal tubera of the adult are oriented transversely (Fig. 30E and 30F). As the individual grows, we also see a larger contribution of the basisphenoid to the basal tubera, which might explain this morphological change. The basioccipital of adult individuals of *Bagaceratops rozhdestvenskyi* differs from that of *P. lujiatunensis* in that it contributes very little to the basal tubera (Maryńska & Osmólska, 1975). Unlike the basal tubera of *Yinlong* (Han et al., 2016) and pachycephalosaurids (Maryńska et al., 2004), the basisphenoid contribution of *P. lujiatunensis* is not visible in caudal view.

During growth, we see an increase in the size of the basal tubera relative to the rest of the braincase. The height to width ratio of the tubera also changes from 1:2 in the two younger specimens, to 1:1 in the adult. The tubera of the adult are wide, plate-like, but clearly bilobate. Neoceratopsians such as *Liaoceratops*, *Auroraceratops* and *Archaeoceratops* have a singular clear plate beneath the occipital condyle with a shallower median cleft (Dodson et al., 2010). Basal tubera act as ligament and muscle attachment sites, stabilizing the head on the neck. This

enlargement of the attachment area may be attributed to the expansion of the parietal shelf and subsequent increase in relative weight of the skull. The growth of the basal tubera likely permitted strengthening of the lateroflexion muscles, such as the *m. longissimus* (Ostrom, 1961), required for movement of the neck in conjunction with the developing skull. This expansion is observed in other non-avian dinosaurs (e.g. Carpenter, 1982; Jacobs et al., 1994; Huebner & Rauhut, 2010).

The occipital condyles studied here, with the possible exception of the juvenile (likely due to sutural obscurity resulting in segmentation imprecision), are made up entirely of the basioccipital, with no evident contribution from the exoccipitals. Several descriptions of *Psittacosaurus* suggest this is the case (Serenio et al., 1988; Serenio, 1992; Xu, 1997; You & Xu, 2005; Zhou et al., 2006; Brinkman et al., 2001; You et al., 2008). This contradicts Averianov et al. (2006) and Serenio (2010), both of whom suggested that the exoccipitals likely contributed to the occipital condyles, as is the case in some other dinosaurs including more derived ceratopsians.

The length ratio of the basioccipital and basisphenoid (disregarding the cultriform process) is approximately 1:1 and this remains relatively static throughout growth (Table 1). Further, the cultriform process stays the same length relative to total basisphenoid length. The cultriform process also moves dorsally as the basisphenoid deepens throughout ontogeny. The anterolateral projection of the basiptyergoid processes observed here are present in all psittacosaurids (Serenio et al., 1988; You et al., 2008; Dodson et al., 2010) and similar rostrally projecting processes are present in several basal neoceratopsians including *Archaeoceratops* (Dodson et al., 2010) and *Protoceratops* (Brown & Schlaikjer, 1940; Chinnery & Weishampel, 1998; Dodson et al., 2010). Conversely, posteroventrally projecting basiptyergoid processes are found in the

Leptoceratopsidae (Chinnery & Weishampel, 1998; Ott, 2006) and the Ceratopsidae (Hatcher et al., 1907; Dodson & Currie, 1990; Chinnery & Weishampel, 1998). Throughout growth, these basiptyergoid processes become progressively more ventrally projecting. The angle at which the basiptyergoid processes diverge also decreases from 81° to 44°. This may be to accommodate the dorsoventral expansion of the skull during growth. When viewed dorsally, the sella turcica changes from triangular to sub-diamond-like in shape.

The supraoccipital contributes to the dorsal margin of the foramen magnum in each specimen reported here. This is also the case in *Protoceratops* (Brown & Schlaikjer, 1940), *Leptoceratops* (Sternberg, 1951) and *Bagaceratops* (Maryńska & Osmólska, 1975). The supraoccipital bisecting the exoccipitals and contributing to the dorsal margin of the foramen magnum is also thought to be a juvenile character within Ceratopsidae (Gilmore, 1917; Lehman, 1989), having been recorded in immature specimens of *Triceratops* (Goodwin et al., 2006; Horner & Goodwin, 2006), *Brachyceratops* (Gilmore, 1917) and *Chasmosaurus* (Lehman, 1989). This contribution to the foramen magnum is then lost in adult ceratopsids as the exoccipitals exclude the supraoccipital from the roof of the braincase (Hatcher et al., 1907; Brown & Schlaikjer, 1940; Dodson & Currie, 1989; Forster, 1996; Dodson et al., 2004). The supraoccipital in *P. lujiatunensis* appears to undergo a reduction in size and dramatic change in shape. The large, thin, plate-like supraoccipital of the hatchling reduces in size (relative to basal skull length) with age and becomes rod-like with a wider ventral base. The midline crest running down the posterior face of the supraoccipital in the hatchling and adult skulls most likely separates an attachment site for epaxial muscles, as is the case for other ceratopsians such as *Triceratops* (Goodwin et al., 2006). Unlike the other individuals, the juvenile supraoccipital shows no evidence of a caudal midline ridge, but this area is incomplete. While the supraoccipital forms

most of the occipital surface of the hatchling skull, much of this surface of the adult skull appears to be taken up by the parietal. As *P. lujiatunensis* grows, the contribution of the supraoccipital to the foramen magnum decreases. A more extreme version of this, where the supraoccipital is fully excluded from the foramen magnum by the exoccipitals, is documented during growth of ceratopsids such as *Triceratops* (Goodwin et al., 2006). The posterior semicircular canal of *P. lujiatunensis* is situated in the supraoccipital of the hatchling, whereas it remains within the confines of the paroccipital processes in the older specimens. It is important to note that compression of the adult skull (Hedrick & Dodson, 2013) may have affected sutural boundaries and segmentation accuracy in this area. While You & Xu (2005) and Taylor et al. (2016) also report a heavily reduced supraoccipital in IVPP V12617, other reconstructions of adult *Psittacosaurus* have depicted the supraoccipital as being wider than it is tall (e.g. Sereno, 1987; Sereno et al., 1988; Zhou et al., 2006). It is therefore possible that the supraoccipital of the adult was more laterally extensive than is apparent in this specimen.

The paroccipital processes expand laterally during growth of *P. lujiatunensis*. The small, rectangular processes of the hatchling become long and slightly distally flared. These gracile, long and dorsoventrally narrow elements are similar to those of basal neoceratopsians such as *Montanoceratops* (Chinnery & Weishampel, 1998), *Leptoceratops* (Sternberg, 1951), *Bagaceratops* (Maryńska & Osmólska, 1975) and *Proceratops* (Brown & Schlaikjer, 1940). Ceratopsid exoccipitals tend to be stouter, more robust, and highly flared distally, contacting the squamosal to support the large parieto-squamosal frill (Brown & Schlaikjer, 1940; Ostrom & Wellnhofer, 1990; Forster, 1996; Chinnery & Weishampel, 1998). Goodwin et al. (2006) note that the paroccipital processes of the juvenile *Triceratops* appear to anticipate the structural requirements of adulthood and are already flared, in contact with the ventral surface of the

squamosal, and laterally expanded to form the buttress for the frill. The expansion of the paroccipital processes of *P. lujiatunensis* increases the surface area of the attachment site of the *m. obliquus capitis magnus*, for lateral and dorsoventral movement of the head. This might have been necessary to accommodate the weight of the mature skull with developed parieto-squamosal shelf and flared jugals, a hypothesis also used to explain the large exoccipitals in ceratopsids (Goussard, 2006). This muscular growth may also be linked to the posited postural shift during ontogeny (Zhao et al., 2013) and the associated possibility of a change in feeding mechanism – i.e. grazing juveniles develop into facultative browsers. Much like those of *Bagaceratops* (Maryńska & Osmólska, 1975), the contribution of the exoccipitals to the occipital condyle of *P. lujiatunensis* is minimal/ absent. The exoccipitals do not contact each other, being separated ventrally by the basioccipital and dorsally by the supraoccipital, as in other basal ceratopsians such as *Yinlong* (Han et al., 2016). In basal Neoceratopsia, the exoccipitals also contribute to the ventral portion of the foramen magnum, excluding the basioccipital (You & Dodson, 2004).

The laterosphenoid undergoes some morphological change and becomes more robust as the individual grows. Laterally, it is triangular and transforms to become anteroposteriorly elongated. The laterosphenoid head displaces anteriorly as the laterosphenoid elongates. The *m. pseudotemporalis superficialis*, *m. tensor periorbitae* and *m. levator pterygoideus* are assumed to have had attachment sites on the laterosphenoid (Holliday, 2009).

The semicircular canals are loosely held within the prootic of the hatchling, which is partially why it was difficult to segment. The prootic develops into a robust element and the semicircular canals of the two older specimens are encased firmly within. The foramen for cranial nerve V becomes orientated more anteriorly through growth along with the development of a pronounced

preprootic strut. A small foramen in the middle of the hatchling and juvenile prootics is thought to be for transmitting cranial nerve VII. If this is the case, this is shared with *Montanoceratops* (Chinnery & Weishampel, 1998) and *Bagaceratops* (Maryńska & Osmólska, 1975).

Initially, the parietal and frontal are convex in accordance with the round skull shape which is also observed in a juvenile specimen of *Bagaceratops* (Maryńska & Osmólska, 1975). These bones become flatter and, as observed in Coombs (1982), a sagittal crest develops with age, a clear indication of strengthening *adductor mandibulae* jaw muscles (Sereno et al., 2010). This crest is also present in several basal ceratopsians including *Yinlong* (Han et al., 2015), *Liaoceratops* (Xu et al., 2002), *Archaeoceratops* (You & Dodson, 2003) and *Bagaceratops* (Maryńska & Osmólska, 1975). Neither the hatchling described here nor the juvenile specimen of *Bagaceratops* described by Maryńska & Osmólska (1975) have a developed parietal crest, so a defined sagittal crest is likely an adult character. During growth, a small parietal shelf extends posteriorly over the occipital surface. This ontogenetic ‘frill’ growth is also seen in basal neoceratopsians such as *Protoceratops* (Maryńska & Osmólska, 1975; Fastovsky et al., 2011) and *Bagaceratops* (Maryńska & Osmólska, 1975). Ceratopsids, such as *Triceratops*, develop a large frill during growth, but an incipient frill is already present in juvenile specimens (Goodwin et al., 2006; Currie et al., 2016). As the parietal expands during growth, the supraoccipital shrinks (relative to basal skull length) and the contact between the parietal and the paroccipital processes extends across the full width of the processes. The fronto-parietal sutural contact of *Protoceratops* migrates posteriorly with growth (Maryńska & Osmólska, 1975), which differs from *P. lujiatunensis* whose contact appears to remain relatively stationary.

The frontals contact the same elements throughout growth. Substantial negative allometry can be observed in the width of the frontals during growth (Table 1). As in juvenile *Bagaceratops*

(Maryńska & Osmólska, 1975), they remain dorsally convex and contribute to the overall roundness of the skull roof. Unlike *Bagaceratops* (Maryńska & Osmólska, 1975), the frontal of *P. lujiatunensis* contributes to a large portion of the orbital margin. A frontal crest develops with age. The juvenile has well defined, deep bulbous concavities where the cerebral hemispheres sat. The cerebral depressions on the frontal become shallower and less defined during growth, likely due to increasing distance between the brain and the braincase through maturation (Jerison, 1973). In cross section, the small convexities present on the midline of the dorsal surface of the frontals appear to be separate, individual ossicles. There are several indicators that these are not an artefact of the scanning process. Firstly, they mirror each other either side of the midline ridge, displaying almost perfect bilateral symmetry. Had the specimen not been set perfectly in the scanner, this would be off. Secondly, the cross section through these ossicles shows the same texture and contrast values as the rest of the skull. We are also confident that these ossicles are not broken sections from other elements due to the perfect circular shape and lack of any broken or damaged surfaces. The midline symmetry also supports this. We considered the possibility that these structures had a function similar to that of an egg-tooth and helped the baby *Psittacosaurus* to hatch. This is, however, unlikely as the egg-tooth of archosaurs (including putative examples in other non-avian dinosaurs) is generally found on the tip of the snout (e.g. Rahn et al., 1979; García, 2007). It is unlikely but possible that they could represent a pathology or a mutation as they have not been observed in other juvenile ceratopsians, including hatchling *Psittacosaurus* (Coombs, 1982). They could be epioossifications much like those seen on the parieto-squamosal frill, but these frontal ossicles are lost during growth.

Semicircular canals

The semicircular canal pathways are not clear in the hatchling IVPP V15451 and, consequently, some sections have been inferred (Fig. 31A). This could be due to cartilaginous surroundings at a young age, and this is more likely than simply poor preservation, as none of the reviewed hatchling specimens has a complete housing for the inner ear. A theorized pathway has been created using what remains of the hatchling's bony labyrinth (Fig. 31A) and the morphology of the canals in the two older specimens.

The semicircular canals of the juvenile are dorsoventrally short. It is possible that this was the case in vivo, but it is quite likely a result of the taphonomic compression that has affected the skull as a whole. Because this stunted morphology spans the entire inner ear, the height relationship between the anterior and posterior semicircular canals is preserved. The posterior semicircular canal is approximately two-thirds the height of the anterior canal (Fig. 31C).

The semicircular canals of the adult are well preserved and maintain their in vivo morphology. Much like those of the juvenile, the anterior semicircular canals are at least twice as large as the posterior semicircular canals (Fig. 31E).

Lateral (horizontal) semicircular canal (LSC). It has been determined that *Psittacosaurus* changed its posture during growth. Juveniles (including IVPP V16902) are reconstructed as quadrupeds, based on the similar lengths of their forelimbs and hindlimbs (Zhao et al., 2013). There is a lot of evidence for bipedality in adult *Psittacosaurus*. The forelimbs are half the length of the hindlimbs (Osborn, 1923; Maryńska & Osmólska, 1975; Sereno, 1990; Zhao et al., 2013) and observed modifications of the pelvis suggest that they were able to support more weight cranially (Chinnery, 2004). Similarly, *Psittacosaurus* display bipedal character states for all

osteological correlates set out by Maidment & Barrett (2014). Bipedality in adult *Psittacosaurus* is also supported by the robustness and mobility of the forelimbs, which led Chinnery (2004) to suggest that they could be used to manipulate the surrounding environment. Further evidence comes from Maidment et al. (2014) who calculated the centre of mass for adult *Psittacosaurus* was located dorsal to the hindfoot, allowing for bipedal locomotion. *Psittacosaurus* are frequently reconstructed, when adult, as facultative bipeds, dropping their bodies and arms to the ground when feeding, for example, but rearing high to detect danger or feed on leaves high on a tree. This postural shift was confirmed by bone histological analysis of forelimb and hindlimb bones, in which the femur of juveniles and adults shows evidence of faster growth than the humerus (Zhao et al., 2013). Bone histology also demonstrated that the shift in posture likely occurred during the third year of life, emphasizing the negative allometric growth of the forelimb relative to overall body length as the animal became more and more adapted to bipedality during ontogeny, after age 4 (Zhao et al., 2013).

