For reefs in SE Asia the synergistic effects of rapid land-development, insufficient environmental policies and a lack of enforcement has led to poor water quality and compromised coral health from increased sediment and pollution. Those inshore turbid coral reefs, subject to significant sediment inputs, may also inherit some resilience to the effects of thermal stress and coral bleaching. We studied the inshore turbid reefs near Miri, in northwest Borneo through a comprehensive assessment of coral cover and health in addition to quantifying sediment-related parameters. Although Miri Reefs had comparatively low coral species diversity, dominated by massive and encrusting forms of *Diploastrea*, *Porites*, *Montipora*, *Favites*, *Dipsastrea* and *Pachyseris*, they were characterised by a healthy cover ranging from 22-39%. We found a strong inshore to offshore gradient in hard coral cover, diversity and community composition as a direct result of spatial differences in sediment at distances <10 kms. As well as distance to shore, we included other environmental variables like reef depth and sediment trap accumulation that explained 62.5% of variation in benthic composition among sites. Miri's reefs showed little evidence of coral disease and relatively low prevalence of compromised health signs including bleaching (6.7%), bioerosion (6.6%), pigmentation (2.2%), scars (1.1%) and mucus production (0.5%). Tagged colonies of *Diploastrea* and *Pachyseris* suffering partial bleaching in 2016 had fully (90-100%) recovered the following year. There were, however, seasonal differences in bioerosion rates, which increased five-fold after the 2017 wet season. Differences in measures of coral physiology, like that of symbiont density and chlorophyll *a* for *Montipora*, *Pachyseris* and *Acropora*, were not detected among sites. We concluded that Miri's reefs may be in a temporally stable state given

minimal recently dead coral and a limited decline in coral cover over the last two decades. This study provides further evidence that turbid coral reefs exposed to seasonally elevated sediment loads can exhibit relatively high coral cover and be resilient to disease and elevated sea surface temperatures.

21 **ABSTRACT**

22 For reefs in SE Asia the synergistic effects of rapid land-development, insufficient
23 environmental policies and a lack of enforcement has led to poor water quality and compromised
24 coral health from increased sediment and pollution. Those inshore turbid coral reefs, subject to
25 significant sediment inputs, may also inherit some resilience to the effects of thermal stress and
26 coral bleaching. We studied the inshore turbid reefs near Miri, in northwest Borneo through a
27 comprehensive assessment of coral cover and health in addition to quantifying sediment-related
28 parameters. Although Miri Reefs had comparatively low coral species diversity, dominated by
29 massive and encrusting forms of *Diploastrea*, *Porites*, *Montipora*, *Favites*, *Dipsastrea* and
30 *Pachyseris*, they were characterised by a healthy cover ranging from 22-39%. We found a
31 strong inshore to offshore gradient in hard coral cover, diversity and community composition as
32 a direct result of spatial differences in sediment at distances <10 kms. As well as distance to
33 shore, we included other environmental variables like reef depth, sediment trap accumulation and
34 particle size that explained 62.5% of variation in benthic composition among sites. Miri's reefs
35 showed little evidence of coral disease and relatively low prevalence of compromised health
36 signs including bleaching (6.7%), bioerosion (6.6%), pigmentation (2.2%), scars (1.1%) and
37 mucus production (0.5%). Tagged colonies of *Diploastrea* and *Pachyseris* suffering partial
38 bleaching in 2016 had fully (90-100%) recovered the following year. There were, however,
39 seasonal differences in bioerosion rates, which increased five-fold after the 2017 wet season.
40 Differences in measures of coral physiology, like that of symbiont density and chlorophyll *a* for
41 *Montipora*, *Pachyseris* and *Acropora*, were not detected among sites. We concluded that Miri's
42 reefs may be in a temporally stable state given minimal recently dead coral and a limited decline
43 in coral cover over the last two decades. This study provides further evidence that turbid coral

44 reefs exposed to seasonally elevated sediment loads can exhibit relatively high coral cover and
45 be resilient to disease and elevated sea surface temperatures.

46

47 **INTRODUCTION**

48 Turbid reefs are commonly regarded as marginal reefs living near their environmental limits
49 (Kleypas et al., 1999; Guinotte et al., 2003; Perry and Larcombe, 2003; Palmer et al., 2010;
50 Goodkin et al., 2011). As such, these reefs are traditionally perceived to be in a reduced health
51 status (Kleypas, 1996; Kleypas et al., 1999) and more sensitive to rising sea surface temperatures
52 (SST; Nugues and Roberts, 2003; Crabbe and Smith, 2005; Fabricius, 2005; Woolridge, 2008).
53 Yet there is growing evidence that turbid reefs may actually be more resilient to future climate
54 change effects (Goodkin et al., 2011; Morgan et al., 2017) and serve as refugia for surviving
55 corals (Cacciapaglia and van Woesik, 2015; 2016; Morgan et al., 2016). This has been
56 demonstrated on turbid reefs with high coral cover and diversity yet experience significant
57 sediment and nutrient inputs, low bleaching, and rapid recovery rates from bleaching and
58 cyclonic events (Larcombe et al., 2001; Browne et al., 2010; Richards et al., 2015; Morgan et al.,
59 2016). Studying the level of resilience and survival of turbid reefs in different environmental
60 settings will provide clearer insights into the future of reefs subject to climate change (Guinotte
61 et al., 2003; Hennige et al., 2010; Richards et al., 2015).