We seek to test this idea by reference to the lateral semicircular canal in the three growth stages, from hatchling to adult. The linkage between the lateral semicircular canal orientation and head posture has been discussed for nearly a century. Although some studies advocated that the orientation of the LSC is variable at both intraspecific and interspecific scales (Duijm, 1951; Taylor et al., 2009; Marugán-Lobón et al., 2013; Coutier et al., 2017), the LSC is generally considered to remain earth-horizontal when the head is in its ‘natural’ alert position (Lebedkin, 1924; Witmer et al., 2003; Chatterjee & Templin, 2004; Sereno et al., 2007; Witmer et al., 2008; Araujo et al., 2017; Coutier et al., 2017; Benoit et al., 2017; Schellhorn, 2018).

When working with semicircular canals, it is important to be sure that the method of measuring orientation is plausible, and indeed our data may contribute to the debate. When Witmer et al.

(2003) used the orientation of the LSC to assume the resting posture of the pterosaur head, critics (e.g., Taylor et al., 2009) pointed out that in living tetrapods the LSC is not always held horizontal. For example, these authors noted that extant animals often hold their heads oriented so the LSC is tilted upwards by 12° in monkeys, 16° in rabbits, 20° in guinea-pigs and domestic cats, and 22° in humans (Graf et al., 1995, Spoor & Zonneveld, 1998). In birds, Duijm (1951) showed that in most species the LSC was held horizontal, but in some species, values were as much as 20° below or 30° above horizontal. Similarly, Magurán-Lobón et al. (2013) showed that LSC orientation was not a reliable indicator of head orientation at rest. However, in studies of modern xenarthrans (Coutier et al., 2017) and rhinos (Schellhorn, 2018), the LSC was near enough horizontal to provide a good indicator of head orientation.

We propose to use our study of *Psittacosaurus* as a test of these opposing views. The angles between the plane of the LSC and the palatal plane were calculated in our study, following the method in Schellhorn (2018). Our analysis shows that the angles are very variable in the ontogenetic series of *Psittacosaurus lujiatunensis*, but they show a clear trend of decline during ontogenetic growth. The angle is 38° in the hatchling stage, and changes to 25° in the juvenile, and reaches 15° in the adult. Based on the isometric growth line of *Psittacosaurus lujiatunensis* (Zhao et al., 2014), we can estimate the hatchling specimen is less than one year old, and the juvenile specimen is approximately two years old. The adult specimen is ten years old, according to bone histology. Under the assumption that the plane of the LSC is earth-horizontal, we reconstruct the head posture of *Psittacosaurus* in different growth stages (Fig. 32). In our reconstruction, the nose-down head posture is quite obvious in the hatchling stage, which implies quadrupedal locomotion as the angle between the skull and neck vertebrae would be too high for a bipedal stance (Coutier, 2017). The nose rises up in the juvenile stage, and points forward in

the adult stage. These changes of head posture are consistent with the previous study on posture shift from quadrupedal to bipedal during growth in *Psittacosaurus* (Zhao et al., 2013). The larger angle present in the hatchling specimen would not be congruent with a bipedal stance (Coutier et al., 2017).

Cranial nerves X-XII. There have been many interpretations and configuration of the foramina exiting through the exoccipitals below the paroccipital processes in early ceratopsians (e.g., Averianov et al., 2006; Brown & Schlaikjer, 1940; Chinnery & Weishampel, 1998; Forster, 1996; Maryńska & Osmólska, 1975; Xu, 1997; Brinkman et al., 2001). Here, CNXII₃ is the posterior-most foramen and is the largest in the hatchling and juvenile specimens. It is doubtful that CN X and CN XI would have individual exits, as they are confluent in ceratopsids and so it seems unlikely that they would separate just to converge again (Brown & Schlaikjer, 1940; Averianov et al., 2006). As noted by Averianov et al. (2006), the foramen for CN XII₁₊₂ is small and can be overlooked, which is why often *Psittacosaurus* can sometimes be mistakenly described as having only two foramina in the exoccipital (e.g., Xu, 1997). This is most likely the case for the adult described here, as only two cranial nerve foramina can be seen exiting the exoccipital, unlike the hatchling and juvenile specimens, which have three clear, separate foramina (Fig. 33). Note that poor contrast values in the adult scan made segmentation difficult in this region.

Conclusion

Braincases are often neglected in cranial descriptions and ontogenetic studies because they are believed to exhibit little variation and are often inaccessible. While some braincase elements

grew in an isometric fashion, many grew at different rates (Table 1). Salient ontogenetic changes in the braincase of *Psittacosaurus lujiatunensis* (Fig. 34) include:

1. The basal tubera expand dorsoventrally and laterally.
2. The angle of divergence of the basiptyergoid processes drops from 81° to 44°.
3. The supraoccipital appears to undergo a dramatic reduction in size from a large, plate-like element to a transversely compressed rod. One caveat is that the accuracy of segmentation in this area may have been affected by damage.
4. The small sub-rectangular paroccipital processes of the hatchling laterally expand and become long and ‘strap-like’.
5. The laterosphenoid becomes anteroposteriorly elongated and the laterosphenoid head displaces rostrally.
6. A sagittal crest develops along the midline of the parietal.
7. A small parietal shelf develops.
8. The width of the frontals relative to basal skull length decreases dramatically during growth.
9. The angle of the lateral semicircular canal decreases from 38° to 15°. This is the first evidence to illustrate the variation of orientation of the LSC in the ontogenetic growth of a species of dinosaur, and it confirms that, at least for this genus, the LSC orientation is well aligned with expectations of head posture. The head was held nose-down in quadrupedal hatchlings and more horizontal in bipedal adults. This shift is in accordance with matching of the occipital condyle and the vertebral column.

Braincases are generally more conservative than other areas of the skeleton that are associated with highly adaptive functions, and so can be valuable in a phylogenetic context (Bakker et al.,

1988; Coria & Currie, 2002). Element characteristics that change dramatically during growth should be excluded from a phylogenetic analysis as ontogenetic variation may be misinterpreted as phylogenetic variation. Elements that remain similar in relative size or morphology throughout growth may prove to be useful phylogenetic characters and should be investigated further. In this case, the proportions of the basioccipital, paroccipital height, parietal length and basal tubera width should be explored in a phylogenetic context, as the relative growth of these elements appears to be close to constant (Table 1).

This is the first time that frontal ossicles have been recorded in basal ceratopsians. The function and origins of these ossicles are unknown. More examples and further analysis of these structures are required to make any reliable assumptions.

Acknowledgements. We thank Yun Feng, the technician at IVPP, for scanning the specimens. We also thank James Brown for his artistic assistance with the *Psittacosaurus* silhouettes.

1009 (Dinosauria: Ceratopsia) based on CT scans of new fossils from the Lower Cretaceous,
1010 China. *Palaeoworld* **16**, 285–293.

Figure 1

Ontogenetic sequence of *P. lujiatunensis*.

(A) Hatchling (IVPP V15451) in lateral view. (B) Hatchling in dorsal view. (C) Juvenile (IVPP V22647) in lateral view. (D) Juvenile in dorsal view. (E) Adult (IVPP V12617) in lateral view. (F) Adult in dorsal view. All shown to the same scale; scale bar represents 20 mm.

Figure 2

Segmented braincase of a hatchling *P. lujiatunensis* (IVPP V15451).

(A) Lateral view. (B) Ventral view. (C) Dorsal view. (D) Posterior view. (E) Anterior view. bo, basioccipital; bpc, basisphenoid-parasphenoid complex; fr, frontal; ls, laterosphenoid; pa, parietal; pp, paroccipital processes; pr, prootic; so, supraoccipital. Scale bar represents 10 mm.

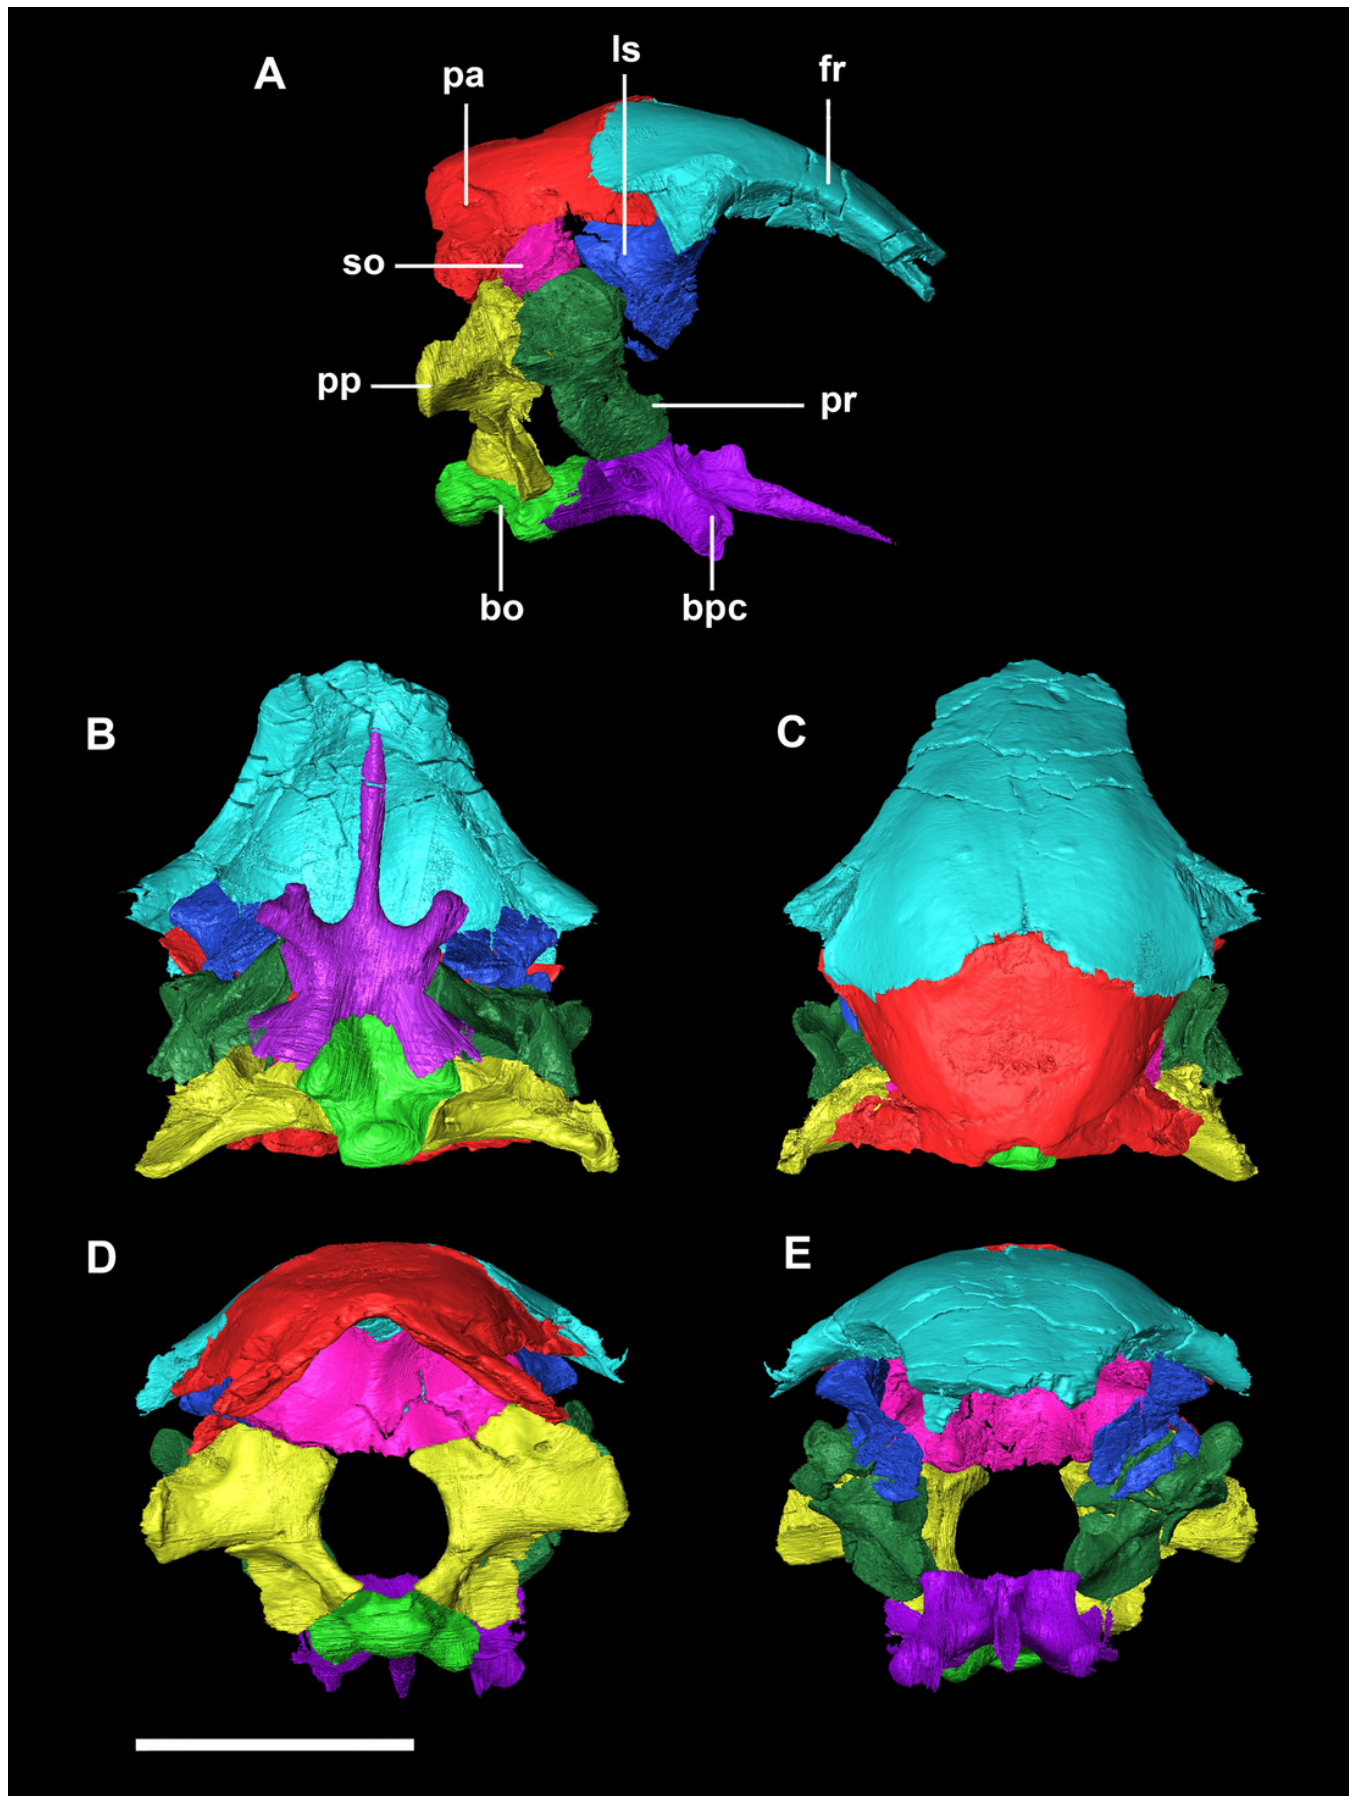

Figure 3

Basioccipital of hatchling *P. lujiatunensis* (IVPP V15451).

(A) Left lateral view. (B) Right lateral view. (C) Ventral view. (D) Dorsal view. (E) Posterior view. (F) Anterior view. boc, basioccipital condyle; bsas, basisphenoid articular surface; bt, basal tubera; btg, basal tubera groove; cdn, condylar neck; eoas, exoccipital articular surface; ng, neural groove. Scale bar represents 5 mm.

Figure 4

Basisphenoid of hatchling *P. lujiatunensis* (IVPP V15451).

(A) Left lateral view. (B) Right lateral view. (C) Ventral view. (D) Dorsal view. (E) Posterior view. (F) Anterior view. boas, basioccipital articular surface; bpp, basipterygoid process; bt, basal tubera; cfo, carotid foramen; cp, cultriform process; pct, paracultriform trough; pras, prootic articular surface; ptas, pterygoid articular surface; st, sella turcica. Scale bar represents 5 mm.

Figure 5

Supraoccipital of hatchling *P. lujiatunensis* (IVPP V15451).

(A) Left lateral view. (B) Right lateral view. (C) Ventral view. (D) Dorsal view. (E) Posterior view. (F) Anterior view. eoas, exoccipital articular surface; paas, parietal articular surface; pras, prootic articular surface; sccp, semicircular canal pathway; somr, supraoccipital midline ridge. Scale bar represents 5 mm.

Figure 6

Paroccipital processes of hatchling *P. lujiatunensis* (IVPP V15451).

(A) Left lateral view. (B) Ventral view. (C) Dorsal view. (D) Posterior view. (E) Anterior view. boas, basioccipital articular surface; fm, foramen magnum; pop, paroccipital process; pras, prootic articular surface; sccp, semicircular canal pathway; soas, supraoccipital articular surface; vcd, *vena capitis dorsalis*; CN X, XI, exit for the vagus nerve and the accessory nerve respectively; CN XII, exit for the hypoglossal nerve. scale bar represents 5 mm.

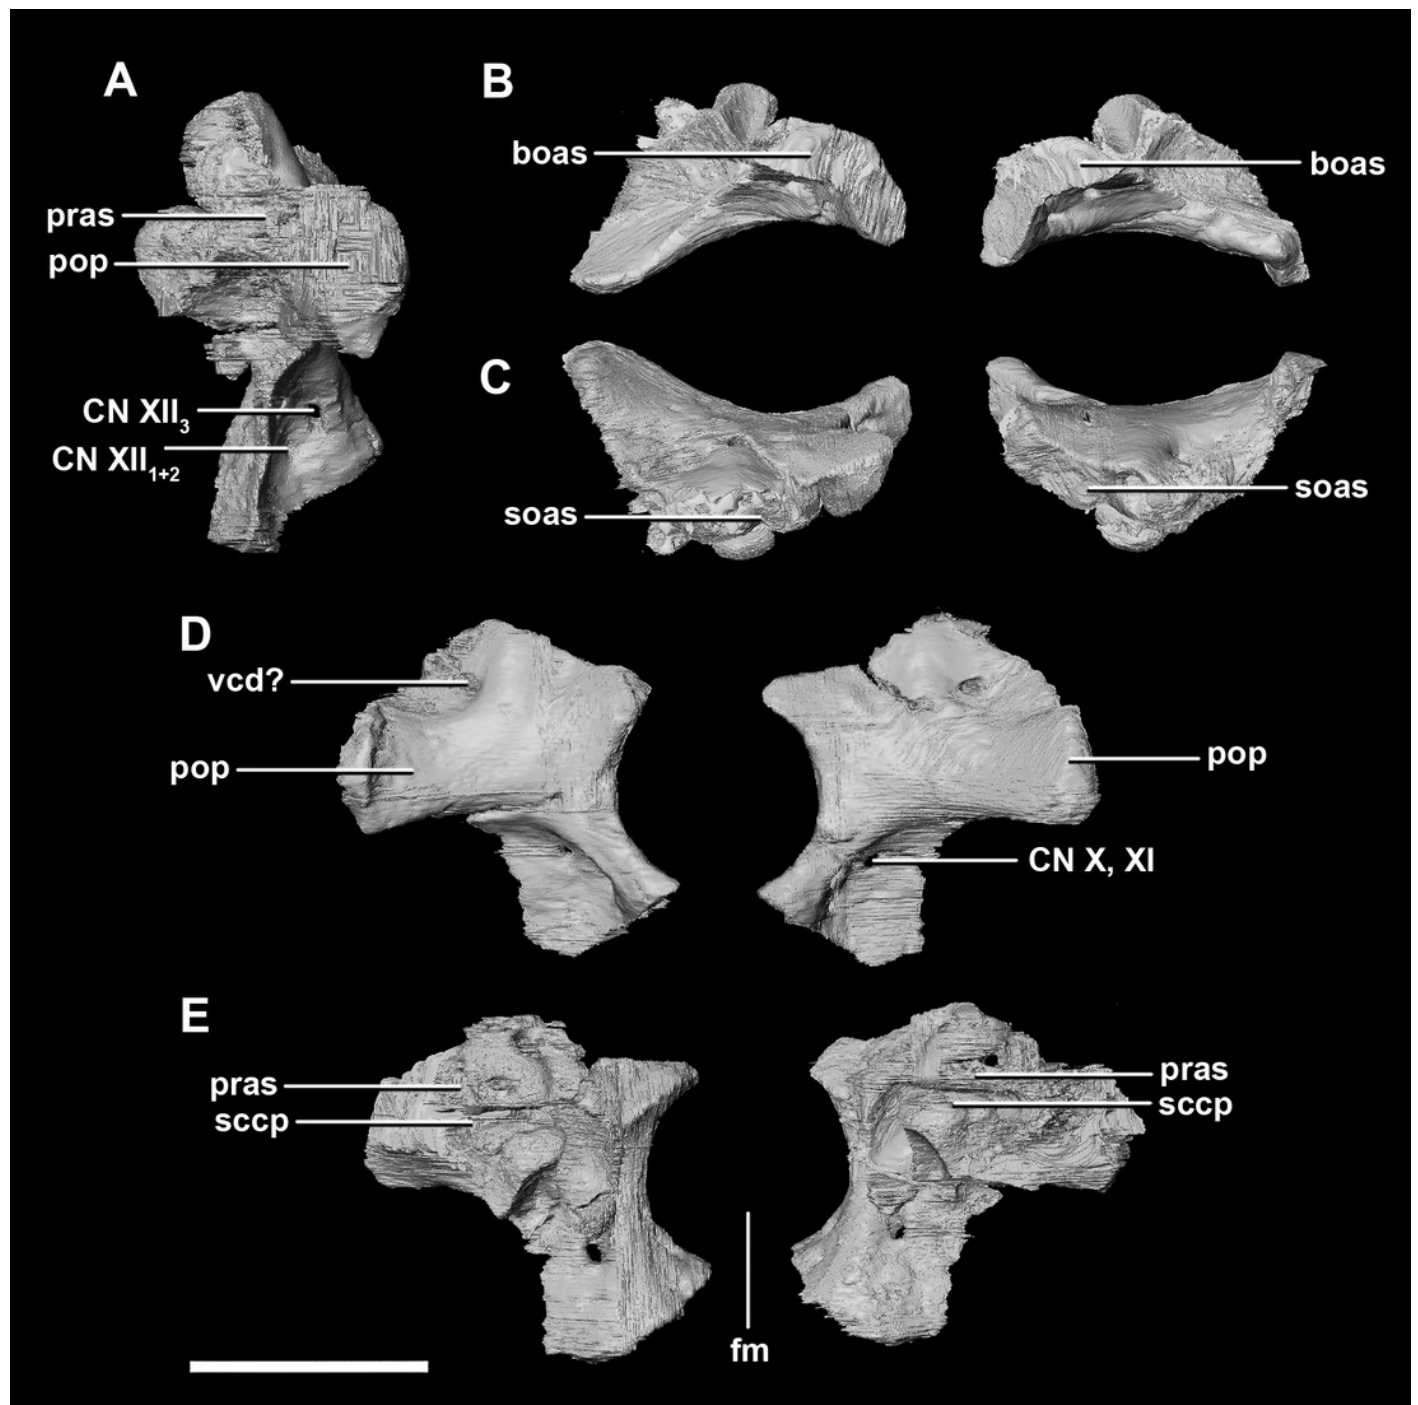

Figure 7

Laterosphenoid of hatchling *P. lujiatunensis* (IVPP V15451).

(A) Left lateral view. (B) Right lateral view. (C) Ventral view. (D) Dorsal view. (E) Posterior view. (F) Anterior view. fras, frontal articular surface; lsh, laterosphenoid head; pras, prootic articular surface; CN V, dorsal margin of trigeminal nerve. Scale bar represents 5 mm.

Figure 8

Prootic of hatchling *P. lujiatunensis* (IVPP V15451).

(A) Left lateral view. (B) Right lateral view. (C) Left medial view. (D) Right medial view. (E) Ventral view. (F) Dorsal view. (G) Posterior view. (H) Anterior view. bsas, basisphenoid articular surface; eoas, exoccipital articular surface; lsas, laterosphenoid articular surface; prmr, prootic midline ridge; sccp, semicircular canal pathway; CN V, trigeminal nerve; CN VII, facial nerve. Scale bar represents 5 mm.