62

63 Despite elevated resilience to naturally turbid conditions, many inshore turbid reefs face threats
64 from local pressures, largely related to declining water quality and increased sediment input. In
65 South East (SE) Asia, 95% of reefs are threatened from local sources and, therefore, are,
66 regarded as the most endangered reefs globally (Burke et al., 2011). From the 1980's to early
67 2000's these reefs have suffered an average 2% loss in coral cover per year with hard coral cover
68 declining from 45% to 22% in 2003 (Bruno and Selig, 2007). Most SE Asian reefs are located in
69 close proximity to countries with rapidly emerging economies and fast population growth
70 (Wilkinson, 2006; Burke et al., 2011; Heery et al., 2018). They are further characterised by
71 poorly developed environmental policies, inadequate regulation, lack of enforcement, a shortage
72 of institutional and technical capacity, insufficient community support and involvement, and
73 conflicts and tensions between stakeholders (Fidelman et al., 2012). The synergistic effects of
74 these factors has led to poor water quality on many inshore reefs via pollution and sediment input
75 derived by rapid land development, and over-fishing activities (McManus, 1997; Wilkinson,

76 2006). As a consequence, sedimentation rates are high ($>10 \text{ mg cm}^2 \text{ day}^{-1}$; Rogers 1990) with SE
77 Asian coastal systems experiencing the highest siltation loads globally (Kamp-Nielsen et al.,
78 2002; Syvitski et al., 2005).

79

80 Nearshore coral reefs along the north central section of Sarawak, on the island of Borneo, are
81 highly diverse with an estimated 518 fish species (Shabdin, 2014) and 203 hard coral species
82 from 66 genera (Elcee Instrumentation, 2002). Sarawak is a deforestation hotspot with only 3% of
83 its forest cover intact (Bryan et al., 2013). Ongoing deforestation and poor land use practices are
84 a growing threat for these biological diverse reefs that also support local fisheries and an
85 expanding dive tourism industry (Elcee Instrumentation, 2002). As such, in 2007 a marine park
86 (the Miri-Sibuti Coral Reef National Park; MSCRNP) that covered 11,020 km^2 was established
87 to promote and protect 30 coral reefs adjacent to Miri, the second largest town in Sarawak. In
88 2001, a broad assessment of coral reef health within the park indicated that live coral cover was
89 approximately 35-50% and dead coral cover was 0.5% (Elcee Instrumentation, 2002). Subsequent
90 Reef Check surveys in 2010 and 2014 concluded these same reefs were experiencing multiple
91 stressors, but were in 'fair' condition ($\sim 40\%$ HCC; Reef Check, 2010;2014). However, despite
92 these claims there is limited quantitative data on coral health and biodiversity (Shabdin, 2014),
93 and more importantly no comprehensive assessment of environmental drivers of reef health. For
94 example, the Baram River (10 km north of the reef complex), is known to discharge 2.4×10^{10}
95 kg yr^{-1} of sediments into the coastal zone (Straub and Mohrig, 2009), such that sediment and
96 nutrient influx are considered to be the greatest threat to these poorly studied reefs (Pilcher and
97 Cabanban, 2000; Ferner, 2013; Shabdin, 2014). Without thoroughly quantifying sediment
98 impacts on corals, no conclusions can be made on coral tolerance levels, the drivers of
99 community composition and future resilience to both local and global pressures. Given the
100 Baram River delta is in a destructive phase due to rising sea level (Lambiase et al., 2002),
101 together with the increased frequency and intensity of rainfall events and plans for future
102 modification of both the river and adjacent land development (Nagarajan et al., 2015), it is likely
103 that threats from sediments will only increase.

104

105 The reefs within the MSCRNP provide a valuable opportunity to address several knowledge gaps
106 on turbid coral reef health and their potential resilience to local and global threats. The last

107 comprehensive assessment of coral cover on Miri's reefs was in 2001, with no assessments of
108 coral taxa health and disease for any Sarawak reefs recorded to date. In particular, coral disease
109 studies are rarely undertaken on SE Asian reefs largely due to a lack of resources and expertise
110 (Green and Bruckner, 2000; Raymundo et al., 2005; Heintz et al., 2015). The lack of quantitative
111 data on the health and stability (as defined by resistance, resilience and maintenance of key
112 functional groups) of these reefs coupled with ongoing unsustainable land use practices in
113 Sarawak, raises concerns over their long-term viability. This is of particular concern as Sarawak
114 reefs currently provide an estimated revenue of 6 million AUD per year in tourism and 13.5
115 million AUD from fisheries (Elcee Instrumentation, 2002). We argue there is an urgent need for a
116 comprehensive assessment of coral cover and health measured alongside key environmental and
117 sediment-related parameters. The key objectives of this study therefore are to: 1) quantify
118 benthic cover, coral cover and health, 2) compare the prevalence of impaired health in the
119 dominant coral species, 3) identify key parameters related to sediment delivery that influence
120 benthic cover and health along an inshore to offshore gradient, and 4) assess how resilient these
121 inshore reefs are to future changes in sediment supply. These data will improve our
122 understanding of turbid coral reefs composition and potential resilience to both local and global
123 stressors, and promote current management strategies that aim to protect inshore turbid reefs
124 from future changes to land use.

125

126 **MATERIALS & METHODS**

127 **Study sites**

128 The study was conducted on three low profile submerged patch reefs (Eve's Garden, Anemone
129 Garden and Siwa Reef) in the MSCRNP (Fig. 1). These sites were of a comparable depth (5-15
130 m) and size ($<0.11 \text{ km}^2$). Eve's Garden (EG) is a shallow inshore reef close to shore (7.3 km)
131 with a coral community dominated by platy and massive corals such as *Pachyseris* sp. and
132 *Porites* sp. (Ferner, 2013). Anemone Garden (AG) is further offshore (11.7 km) and consists of a
133 considerable density of anemone colonies, with platy forms of *Acropora* sp. and exceptionally
134 large massive *Porites* sp. and *Diploastrea* sp. colonies (1-5 m length). Siwa Reef (SW) situated
135 further to the south is the most biologically diverse of the studied reefs consisting of encrusting
136 and massive coral forms (Ferner, 2013). These reefs lie on an inshore to offshore transect from

137 the Baram (sediment influx 2.4×10^{10} kg.year⁻¹; Nagarajan et al., 2015) and Miri River mouths,
138 located to the north of EG (10 km from Miri River and 30 km from Baram River).

139

140 Physical (temperature, light, turbidity and sediment trap accumulation) and biological (benthic
141 cover, coral health) data were collected at the end of the dry season (15th September to 20th
142 October 2016) and during the wet season (11th May to 3rd June 2017). At each of the three reefs,
143 six replicate line transects (20 m), separated by 20 m intervals to ensure independence were run
144 across the reef surface (EG = 8-12 m; AG =10-14 m; SW= 8-14 m). These reefs are not
145 characterized by typical windward and leeward reef edges, but are low profile patch reefs where
146 the majority of the reef sits in one relatively flat plane, sloping gently on all sides to the sea floor.
147 As such, all transects were laid out along the same axis across the flat section of each reef.

148

149 **Physical data collection**

150 Seasonal changes in light (measured with Photosynthetic Irradiance Recording System by
151 Odyssey, New Zealand) and temperature (measured with HOBO Pro V2 loggers, Australia) were
152 recorded every 10 minutes from September 2016 for 9 months (temperature at EG and AG) and
153 12 months (light at EG). To capture changes in suspended sediment loads over a tidal cycle,
154 turbidity loggers were deployed (in a horizontal position) for two weeks at the end of the 2016
155 dry season (September; EG and SW) and end of the 2017 wet season (May; EG; AQUA logger
156 210/310TY, Aquatech, UK). Data on cloud cover, rainfall and wind speed over the period from
157 October 2016 to October 2017 was retrieved from the online database World Wide Weather
158 (2017).

159

160 To assess small-scale spatial variation in sediment trap accumulation, four sediment traps per
161 three transects (8 traps in total per reef) were deployed at each reef in September 2016 to collect
162 sediments during the NE monsoon. Each trap consisted of 3 cylindrical PVC plastic containers
163 (diameter of 7.6 cm) attached to a metal rod positioned 30 cm above the substrate (Storlazzi et
164 al., 2011). The traps remained *in-situ* until May 2017. To determine if trapped sediments were
165 from local resuspension or transported on to the reef, 500 g of benthic sediment at the base of
166 each trap was sampled. The content of each container was emptied into a labelled plastic bag

167 and stored at -20°C until further analysis at the Curtin University Malaysia Laboratory facilities
168 (Laboratory SK2 204), Malaysia.

169

170 Sediment samples were analysed for weight and particle size characteristics. Frozen samples
171 were thawed and allowed to settle overnight. Water remaining on the surface was filtered (0.45
172 μm filter paper) to capture the fine suspended sediments. The sediments (washed, settled and
173 filtered) were oven-dried at 60°C for 2-3 weeks and weighed to the nearest 0.001 g .

174 Sedimentation accumulation rate ($\text{g cm}^2 \text{ day}^{-1}$) was calculated as the weight of sediment trapped
175 (g) divided by the number of days the trap was deployed and the surface area of the trap (cm^2).

176 For the grain size analysis, the settled dry sediments were manually homogenized and weighed
177 before sieving. The sediments were homogenized using a pestle and mortar given the sediments
178 were mostly sand and loosely aggregated. Sediments were separated into 5 class fractions (>1
179 mm , 500 to $<1000\ \mu\text{m}$, 250 to $<500\ \mu\text{m}$, 125 to $<250\ \mu\text{m}$ and 63 to $125\ \mu\text{m}$) by placing the sieve
180 stack on a mechanical shaker for 20 minutes. Each of the 5 sediment fractions were weighed to
181 the nearest 0.001 g .

182

183 **Biological data collection**

184 *In water data collection*

185 The benthic cover and coral diversity (to genus level) were assessed in September 2016 using the
186 photographic transect method (Bégin et al., 2013). Photographs were taken using a Canon
187 Powershot G7 mark II digital camera at a fixed height of 0.75 m above the transect line every 1
188 m along the transect ($n = 21$). Photographs ($1\ \text{m}^2$) were analysed in Coral Point Count (CPCe)
189 with a uniform grid of 25 points to calculate benthic cover for each of 7 categories (hard coral,
190 soft coral, recently dead coral, turf algae, macroalgae, sponge, abiotic substance) (CPCe; Kohler
191 and Gill, 2006). The hard coral category was further subdivided into 38 genera common to the
192 Indo-Pacific region according to Kelley (2009).

193

194 To assess seasonal fluctuations in coral reef health, signs of compromised health (disease,
195 bleaching, bioerosion, pigmentation, mucus production, scars) were recorded in September 2016
196 and May 2017. The belt transect methodology was used, covering a wider area along the transect
197 line via a zig-zag pattern ($40\ \text{m}^2$ for each $20\ \text{m}$ transect). Coral colonies within each belt transect

198 were identified to genus level and classified as either healthy or affected by an impaired health
199 sign (Beeden et al., 2008). Signs of bioerosion included the presence of organisms such as
200 Christmas tree worms, boring bivalves and sponges, and bleaching was further subdivided into
201 whole, partial, focal and non-focal bleaching (as defined in Beeden et al., 2008). To determine if
202 bleached corals recovered or died, a total of 14 coral colonies from EG and SW in both sampling
203 seasons that showed signs of bleaching were tagged and photographed (4 *Diploastrea* sp., 6
204 *Pachyseris* sp., 4 *Porites* sp.). The percentage of bleached tissue was assessed from scaled
205 photographs using CPCe software (1=normal, 2=pale, 3=0-20%, 4=20-50%, 5=50-80% and
206 6=80+% bleached). While this is a low sample size, the data is included to provide further
207 insight into the recovery potential of corals on these reefs. Field work was approved by the
208 Sarawak Forestry Commission (#61JHS/NCCD/600-7/2/107).