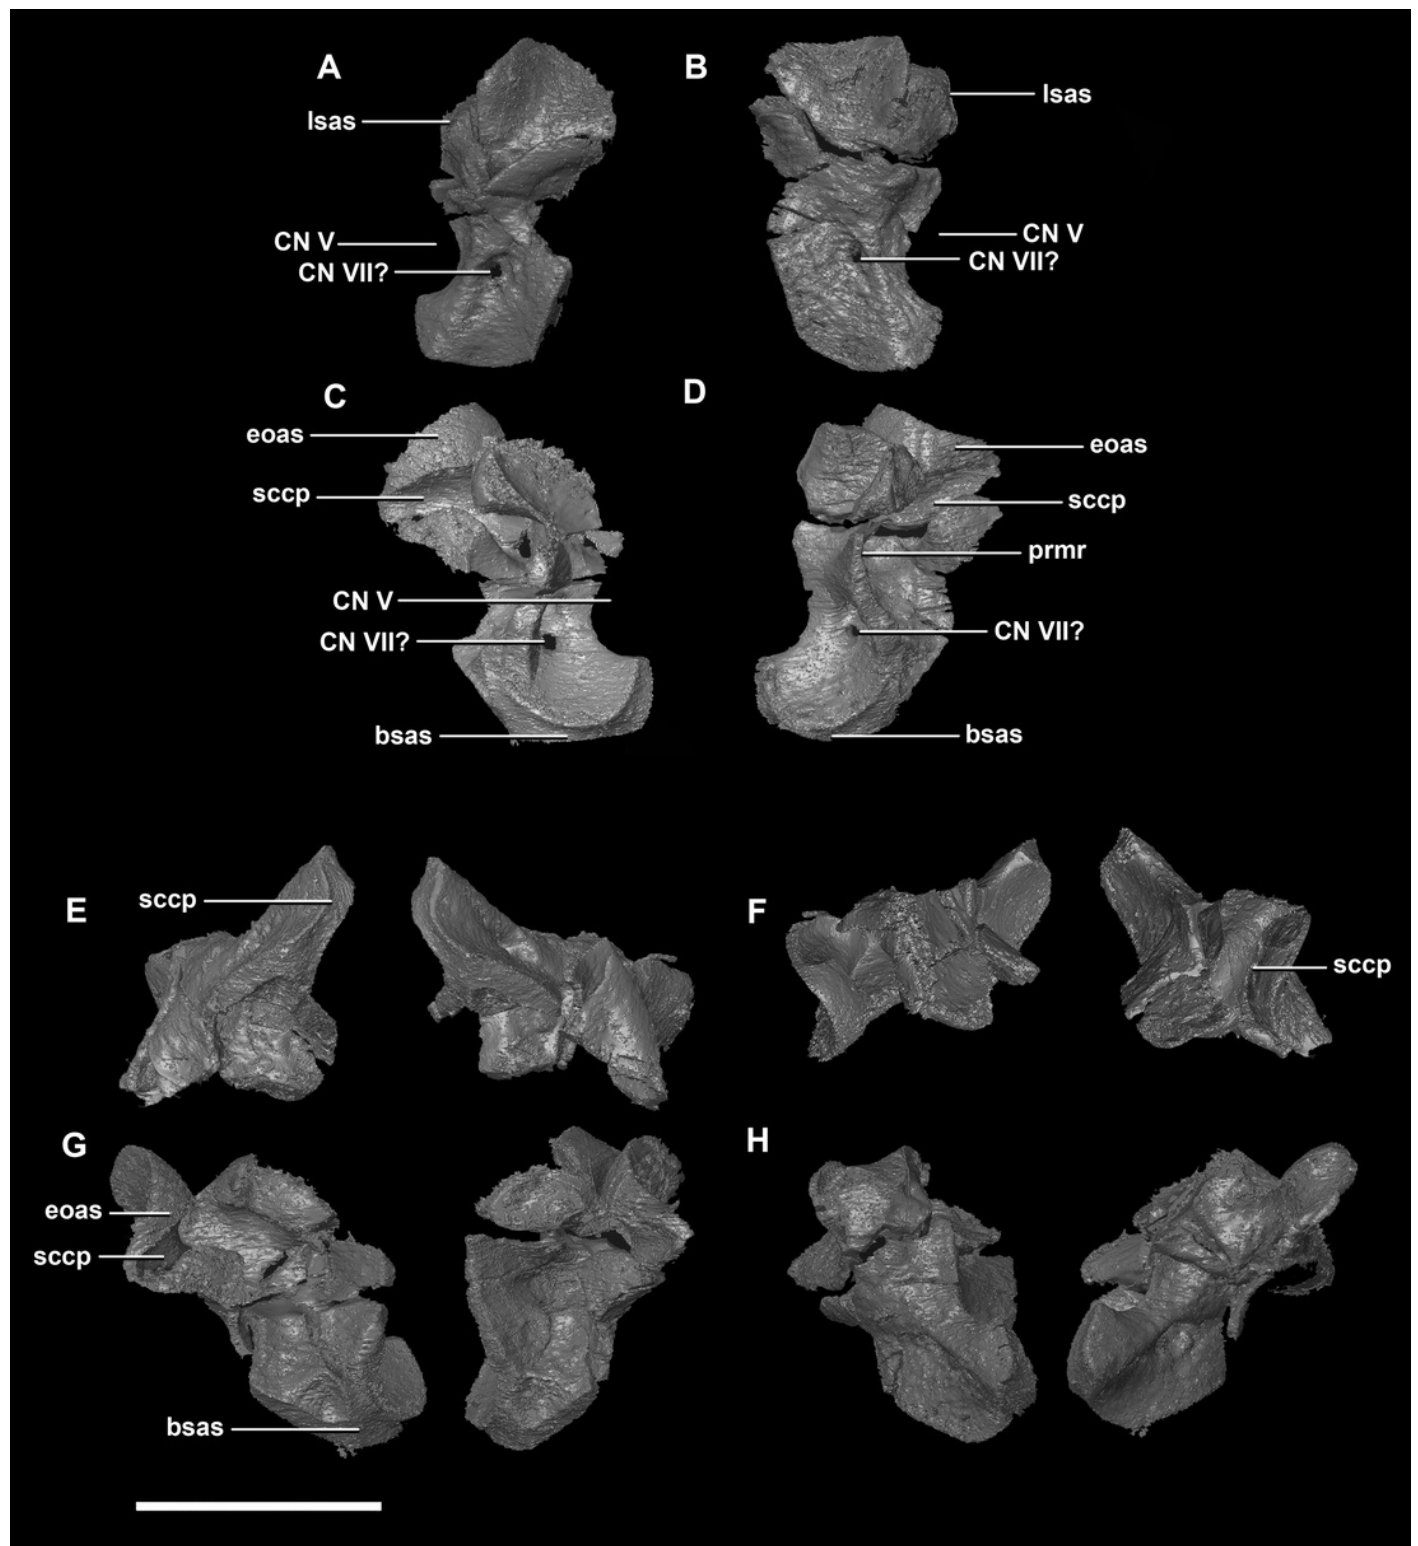

Figure 9

Parietal of hatchling *P. lujiatunensis* (IVPP V15451).

(A) Left lateral view. (B) Right lateral view. (C) Ventral view. (D) Dorsal view. (E) Posterior view. (F) Anterior view. fras, frontal articular surface; lsas, laterosphenoid articular surface; soas, supraoccipital articular surface; sqas, squamosal articular surface; UTF, upper temporal fenestra. Scale bar represents 5 mm.

Figure 10

Frontal of hatchling *P. lujiatunensis* (IVPP V15451).

(A) Left lateral view. (B) Right lateral view. (C) Ventral view. (D) Dorsal view. (E) Posterior view. (F) Anterior view. cc, cerebral cavity; fro, frontal ossicle; lsas, laterosphenoid articular surface; nas, nasal articular surface; om, orbital margin; paas, parietal articular surface; poas, postorbital articular surface. Scale bar represents 5 mm.

Figure 11

Segmented braincase of a juvenile *P. lujiatunensis* (IVPP V22647).

(A) Lateral view. (B) Ventral view. (C) Dorsal view. (D) Posterior view. (E) Anterior view. bo, basioccipital; bpc, basisphenoid-parasphenoid complex; fr, frontal; ls, laterosphenoid; pa, parietal; pp, paroccipital processes; pr, prootic. Scale bar represents 10 mm.

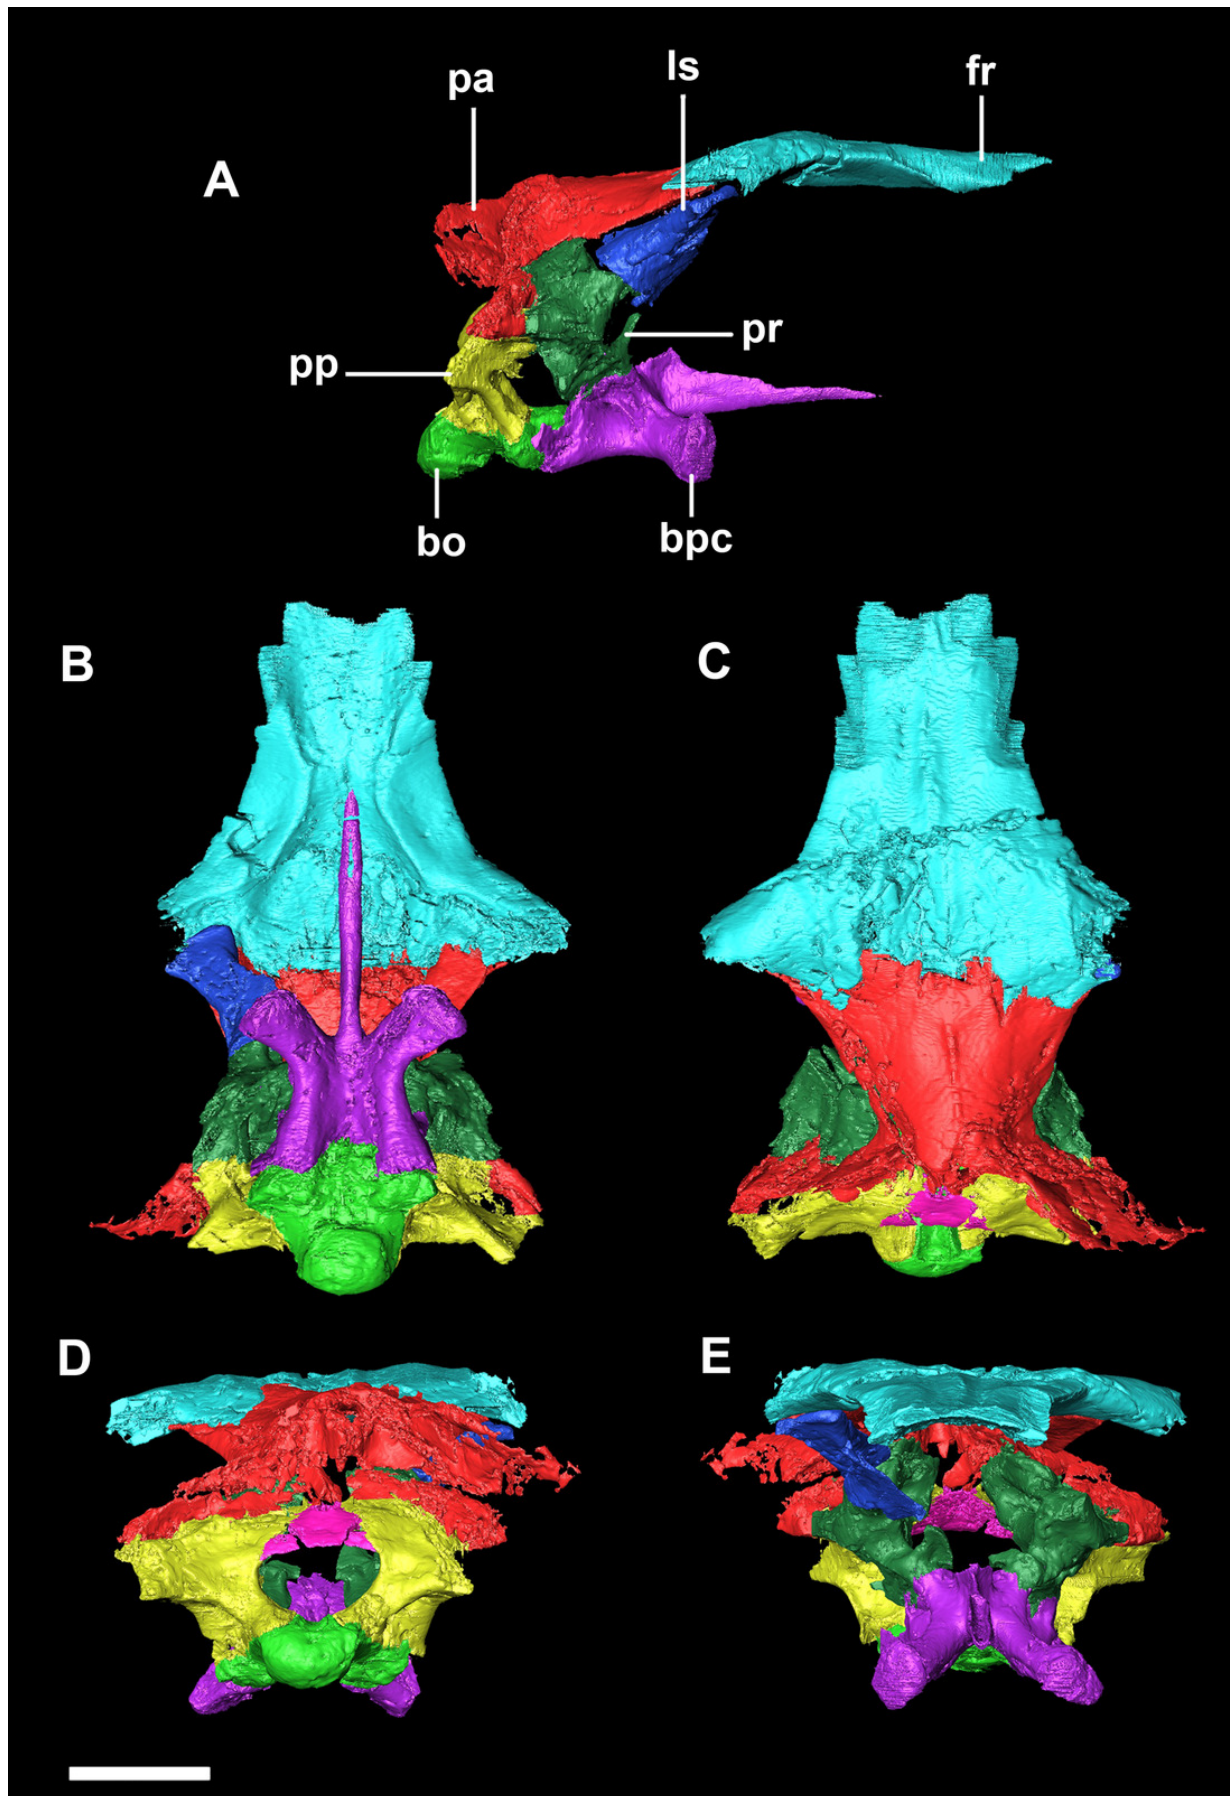

Figure 12

Basioccipital of juvenile *P. lujiatunensis* (IVPP V22647).

(A) Left lateral view. (B) Right lateral view. (C) Ventral view. (D) Dorsal view. (E) Posterior view. (F) Anterior view. boc, basioccipital condyle; bsas, basisphenoid articular surface; bt, basal tubera; btg, basal tubera groove; cdn, condylar neck; eoas, exoccipital articular surface; ng, neural groove. Scale bar represents 10 mm.

Figure 13

Basisphenoid of juvenile *P. lujiatunensis* (IVPP V22647).

(A) Left lateral view. (B) Right lateral view. (C) Ventral view. (D) Dorsal view. (E) Posterior view. (F) Anterior view. boas, basioccipital articular surface; bpp, basipterygoid process; bt, basal tubera; cfo, carotid foramen; cp, cultriform process; pct, paracultriform trough; pras, prootic articular surface; ptas, pterygoid articular surface; st, sella turcica. Scale bar represents 10 mm.

Figure 14

Supraoccipital of juvenile *P. lujiatunensis* (IVPP V22647).

(A) Posterior view. (B) Anterior view. eoas, exoccipital articular surface; fm, foramen magnum; paas, parietal articular surface. Scale bar represents 10 mm.

Figure 15

Paroccipital processes of juvenile *P. lujiatunensis* (IVPP V22647).

(A) Left lateral view. (B) Right lateral view. (C) Posterior view. (D) Anterior view. boas, basioccipital articular surface; fm, foramen magnum; pop, paroccipital process; pras, prootic articular surface; sccp, semicircular canal pathway; soas, supraoccipital articular surface. Scale bar represents 10 mm.

Figure 16

Laterosphenoid of juvenile *P. lujiatunensis* (IVPP V22647).

(A) Right lateral view. (B) Right medial view. (C) Ventral view. (D) Dorsal view. (E) Posterior view. (F) Anterior view. fras, frontal articular surface; lsh, laterosphenoid head; paas, parietal articular surface; pras, prootic articular surface; CN V, dorsal margin of trigeminal nerve. Scale bar represents 10 mm.

Figure 17

Prootics of juvenile *P. lujiatunensis* (IVPP V22647).

(A) Left lateral view. (B) Right lateral view. (C) Left medial view. (D) Right medial view. (E) Ventral view. (F) Dorsal view. (G) Posterior view. (H) Anterior view. bsas, basisphenoid articular surface; eoas, exoccipital articular surface; lsas, laterosphenoid articular surface; paas, parietal articular surface; pps, preprootic strut; CN V, trigeminal nerve; CN VII, facial nerve. Scale bar represents 10 mm.

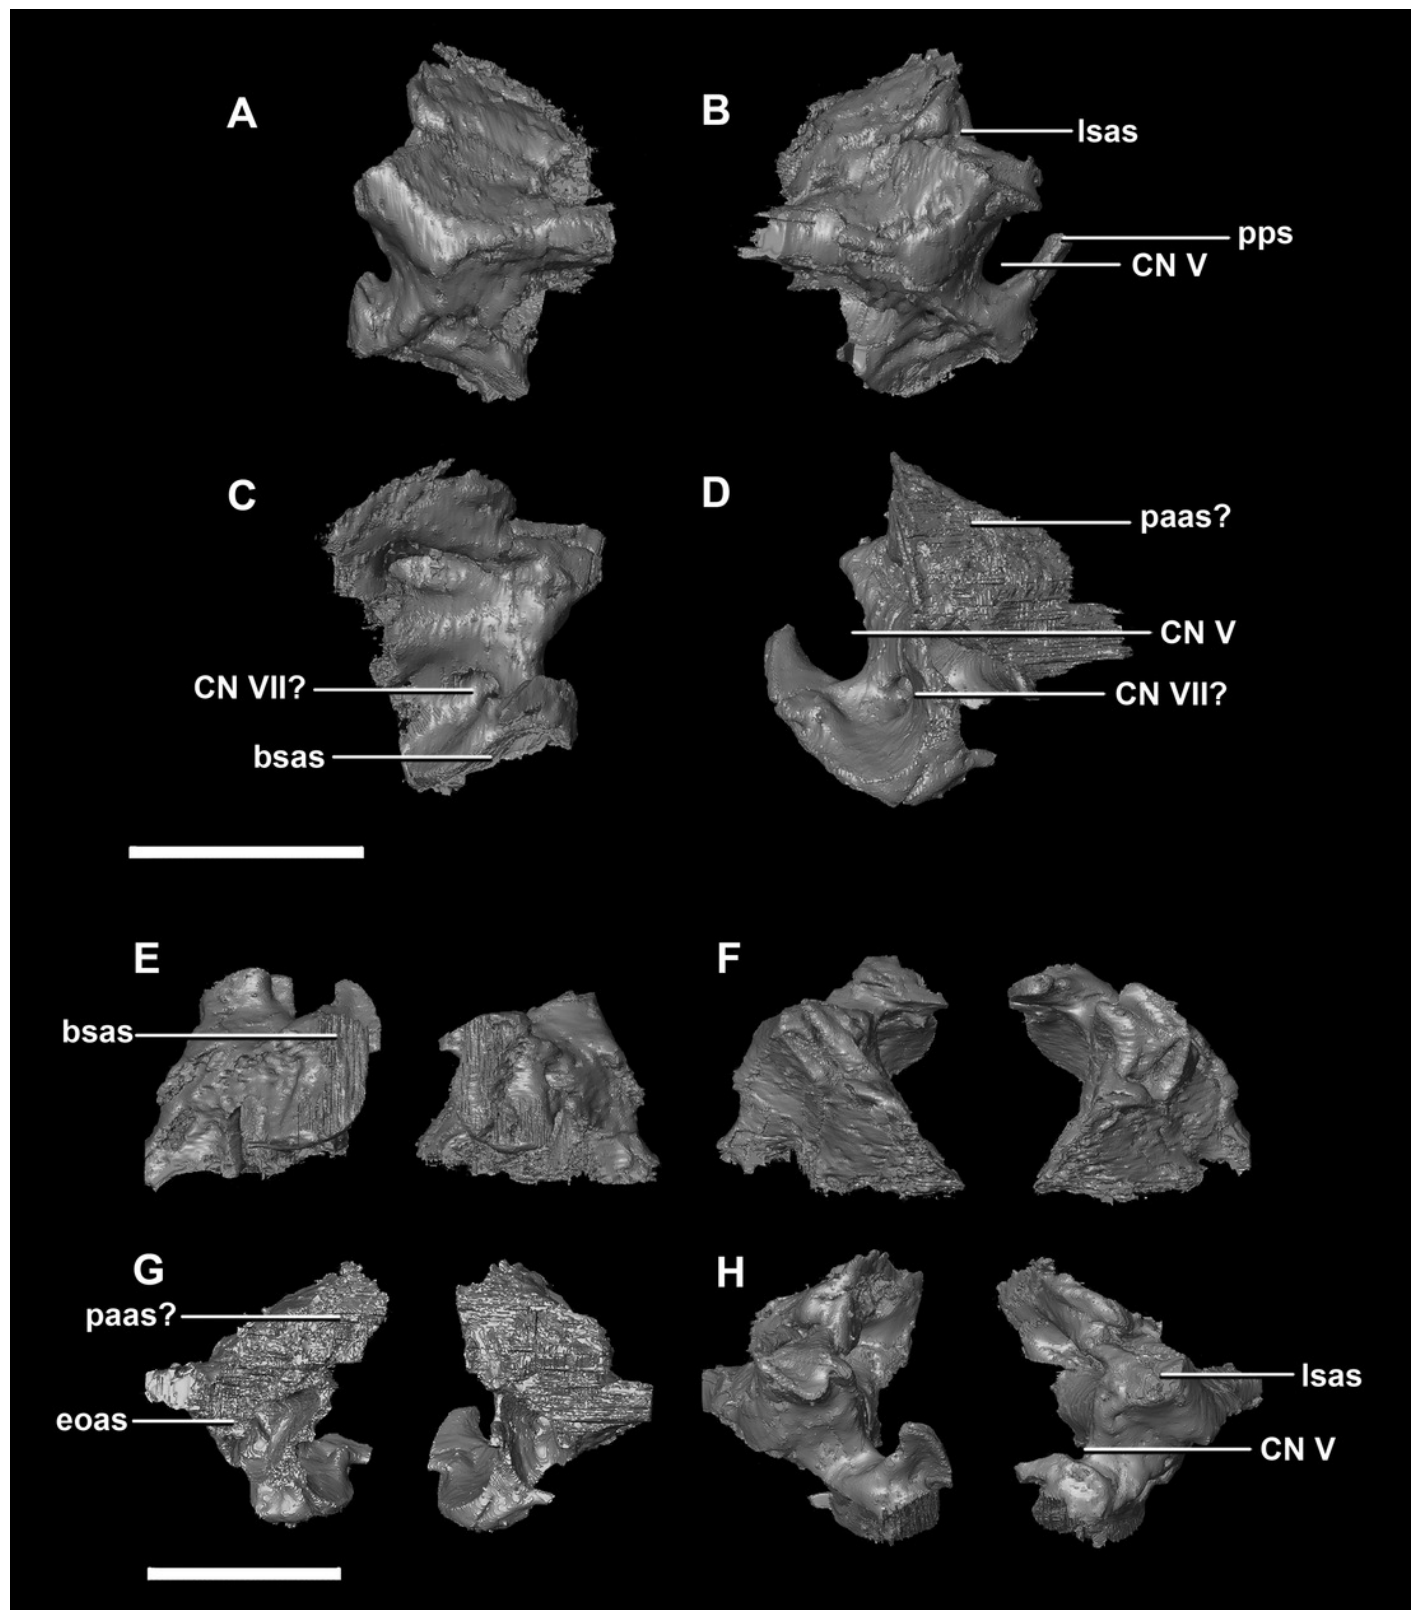

Figure 18

Parietals of juvenile *P. lujiatunensis* (IVPP V22647).

(A) Left lateral view. (B) Right lateral view. (C) Ventral view. (D) Dorsal view. (E) Posterior view. (F) Anterior view. fras, frontal articular surface; lsas, laterosphenoid articular surface; pras, prootic articular surface; ps?, potential parietal shelf; sc, sagittal crest; soas, supraoccipital articular surface. Scale bar represents 10 mm.

Figure 19

Frontals of juvenile *P. lujiatunensis* (IVPP V22647).

(A) Left lateral view. (B) Right lateral view. (C) Ventral view. (D) Dorsal view. (E) Posterior view. (F) Anterior view. cc, cerebral cavity; fc, frontal crest; lsas, laterosphenoid articular surface; nas, nasal articular surface; no, notch; om, orbital margin; paas, parietal articular surface; poas, postorbital articular surface. Scale bar represents 10 mm.

Figure 20

Segmented braincase of adult *P. lujiatunensis* (IVPP V12617).

(A) Lateral view. (B) Ventral view. (C) Dorsal view. (D) Posterior view. (E) Anterior view. bo, basioccipital; bpc, basisphenoid-parasphenoid complex; fr, frontal; ls, laterosphenoid; os, orbitosphenoid; pa, parietal; pp, paroccipital processes; pr, prootic; so, supraoccipital. Scale bar represents 20 mm.

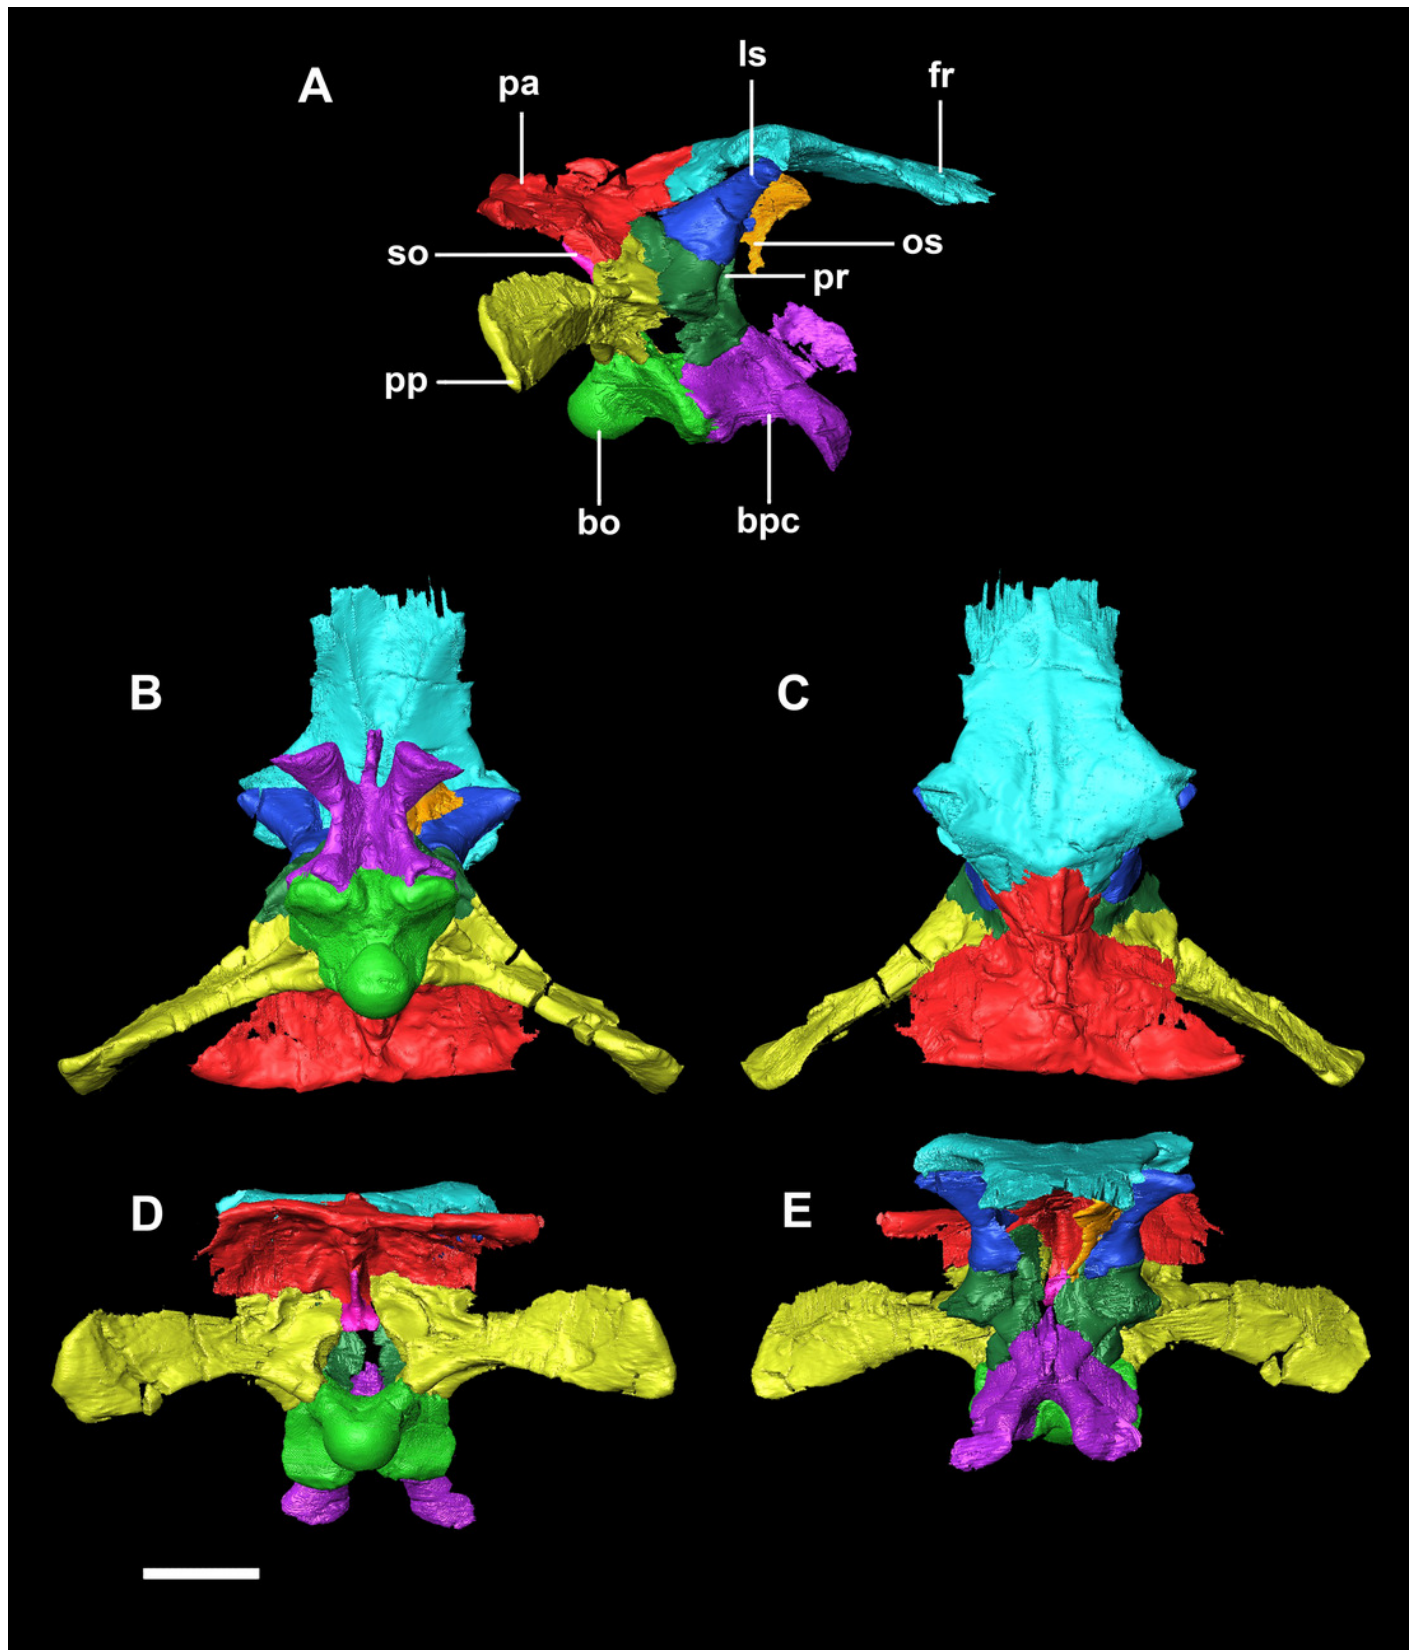

Figure 21

Basioccipital of adult *P. lujiatunensis* (IVPP V12617).