209

210 ***Symbiont density and chlorophyll a analysis***

211 In May 2017, fragments of three coral genera (*Montipora* sp., *Pachyseris* sp. and *Acropora* sp.)
212 were collected from EG, AG and SW for chlorophyll *a* and symbiont density analysis. Higher
213 chlorophyll *a* and symbiont densities are typically recorded on turbid reefs (Browne et al., 2015)
214 as this increases the coral's ability to photosynthesis under low light levels as they acclimate to
215 suspended sediments (Hennige et al., 2010). Fragments (5-10 cm for branching corals and ~10 x
216 10 cm for foliose corals) were collected using cutters and placed in plastic bags. Samples were
217 placed on ice during transportation back to the laboratory where they were stored at -80 °C until
218 further analysis. Symbiont density and chlorophyll *a* content were quantified following the
219 removal of coral tissue from the skeleton. The protocol for extracting tissue was adapted from
220 Ben-Haim et al. (2003) (Supplementary material).

221

222 **Statistical analysis**

223 Univariate statistical analysis was conducted in R Studio Desktop version 1.1.383. Prior to
224 analysis, normal distribution and homogeneity of variances were checked using the Shapiro Wilk
225 test and the Levene's test, respectively. To assess if there were significant differences in benthic
226 cover (hard coral, soft coral, algae) and diversity among sites a one way analysis of variance
227 (ANOVA, $n = 6$, $\alpha = 0.05$) was used followed by a Tukey HSD post-hoc test (Bonferroni
228 method), if necessary. Significant differences in the prevalence of compromised health signs

229 (bleaching, bioerosion, mucus production, pigmentation and scars) among sites and between
230 seasons were identified for both total hard coral cover and for the most abundant coral genera
231 (*Porites*, *Pachyseris*, *Montipora*, *Diploastrea*, *Acropora*) using a Full Factorial ANOVA (FF
232 ANOVA, $n=6$, $\alpha=0.05$) and a Tukey HSD post-hoc test. If required, a log₁₀ transformation
233 was carried out for datasets to meet homogeneity of variance. However, as the bleaching
234 recovery was assessed using a scale, these data were tested using a Wilcoxon test to determine if
235 there had been a significant recovery in tagged coral colonies between years. To determine
236 differences in physiology (chlorophyll *a* content and zooxanthellae density) between the three
237 coral genera sampled (*Acropora* $n=17$, *Pachyseris* $n=13$, *Montipora* $n=15$) and across sites, a
238 non-parametric Kruskal Wallis test was performed. Furthermore, to evaluate cell health
239 differences between the three genera and among reefs, the percentage of cells from each grade
240 were compared using the Kruskal –Wallis test. Differences in sediment trap accumulation rates
241 was tested among reefs (Kruskal – Wallis). In addition particle size characteristics (median,
242 fine/coarse fraction) among reefs, and between the trapped sediments and the benthic sediments
243 were also tested (FF ANOVA, $n=18$).

244

245 Permutational multivariate analysis was conducted in PRIMER-7 version 7.0.13. A Distance-
246 based Linear Model (DISTLM) was used to determine how much of the variation in community
247 assemblage (hard coral cover=HCC, soft coral cover=SCC, algae, recently dead coral
248 cover=DCC, H' index, number of coral genera) among transects and reefs was driven by depth,
249 distance from the two nearby river mouths, distance from shore and differences in sediment trap
250 accumulation rates and particle size characteristics. Depth was included in the analysis as depth
251 is known to influence sediment dynamics (Wolanski et al., 2005) as well as declines in light
252 associated with suspended sediments (Falkowski et al., 1990). A distance- based resemblance
253 matrix was created for the biological data set using Bray - Curtis similarity values following a
254 square-root transformation and for the environmental data using Euclidean distances and
255 normalised values. A DISTLM, using the BEST fit model with the Akaike's Information
256 Criterion (AIC) and 9,999 permutations was performed using the resemblance matrices. The
257 multivariate scale relationship between the predictor (environmental) and response variables
258 (biological) was presented on a plot with a distance- based redundancy analysis (dbRDA;
259 Legendre and Anderson, 1999). To investigate whether environmental factors contributed to

260 differences in health status among sites again a DISTLM model was used followed by dbRDA
261 plotting as above. Predictor variables included substrate structure (hard coral cover (HCC),
262 diversity) and physical conditions (depth, sediment trap accumulation rate, particle size
263 characteristics, distance from both river mouths and distance from shore). Hard coral cover
264 (HCC) and diversity were used since higher HCC can contribute to a greater probability of
265 impaired coral health (Bruno and Selig, 2007). In contrast, reefs that are more diverse can lower
266 susceptibility as it reduces the quick spread of a disease (Raymundo et al., 2005; Aeby et al.,
267 2011). As sediment data were obtained at the end of the wet season (May 2017), these were used
268 to explain the 2017 health data. For the 2016 coral health data, which had no associated sediment
269 data, only sampling year, HCC and coral diversity together with distance from shore and rivers
270 were used as explanatory variables.

271

272

273 **RESULTS**

274 *Physical parameters*

275 The dry season was characterized by less variable, warmer SST's (mean monthly range = 30.0 to
276 30.7 °C; sup Fig. 2), greater in-water light penetration (mean monthly range at EG = 156 to 320
277 $\mu\text{mol photons m}^{-2} \text{s}^{-1}$) and reduced rainfall (mean monthly rainfall range = 78 to 166 mm) and
278 cloud cover (Fig. 2). In contrast, the wet season was cooler (mean monthly range = 28.0 to 30.1
279 °C) with higher rainfall (mean monthly range 126 to 234 mm) and reduced light levels on the
280 reef (mean monthly range at EG = 19 to 150 $\mu\text{mol photons m}^{-2} \text{s}^{-1}$). Wind speeds were also
281 slightly elevated during the wet season months (Fig. 2d). Mean sediment trap accumulation rates
282 following the wet season ranged from 13 to 28 $\text{mg cm}^{-2} \text{day}^{-1}$, with a rate almost three times
283 higher at EG compared to AG and SW ($H_2 = 10.3$, $p < 0.005$; Fig. 3). Site differences in potential
284 sediment load were also observed during the dry season with higher and more variable turbidity
285 recorded at the nearshore EG reef (mean monthly range = <1 to 24 FTU) than at SW (mean
286 monthly range = 1-7 FTU) located 10 km further south from the large Baram River mouth (sup
287 Fig. 3).

288

289 All three reefs were dominated by sand (>98%), with the median particle size of benthic
290 sediments significantly increasing ($F_2=13.6$, $p < 0.005$) with distance from the mouths of the
291 Baram and Miri Rivers (Fig. 4). Benthic sediments at SW comprised 58% of very coarse sand,

292 nearly three times that of EG (20%) ($F_3=24.9$, $p<0.001$; PH: SW>EG, AG; sup Fig. 4) and a
293 significantly smaller proportion of medium/fine sands ($F_2=17.2$, $p<0.001$; PH: SW>AG>EG).
294 In contrast there was little difference in the median particle size from the sediment traps among
295 sites ($F_2=2.25$, $p=0.133$), although particle sizes of the benthic sediment were significantly
296 greater compared to the trapped sediments ($F_1=60.93$, $p<0.001$).

297

298 ***Benthic cover***

299 Hard coral cover increased with distance from the major sediment source (Baram River) and
300 varied significantly among sites ($F_2=5.3$, $p=0.01$; PH: SW>EG). SW had the highest HCC
301 (39.3%) and EG almost half the HCC (21.9%; Fig. 5). Soft corals also varied significantly but
302 declined with increasing distance from the major sediment source ($H_2 = 8.6$, $p=0.01$; MWPH:
303 EG>AG, SW) with EG having nearly 15-fold higher cover than SW. Turf algae dominated the
304 algal community and contributed to 52-57% of all reefs' benthos. However, there was no
305 significant difference in turf algal cover among reefs ($F_2=0.103$, $p>0.05$). Dead coral cover was
306 consistently low among sites (4.25%).

307

308 In total 28 genera were recorded (Table 1). Coral diversity was considerably different among
309 sites ($F_2=4.6$, $p=0.03$; PH: SW>EG) with SW the highest richness and 25 genera ($H'=1.93$), and
310 EG and AG 16 and 14 genera, respectively ($H' \sim 1.4$). The surveyed sites were composed of
311 similar communities, with the most dominant genera including *Diploastrea* sp., *Porites* sp.,
312 *Montipora* sp., *Favites* sp., *Dipsastrea* sp. and *Pachyseris* sp. (Table 1). All other species
313 comprised a small fraction of the community (<2% cover). Most notable differences in the
314 composition were with the high cover of *Diploastrea* sp. at AG and EG, *Galaxea* sp. at EG, and
315 *Acropora* and *Montipora* sp. at SW.

316

317 ***Coral reef health***

318 Of the compromised health signs recorded at each reef, the five most commonly observed were
319 mucus production ($0.5 \pm 0.3\%$), pigmentation ($2.2 \pm 0.7\%$), bioerosion ($6.6 \pm 2\%$), bleaching
320 ($6.7 \pm 0.9\%$) and scars ($1.1 \pm 0.4\%$; Fig. 6). No diseases *per se* were observed except at EG
321 where one colony of massive *Porites* sp. had ulcerative white spots. Despite a clear decline in
322 prevalence along an inshore to offshore gradient following the dry season in 2016 (Fig. 7), total

323 prevalence of compromised health (sum of the five commonly observed signs) was not
324 statistically significant among sites and seasons ($p > 0.05$; Table 2). The prevalence of mucus
325 production by corals at Eves Garden (5%), however, was nearly five times that of other reefs
326 ($F_2 = 3.6$; $p < 0.05$; $EG < AG, SW$), and SW recorded the lowest levels of pigmentation prevalence
327 (Fig 7b; Table 2; $F_2 = 5.3$; $p < 0.05$; $AG > SW$). In contrast, bioerosion was comparatively similar
328 among sites within each season, but increased five-fold from $2.7 \pm 0.6\%$ to $10 \pm 1.3\%$ following
329 the 2017 wet season (Table 1; $F = 20.2$; $p < 0.001$; $2017 > 2016$). During both seasons, overall
330 bleaching prevalence was $\leq 10\%$ with partially bleached the most common form and whole
331 bleaching the least observed (sup Fig. 5). Bleaching prevalence declined from $8.1 \pm 1.4\%$
332 following the dry season to $5.4 \pm 1.1\%$ after the wet season. Although this decline was not
333 statistically significant ($F = 3.3$; $p = 0.08$), the recovery of bleached corals that had been tagged the
334 year before was significant ($p = 0.002$). The average bleaching scale dropped from 3.9 ± 0.4 to 1.6
335 ± 0.2 (Fig. 8) with all *Diploastrea* sp. and *Pachyseris* sp. colonies recovered by 90-100% in
336 2017.

337

338 Patterns of compromised health differed among five representative coral genera (*Acropora* sp.,
339 *Montipora* sp., *Pachyseris* sp., *Diploastrea* sp. and *Porites* sp.). *Acropora* sp. displayed the least
340 signs of stress in both seasons ($< 3.5\%$). *Porites* sp. were the most compromised (2016 = $50.8 \pm$
341 6% ; 2017 = $72 \pm 5\%$; Fig. 9) and the only coral genera with a significant increase in stress
342 symptoms ($p = 0.004$), because of a 40% increase in bioerosion after the wet season ($F_1 = 10.17$;
343 $p < 0.001$; Table 3). *Montipora* sp. and *Diploastrea* sp. also suffered from an increase in
344 bioerosion between sampling seasons, although this was not statistically significant ($p > 0.05$; Table
345 3). Despite a slight increase in the number of bleached *Porites* sp. corals, bleaching occurrence
346 for the other four corals declined, most notably for *Pachyseris* sp. (55% to 3%; $F_1 = 9.03$;
347 $p = 0.008$). Furthermore, the most abundant genera *Porites* sp. was the only coral to show
348 elevated signs of pigmentation ($> 10\%$) although this health sign was less prevalent at SW, the
349 most offshore site ($F_2 = 5.3$; $p = 0.01$; Table 3).