(A) Left lateral view. (B) Right lateral view. (C) Ventral view. (D) Dorsal view. (E) Posterior view. (F) Anterior view. boc, basioccipital condyle; bsas, basisphenoid articular surface; bt, basal tubera; btg, basal tubera groove; cdn, condylar neck; eoas, exoccipital articular surface; ng, neural groove. Scale bar represents 10 mm.

Figure 22

Basisphenoid of adult *P. lujiatunensis* (IVPP V12617).

(A) Left lateral view. (B) Right lateral view. (C) Ventral view. (D) Dorsal view. (E) Posterior view. (F) Anterior view. boas, basioccipital articular surface; bpp, basipterygoid process; bsr, basisphenoid recess; bt, basal tubera; cfo, carotid foramen; cp, cultriform process; pct, paracultriform trough; pras, prootic articular surface; ptas, pterygoid articular surface; st, sella turcica. Scale bar represents 10 mm.

Figure 23

Supraoccipital of adult *P. lujiatunensis* (IVPP V12617).

(A) Left lateral view. (B) Right lateral view. (C) Ventral view. (D) Dorsal view. (E) Posterior view. (F) Anterior view. eoas, exoccipital articular surface; paas, parietal articular surface. Scale bar represents 10 mm.

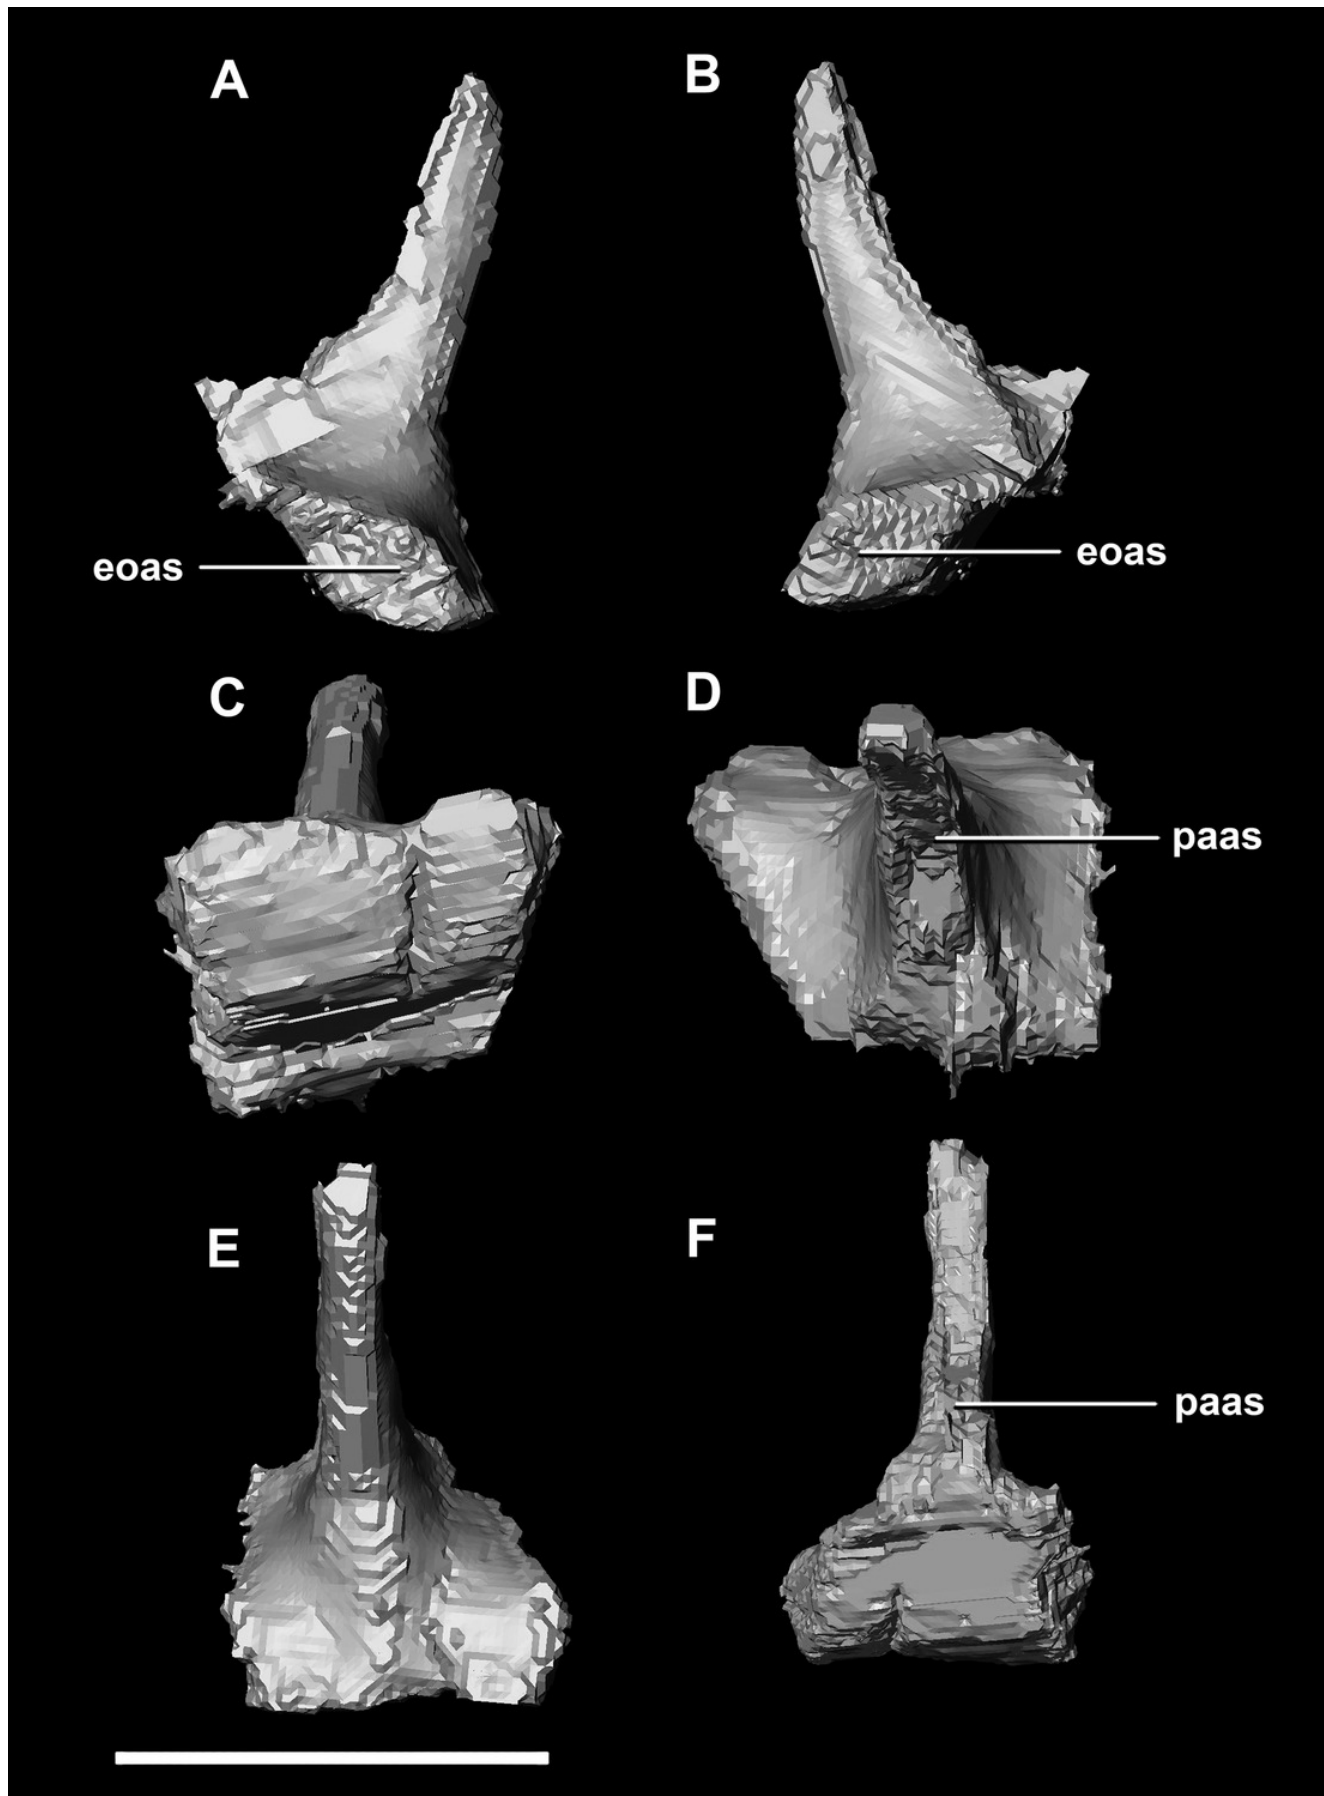

Figure 24

Paroccipital processes of adult *P. lujiatunensis* (IVPP V12617).

(A) Left lateral view. (B) Right lateral view. (C) Left medial view. (D) Right medial view. (E) Ventral view. (F) Dorsal view. (G) Posterior view. (H) Anterior view. boas, basioccipital articular surface; fm, foramen magnum; pop, paroccipital process; pras, prootic articular surface; CN X-XII, approximate location of the foramen transmitting the vagus nerve, accessory nerve, and the hypoglossal nerve. Scale bar represents 10 mm.

Figure 25

Laterosphenoid of adult *P. lujiatunensis* (IVPP V12617).

(A) Left lateral view. (B) Right lateral view. (C) Ventral view. (D) Dorsal view. (E) Posterior view. (F) Anterior view. fras, frontal articular surface; lsh, laterosphenoid head; osas, orbitosphenoid articular surface; pras, prootic articular surface. Scale bar represents 10 mm.

Figure 26

Orbitosphenoid of adult *P. lujiatunensis* (IVPP V12617).

(A) Left lateral view. (B) Left medial view. (C) Posterior view. (D) Anterior view. Isas, laterosphenoid articular surface; CN II, optic nerve. Scale bar represents 10 mm.