350

351 For the three coral genera, *Montipora* sp., *Pachyseris* sp. and *Acropora* sp., there was no
352 difference in symbiont density ($H = 4.0397$, $df = 2$, $p > 0.05$) and chlorophyll *a* among sites ($H =$
353 2.3769 , $p > 0.05$) although SW scored the highest of both measures ($3.2 \times 10^6 \pm 5.5$ cells/cm²; 4.94

354 $\pm 0.75 \mu\text{g}\cdot\text{cm}^{-2}$; Fig. 10a,b). Symbiont density differed among the three coral genera (chi-square =
355 23.1, $\text{df}=2$, $p<0.001$; MWP: AC>MT,PH) with *Acropora* sp. scoring four and five times higher
356 symbiont densities (sup Fig. 6). Over 50% of the symbionts observed were healthy (stage 1;
357 sup Fig. 7a) with slightly more healthy cells observed at SW ($H=1.7$, $p>0.05$) and marginally
358 more degraded cells (stage 5) observed at AG ($H=3.4$, $p>0.05$). Among genera, *Acropora* had a
359 greater number of healthy cells ($69 \pm 3.9\%$) than both *Montipora* (49.4 ± 5) and *Pachyseris* ($52.6 \pm$
360 4.8 ; $H=14.4$, $p<0.001$; sup Fig. 7b).

361

362 ***Drivers of benthic cover and health***

363 Environmental variables (depth, sediment trap accumulation rate, distances from shore/river
364 mouth, concentration of silt/fine/coarse particles, median particle size) explained 62.5% of the
365 variation in benthic composition among reefs. Key drivers ($p<0.05$) were distances from river
366 mouth (30.3%) and shore (1%), median particle size (16.4%), and sediment trap accumulation
367 rate (2.3%; Table 4). Variability among sites was higher than within, with sediment trap
368 accumulation rate and particle size a key driver of benthos at EG and AG, and distance of river
369 and shore more closely associated with SW (Fig. 11).

370

371 To determine key drivers of coral health, two DistLM models were run. The first model
372 included health data from both sampling seasons, with six explanatory variables (season, HCC,
373 diversity, distance from river mouth and shore, and depth). The second model included health
374 data and sediment related variables following the wet season and sediment trap contents
375 (sediment trap accumulation rate, concentration of silt/fine/coarse sediments, median particle
376 size). For the first model, year, HCC and diversity significantly explained <31% of the variation
377 in coral health among transects and sites (Table 5). Sites within a sampling season were
378 separated along a HCC and diversity gradient (Fig. 12), with transects at SW typically
379 characterised by higher HCC and diversity but lower prevalence of scars, pigmentation and
380 bleaching (sup Fig. 8). Furthermore, repeat transects were separated between seasons, with those
381 completed in 2017 recording higher bioerosion, but lower bleaching and pigmentation (sup Fig.
382 7), supporting our previous results. Of the sediment drivers, the BEST model included both silt
383 and the coarse sediments, which explained 18% of the variations in coral health in 2017. Higher
384 sediment trap accumulation rates, although not statistically significant ($p=0.06$; Table 5),

385 explained 7% of the variation in health, and were most often associated with higher prevalence
386 of pigmentation, bioerosion and bleaching (sup Fig. 9).

387

388 **DISCUSSION**

389 The three reef sites in the MSCRNP are characterised by healthy coral cover yet low coral
390 diversity. Average live coral cover among the three reefs was 30%, ranging from 22% at EG to
391 39% at Siwa Reef. This is lower than reefs to the north in Sabah, with reports of live coral cover
392 from 23 to 75% (Pilcher and Cabanban, 2000; Chou and Tun, 2002; Lee, 2007; Praveena et al.,
393 2012; Waheed et al., 2016), but greater than the average coral cover for the wider Pacific region,
394 estimated at 22% in 2003 (Bruno and Selig, 2007). Previous assessment of coral cover in 2000
395 on the Miri reefs range from 28% (Pilcher and Cabanban, 2000) to 22-58% (Elcee
396 Instrumentation, 2002). Although the higher coral cover reported by the latter study is most likely
397 an artefact of the methodology used (ex-situ Acoustic Ground Discrimination System), which
398 can result in the misidentification and, therefore, quantification of live coral cover. Regardless,
399 our data suggest that coral cover at Miri's reefs has been relatively stable over the last two
400 decades. Miri's coral cover is comparable to both turbid and clear water reefs (Roy and Smith,
401 1971; Loya, 1976; Larcombe et al., 2001; Wesseling et al., 2001; Palmer et al., 2010; Goodkin et
402 al., 2011), yet diversity was comparatively low (14 to 25 genera per reef) for the Coral Triangle
403 region. Turak and Devantier (2010) reported 391 coral species (~70 genera) on reefs near Brunei
404 (~80 km from Miri), and Teh and Cabanban (2007) reported 120 species within 71 hard coral
405 genera for Banggi Island in Sabah. A comprehensive biodiversity assessment of all 30 reefs with
406 the MSCRNP in 2000 reported 66 genera (203 coral species; Elcee Instrumentation, 2002). We
407 only observed a third of the number of coral genera (n=28), which is expected given we surveyed
408 only 10% (n=3) of the reefs surveyed in 2002. However, this report also found that coral
409 diversity was highly variable among reefs, with an average of nine coral genera per transect. It is
410 likely that MSCRNP reefs found further to the south and in deeper (15-35 m) offshore waters but
411 outside the scope of this study (characterized by different environmental conditions) include
412 several coral species not observed at our shallow nearshore sites, which are influenced by
413 terrestrial sedimentation from both natural and anthropogenic processes.