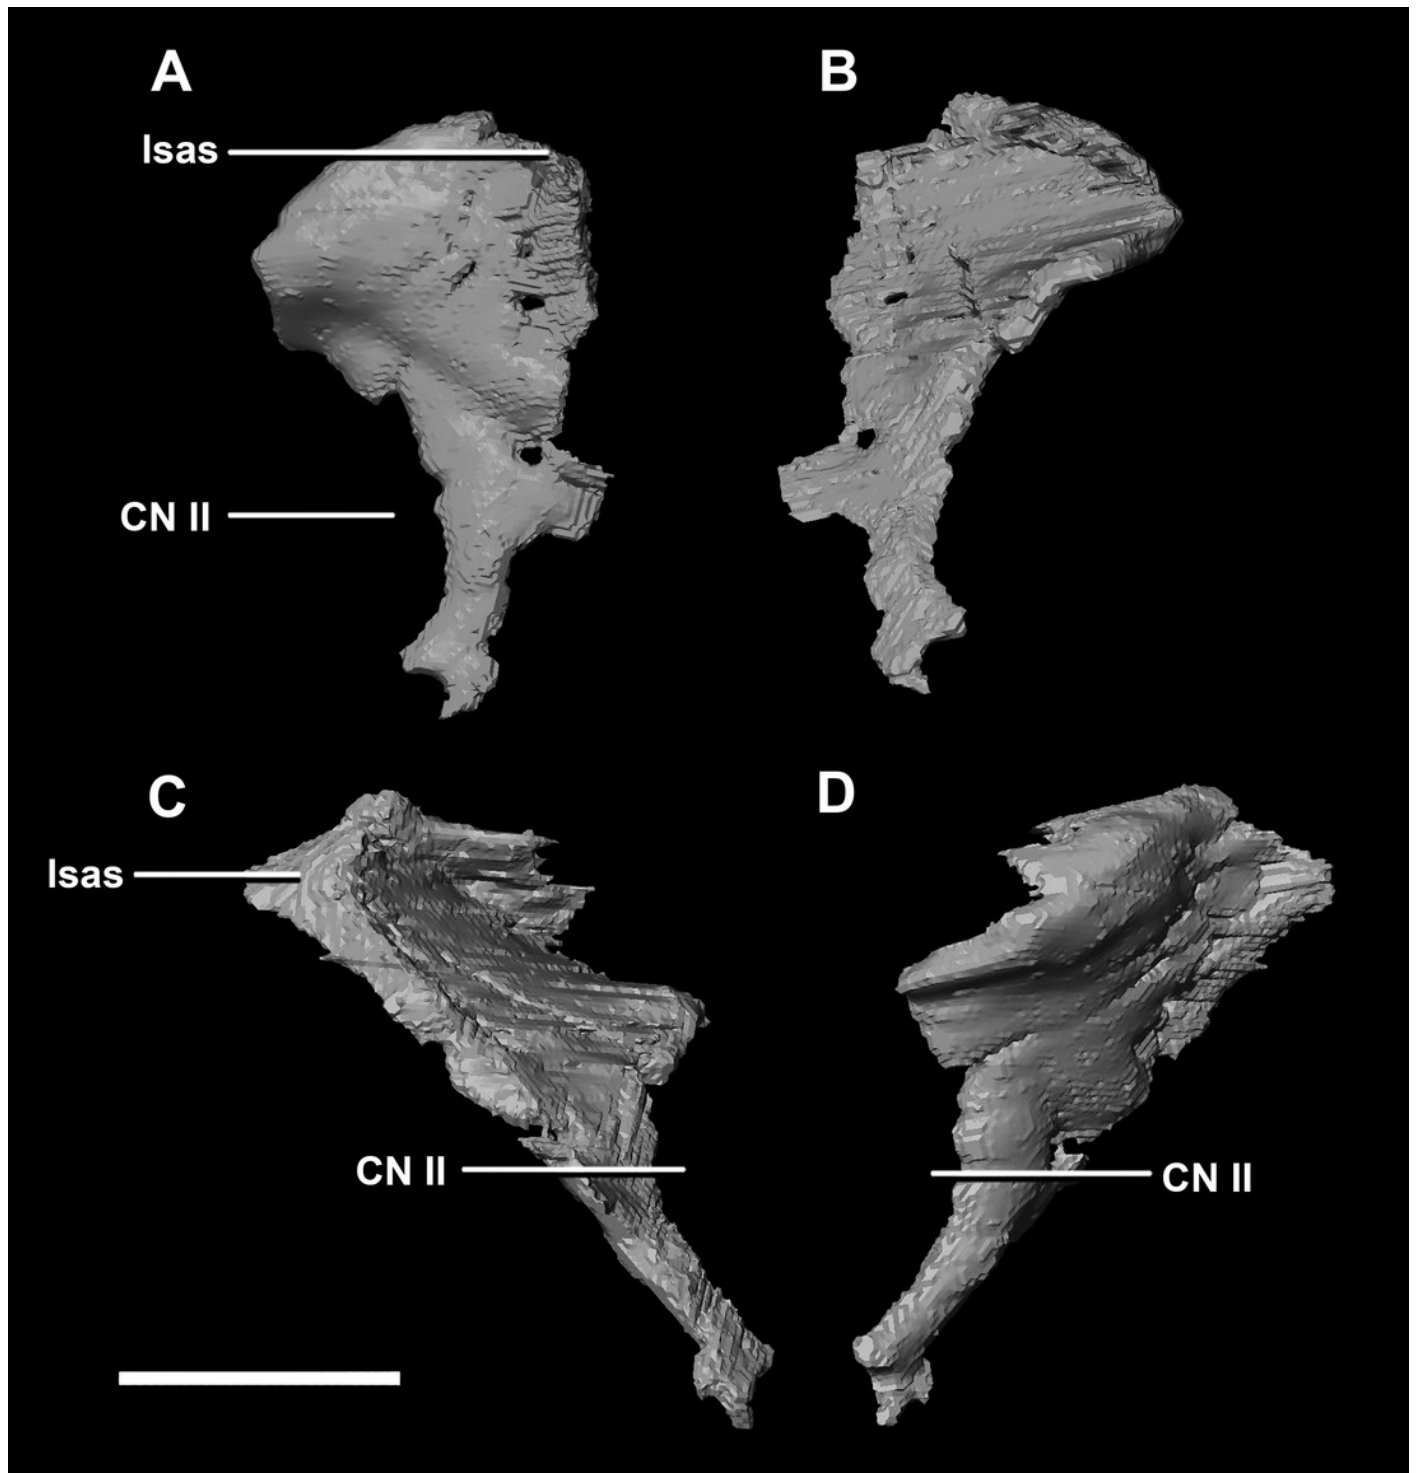

Figure 27

Prootics of adult *P. lujiatunensis* (IVPP V12617).

(A) Left lateral view. (B) Right lateral view. (C) Left medial view. (D) Right medial view. (E) Ventral view. (F) Dorsal view. (G) Posterior view. (H) Anterior view. bsas, basioccipital articular surface, eoas, exoccipital articular surface; lsas, laterosphenoid articular surface; pps, preprootic strut; sccp, semicircular canal pathway; CN V, trigeminal nerve. Scale bar represents 10 mm.

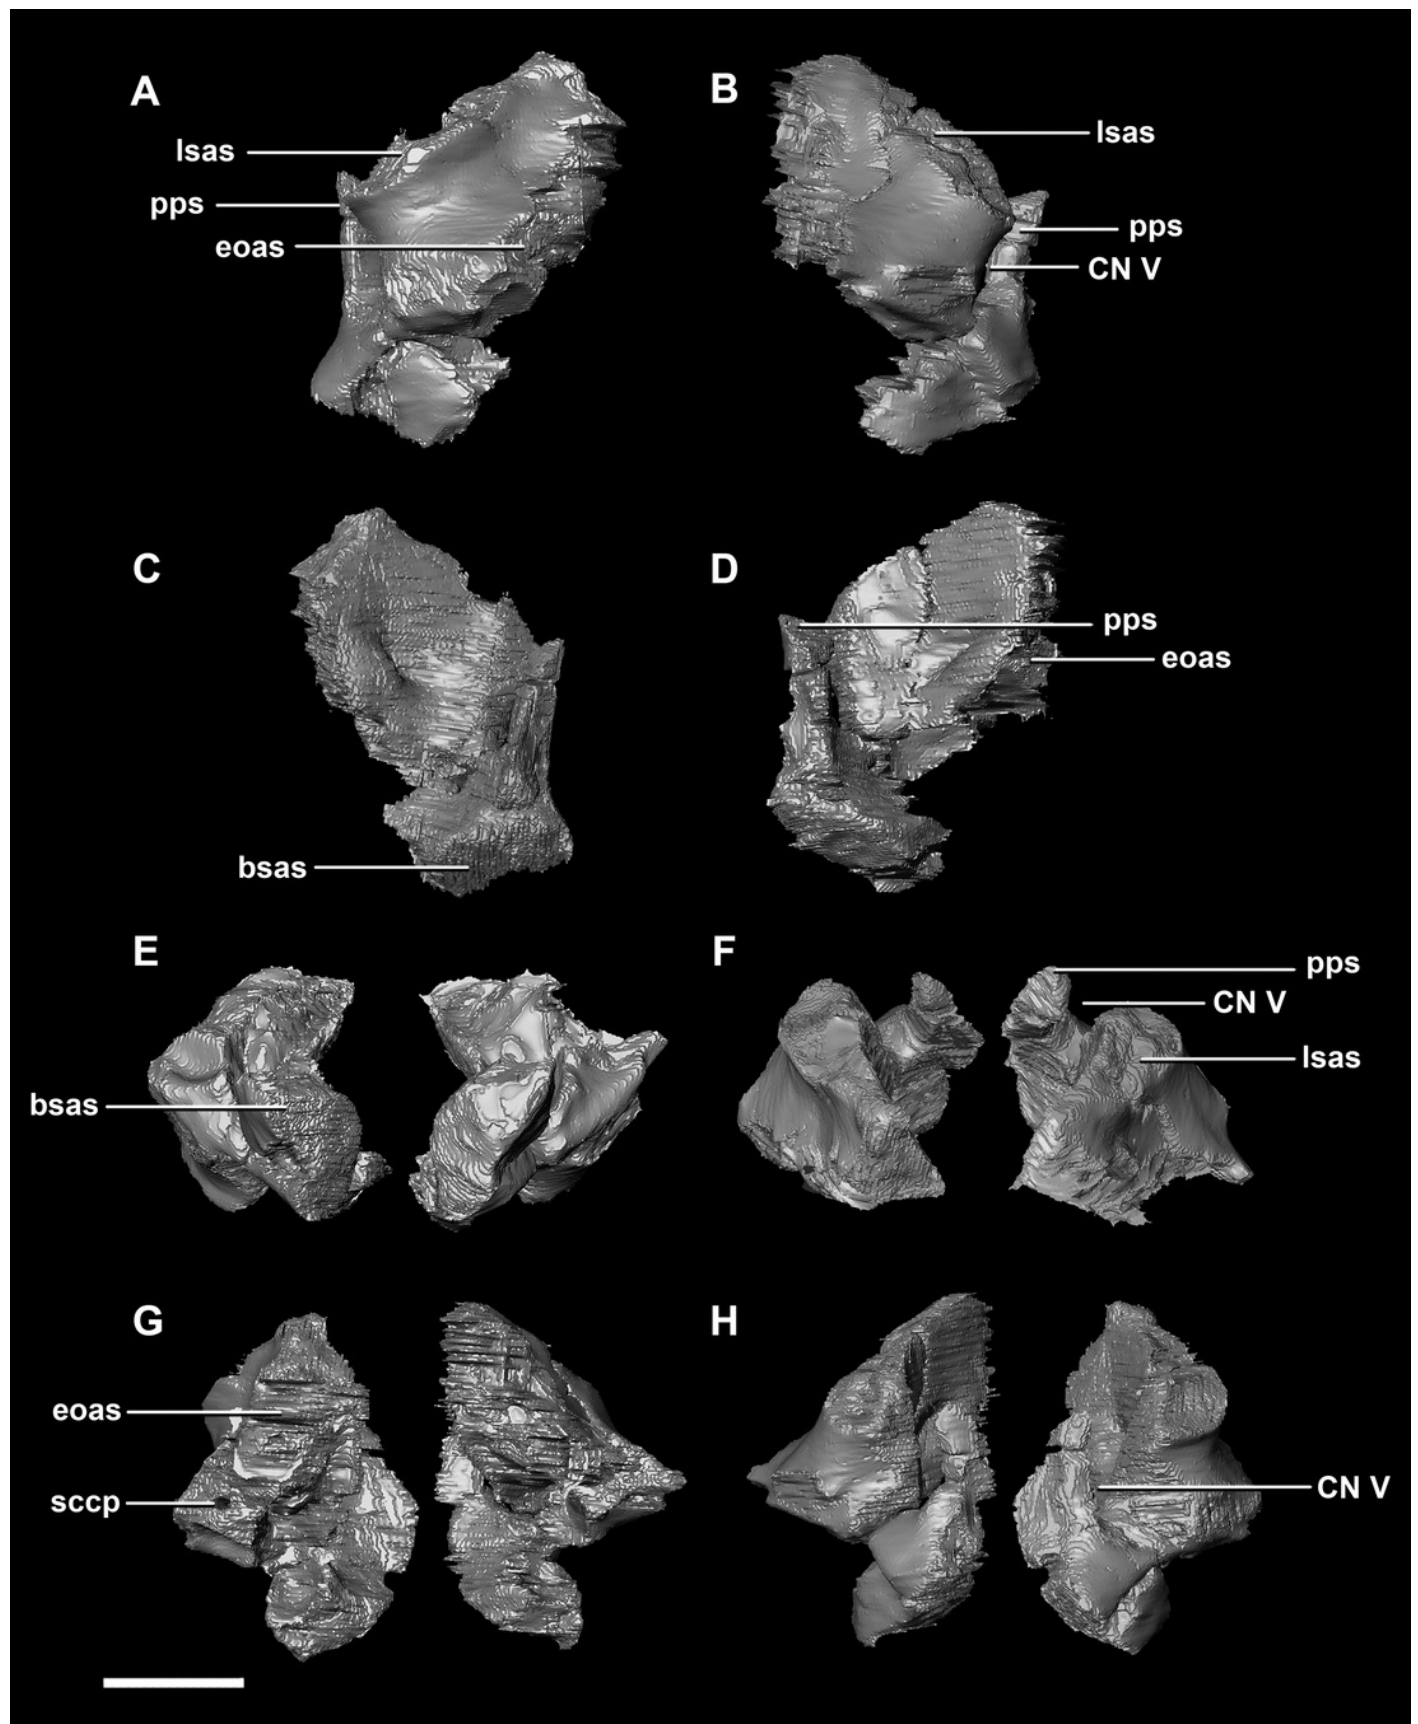

Figure 28

Parietals of adult *P. lujiatunensis* (IVPP V12617). (A) Left lateral view.

(A) Left lateral view. (B) Right lateral view. (C) Ventral view. (D) Dorsal view. (E) Posterior view. (F) Anterior view. eoas, exoccipital articular surface; fras, frontal articular surface; lsas, laterosphenoid articular surface; pmr, parietal midline ridge; sc, sagittal crest; soas, supraoccipital articular surface; sqas, squamosal articular surface. Scale bar represents 10 mm.

Figure 29

Frontals of adult *P. lujiatunensis* (IVPP V12617).

(A) Left lateral view. (B) Right lateral view. (C) Ventral view. (D) Dorsal view. (E) Posterior view. (F) Anterior view. cc, cerebral cavity; fc, frontal crest; lsas, laterosphenoid articular surface; nas, nasal articular surface; no, notch; om, orbital margin; paas, parietal articular surface; poas, postorbital articular surface. Scale bar represents 10 mm.

Figure 30

Morphological changes of the basioccipital contribution to the basal tubera in ventral view and the location of the basal tubera within the braincase.

(A) Schematic view and (B) location of basal tubera of hatchling. (C) Schematic view and (D) location of basal tubera of juvenile. (E) Schematic view and (F) location of basal tubera of adult. Not to scale.

Figure 31

Left semicircular canals displaying the angle between the ASC and the PSC.

Hatchling in (A) lateral and (B) dorsal views. Juvenile in (C) lateral and (D) dorsal views. Adult in (E) lateral and (F) dorsal views. ASC, anterior semicircular canal; PSC, posterior semicircular canal; HSC, horizontal semicircular canal. Inferred sections in red. Not to scale.