414

415 Low diversity at the surveyed sites is likely the result of poor water quality in the nearshore
416 shallow coastal zone. The inshore reefs of Miri are found in a narrow depth range between 7 and
417 15 m, hence there is a complete lack of reef structure in 1-5 m depth range. These very shallow
418 depths, however, are often characterised by a distinct set of coral species (Morgan et al., 2016;
419 DeVantier and Turak, 2017) which in part may explain lower coral diversity than on reefs to the
420 north in Brunei and Sabah that have reached sea level. But these inshore reefs are also
421 characterised by high levels of terrigenous sediments, which can also reduce coral diversity
422 (Rogers, 1990; Fabricius, 2005). High sediment input from rivers are typically correlated with
423 high nutrient loads that can lead to increase in reef algal biomass (De'ath et al., 2012). Algal
424 cover on all three reefs was high (>50%) compared to reefs in northern Borneo (0 to 29%;
425 Waheed et al., 2015), and will most likely be competing with corals for reef space. Some coral
426 taxa will be less resilient to both sediments and algal competition resulting in lower coral
427 diversity (Fabricius et al., 2005; De'ath and Fabricius, 2010). In Indonesia, Edinger et al. (1998),
428 recorded lowest coral diversity on reefs with algae cover reaching 46%. Reduced diversity was
429 also attributed to land pollution as well as destructive and over-fishing practices that destroy the
430 reef structure and reduce fish biomass thereby removing the top-down control on algal growth by
431 herbivore browsers (Hughes, 1994; Rogers and Miller, 2006; De'ath and Fabricius, 2010). In
432 Miri, overfishing and poor land management practices have been a long-term concern for the
433 regional government (Elcee Instrumentation, 2002) but there are limited funds to actively protect
434 the reefs (Teh and Teh, 2014) and collect data on these impacts.

435

436 Low coral diversity does not necessarily suggest a degraded reef condition. Typically, low
437 diversity in nature results in lower resilience (Raymundo et al., 2005) and community stability
438 (Bellwood et al., 2004). Yet there is growing evidence to suggest that a few but tolerant species
439 can maintain reef resilience to local and global impacts, and implies that the diversity-resilience
440 links need further investigation (Bellwood et al., 2004; Fabricius et al., 2005; Nystrom et al.,
441 2008). A recent study on relatively undisturbed and well protected reefs in the Philippines that
442 looked to identify site specific benchmarks for coral diversity, measured high coral cover (>30%)
443 at the majority of sites, but lower generic diversity (10 to 25 coral genera per 75 m by 25 m area;
444 Licuanan et al., 2017). This highlights that high diversity is not necessarily a key benchmark for
445 a healthy reef system. As well as assessing the number of coral species on a reef, it is important

446 to determine if and how coral community structure has changed over time. Significant shifts in
447 coral composition can affect the reef's ecological function such as framework building, habitat
448 complexity and food source diversity (Aronson et al., 2004; Pratchett, 2005; Graham et al.,
449 2006). At six reef sites on the Great Barrier Reef coral communities shifted over 12 years
450 towards a high abundance of *Porites* spp. and soft corals; a community assemblage that is less
451 likely to re-establish to the pre-disturbance coral assemblage (Johns et al., 2014). Inshore reefs
452 in Miri are similarly dominated by massive corals including *Porites* sp. and *Diploastrea* sp., with
453 some (e.g. EG) also characterized by high soft coral cover (>10%). While we have no long-term
454 data sets to evaluate change in both diversity and composition, Miri's reefs may have
455 experienced a community shift due to reduction in water quality. Yet our tendency as coral reef
456 ecologists to focus on coral cover, composition and diversity, has resulted in a misconception as
457 to what constitutes an overall healthy reef (Vroom, 2011). Some reefs may naturally be
458 dominated by non-coral organisms, such as calcifying algae that are equally important for reef
459 accretion and stability but possibly less resilient to climate change. Thus our perception of the
460 reefs current state and its future trajectory are likely inaccurate and need adjusting to go beyond
461 diversity assessments.

462

463 The MSCRNP reef community can best be described as representative of turbid reefs in the
464 Indo-Pacific. The dominant coral species include several genera (*Acropora*, *Montipora*, *Porites*,
465 *Pachyseris*, *Faviidae* and *Galaxea* spp.) that have been observed on nearshore reefs in Singapore
466 (Chou, 1988; Dikou and van Woessik, 2006), the Great Barrier Reef (GBR) (Ayling and Ayling,
467 1991; Larcombe et al., 2001; Browne et al., 2010; Morgan et al., 2016), Thailand (Tudhope and
468 Scoffin, 1994), Hong Kong (Goodkin et al., 2011) and Sabah (Pilcher and Cabanban, 2000).
469 These corals are considered to be more resilient to sediment influx either through: 1) enhanced
470 photo-acclamatory abilities required during periods of low light (e.g. *Stylophora*; Dubinsky et al.,
471 1984; Browne et al., 2014), 2) active sediment removal processes by the coral polyp (e.g.
472 *Goniastrea*; Rogers, 1990; Erftemeijer et al., 2012), 3) enhanced mucus production to remove
473 settled sediments (e.g. *Porites*; Bessell-Browne et al., 2017) or, 4) morphological advantages that
474 result in greater degree of vertical growth thereby reducing tissue mortality from sediment burial
475 (e.g. *Acropora* and *Montipora*; Erftemeijer et al., 2012). There were also distinct differences in
476 the community assemblages particularly between SW Reef and EG. Siwa Reef had a mixed

477 assemblage of branching, foliose and massive corals, whereas EG was dominated by massive
478 corals, such as *Porites* sp. and *Diploastrea* sp. These coral community differences suggest there
479 are significant differences in environmental drivers (including sediments) over a comparatively
480 small spatial scale (10 km's).