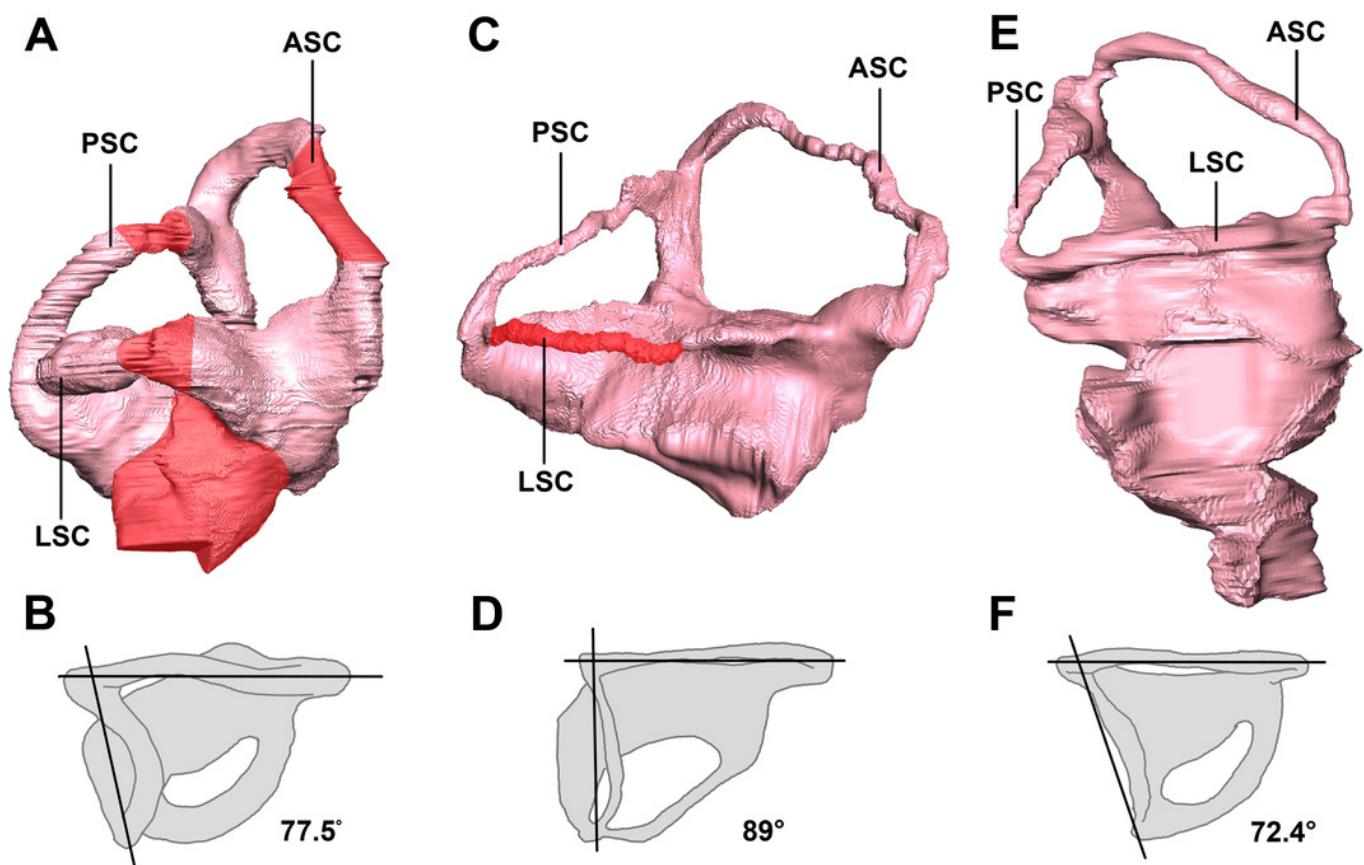

Figure 32

Head posture if LSC is parallel to the ground.

(A) Hatchling. (B) Juvenile. (C) Adult. Not to scale.

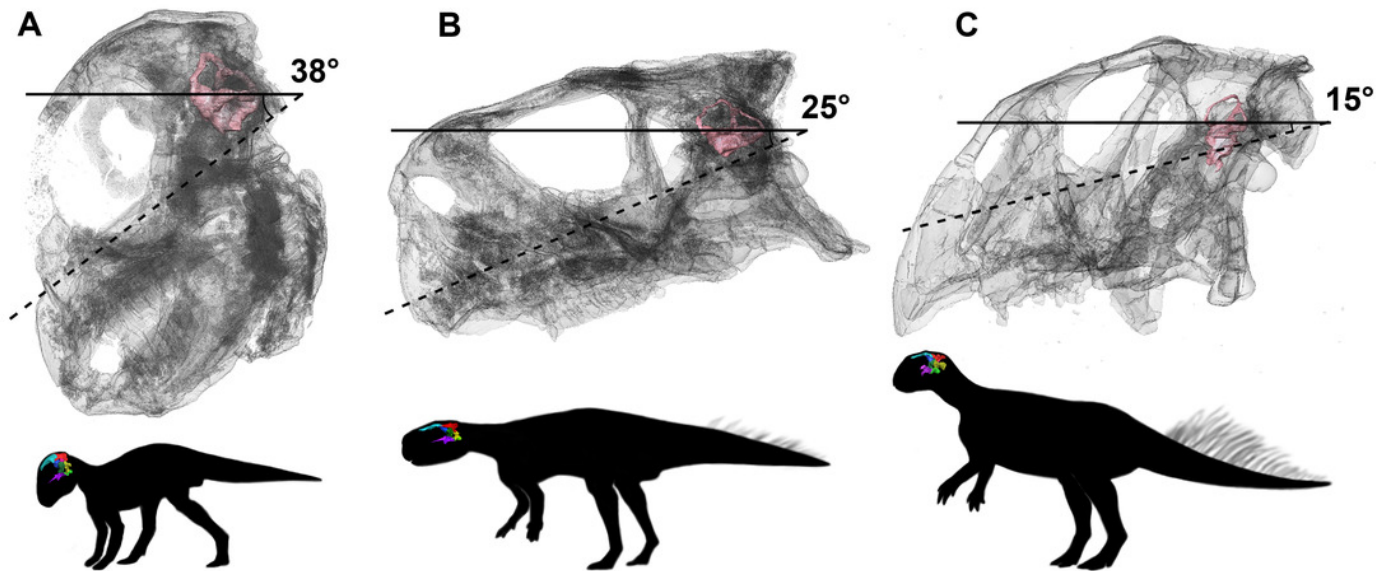

Figure 33

Schematic drawing of foramen for cranial nerves X-XII.

(A) Hatchling. (B) Juvenile. (C) Adult. Not to scale.

Figure 34

Prominent ontogenetic changes in the braincase of *Psittacosaurus lujiatunensis*.

(A) Lateral view. (B) Posterior view. (C) Hatchling and (D) adult braincases *in situ*. Not to scale.

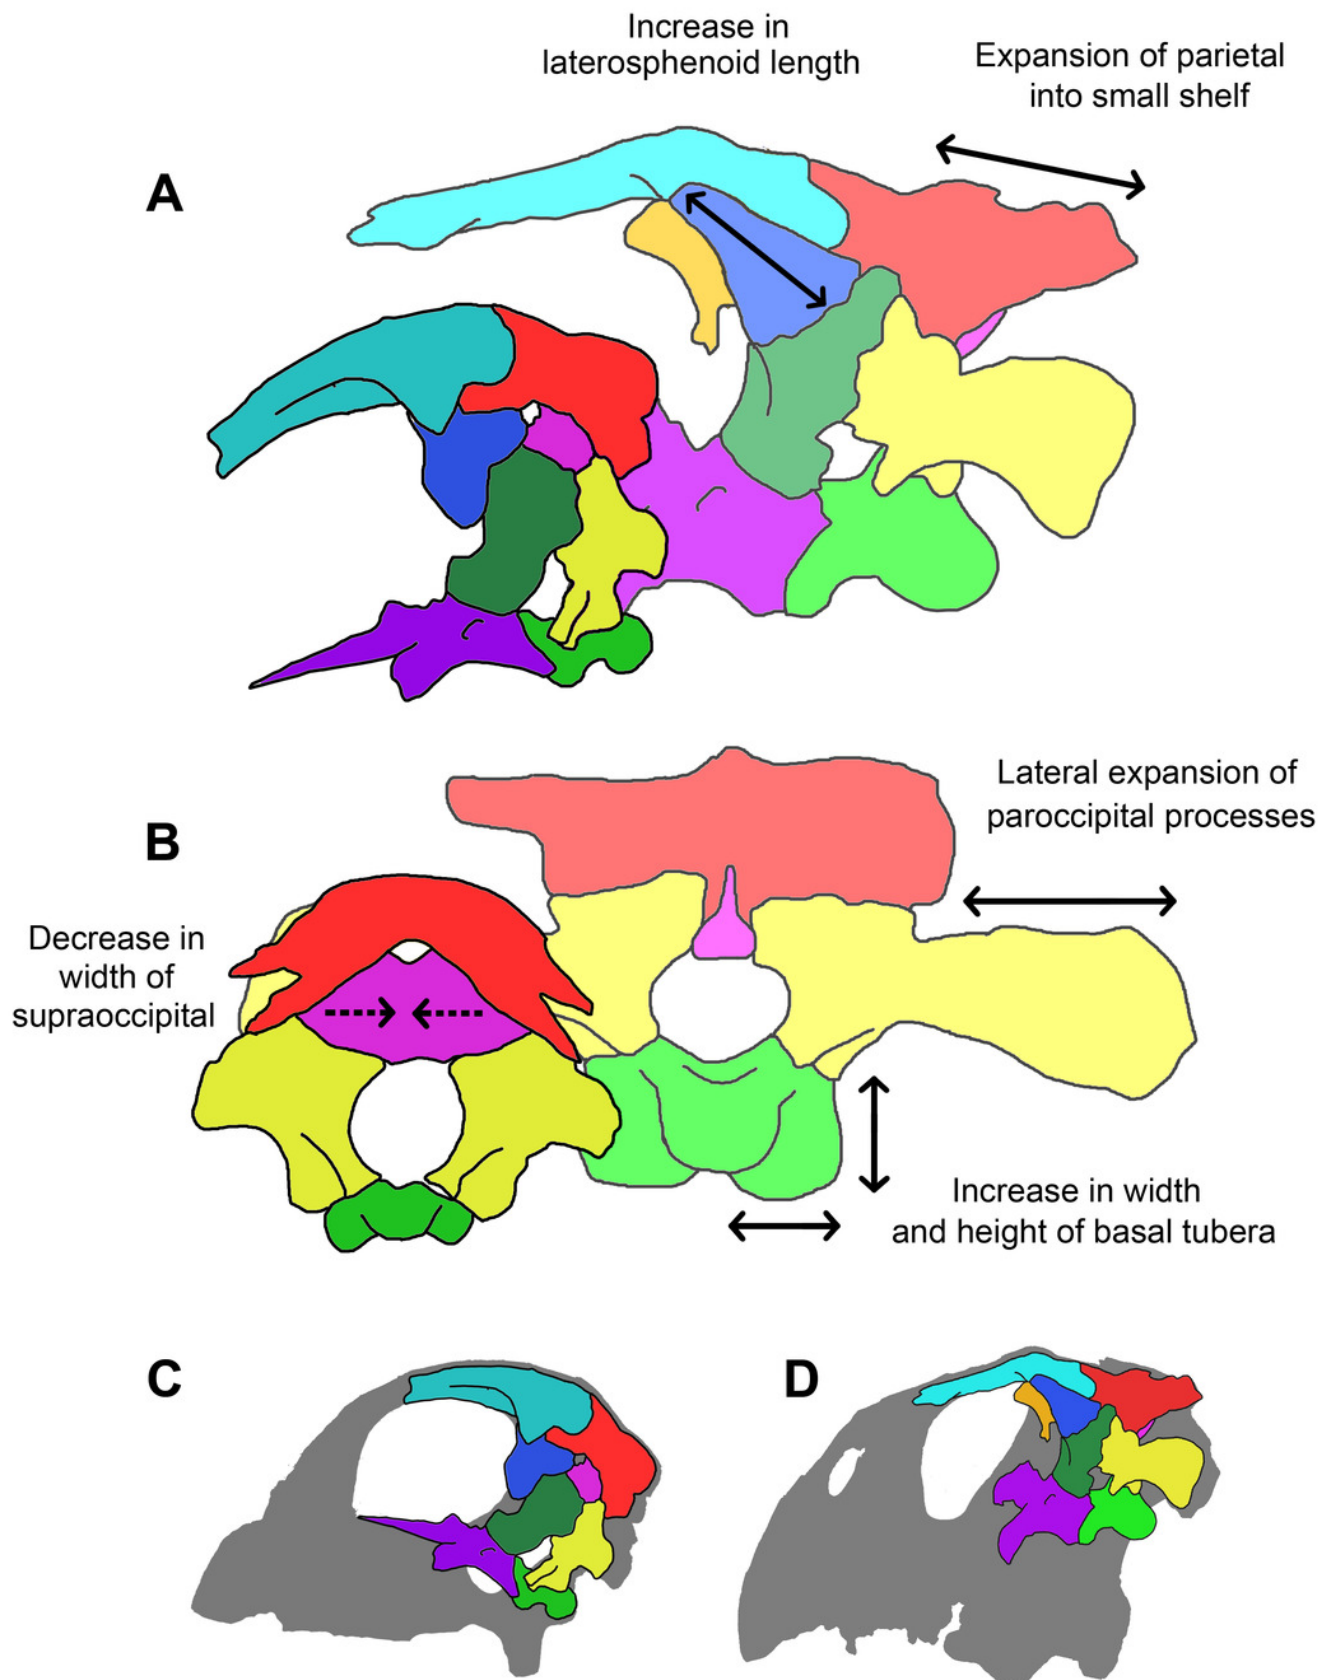

Table 1(on next page)

Element sizes in relation to base skull length (%) and the total % change between hatchling and adult.

bo, basioccipital; bsp, basisphenoid; bt, basal tubera; cp, cultriform process; fr, frontal; lsp, laterosphenoid; OC, occipital condyle; par, parietal; pop, paroccipital process; pr, prootic; soc, supraoccipital. W, width; l, length; h, height.

	Hatchling			Juvenile			Adult			
	Element (mm)	Skull (mm)	%	Element (mm)	Skull (mm)	%	Element (mm)	Skull (mm)	%	Total % change