481

482 The inshore to offshore gradient in hard coral cover and diversity, and differences in coral
483 composition is heavily influenced by the spatial differences in sediment related parameters. Over
484 62% of the variation in benthic cover at our three reef sites is explained by differences in depth,
485 sediment trap accumulation rates and distance from sediment sources as well as sediment particle
486 size characteristics. Consequently, we saw a significant increase in both coral cover and diversity
487 with increasing distance from the river mouths. Similar observations have been reported from
488 Indonesia and Puerto Rico, where hard coral cover nearly halved towards shore (Loya, 1976;
489 Edinger et al., 2000), and in Hong Kong, where inshore coral cover was 20% lower than offshore
490 (Goodkin et al., 2011). Reduced coral cover occurs because of low larval recruitment as a
491 consequence of limited hard substrate following sediment settling (Birrell et al., 2005; Fabricius,
492 2005; Dikou and van Woesik, 2006), or colony mortality caused by anoxic conditions that occur
493 under sediment layers (Rogers, 1983; Riegl and Branch, 1995; Wesseling et al., 2001). The
494 sediment particle size and source (marine versus terrestrial) are considered equally important to
495 sediment volume in assessing the impacts of sediments on coral health (Weber et al., 2006).
496 Recent studies show that as the percentage of terrestrial sediments increases, there are greater
497 declines in coral cover either through direct contact of sediments on corals (Bégin et al., 2016) or
498 following the reduction of coral recruitment (Fourney and Figueiredo, 2017). The significantly
499 lower hard coral cover and diversity at EG than at SW could be driven in part by a higher
500 percentage of terrestrial sediments from the Baram and Miri Rivers. Although we did not assess
501 sediment origin, sediment trap accumulation rates at EG were over double that at AG and SW,
502 which may be due to the reefs closer proximity to the two river mouths. However, it could also
503 be the result of increased sediment resuspension in shallow water or a combination of these
504 factors. Sediment traps do not provide a comprehensive assessment of sediment dynamics on
505 reefs, and given that our traps were out for 7 months, we recognize that our monthly sediment
506 trap accumulation rates can only be compared among our study sites and not to other studies.
507 Regardless, it is likely that river flow and sediments are influencing reef health, but these reefs

508 appear to be in a temporally stable state given low recently dead coral cover (4.35%) and the
509 limited decline in coral cover over the last two decades.

510

511 The prevalence of impaired health signs was dominated by bioerosion and pigmentation with no
512 signs of coral disease (with one exception). These health indicators are typically related to high
513 sediment and nutrient influx. High levels of bioerosion in particular has been linked to land
514 based pollution whereby lower light, from high turbidity, reduces CaCO_3 density (Risk and
515 Sammarco, 1991; Lough and Barnes, 1992) weakening the coral skeleton and increasing
516 susceptibility to bioeroders (e.g. molluscs, worms etc.; Prouty et al., 2017). Furthermore, even
517 modest increases in nutrient levels can lead to an increase in the abundance of bioeroding
518 organisms shifting a reef community from one of net production to net erosion (Hallock and
519 Schlager, 1986; Hallock, 1988; Prouty et al., 2017). Bioerosion levels were significantly greater
520 following the wet season when the impact of sediments on the Miri reefs were elevated as
521 indicated by declines in light and higher suspended sediment loads. Conversely, pigmentation
522 rates were higher following the dry season. Pigmentation is an indicator of immune function in
523 response to a stressor (Willis et al., 2004; Palmer et al., 2009). These stressors have been related
524 to settling sediments (Pollock et al., 2014) or lesions from abrasion or scars (Willis et al., 2004),
525 or for the case of Miri reefs elevated SST's recorded in the region in 2016 leading to the
526 moderate bleaching event as observed by the diving operators and fisherman. Spatially,
527 pigmentation rates were significantly lower at SW, which may suggest that corals at the least
528 sediment impacted site were also less stressed than at AG and EG. Sediments can also promote
529 diseases in corals (Voss and Richardson, 2006; Haapkyla et al., 2011; Pollock et al., 2014) with
530 Black Band Disease and White Plaque widely observed in the Indo-Pacific (Harvell et al., 2007;
531 Beeden et al., 2008), although generally low (~8% of current global records) in SE Asian reefs
532 compared to the Caribbean (Green and Bruckner, 2000). Suggested explanations for this include
533 poor reporting of coral diseases and relatively high coral diversity that might aid in diminishing a
534 quick spread of a disease (Raymundo et al., 2005). At Miri, the more likely explanation of low to
535 no coral diseases are more resilient individual corals and coral species, and potentially limited
536 connectivity with nearby coral populations, although this remains speculative until further work
537 is carried out.

538

539 Hard coral cover and diversity also explained a significant portion of the variation in coral
540 health. Miri reefs with a higher frequency of impaired health at sites recorded less coral cover
541 and diversity. In a recent study by Miller et al. (2015) reefs in Sabah, had four common coral
542 diseases at varying frequencies (<0.1 to 0.6 per affected colonies in an m²) and signs of tissue
543 necrosis and pigmentation responses. They found a positive correlation between disease
544 frequency and coral cover, which suggested that host density was a key driver of disease
545 prevalence and compromised health. This relationship is due to reduced distances between
546 colonies, and greater shading and competition by fast growing species as coral cover increases
547 (Bruno and Selig, 2007). In Miri, we see the reverse trend suggesting that factors other than host
548 density are driving coral health, most likely changing sediment loads and finer sediment particles
549 not present in Sabah. However other variables often associated with sediment such as nutrient
550 levels and pollution such as heavy metal loads are also worth investigating.

551

552 Variable species composition among sites would also partly explain the spatial variation in coral
553 health. Different coral taxa have different susceptibilities to bioerosion, bleaching, disease and
554 compromised health (Raymundo et al., 2005; Couch et al., 2014; Heintz et al., 2015). In Miri
555 signs of pigmentation and bioerosion were most prominent on massive *Porites* sp. colonies.
556 *Porites* sp., although typically considered a hardier coral taxa (Raymundo et al., 2005) tolerant of
557 turbid waters, often have the most lesions, highest tissue loss and pigmentation response
558 (Tribollet et al., 2011; Pollock et al., 2014; Heintz et al., 2015) as well as being a target for
559 disease (Raymundo et al., 2005). The level of bleaching observed in *Porites* at Miri was
560 comparable to other abundant coral genera, but recovery potential after 9 months was lower,
561 possibly due to other stress symptoms. Bleaching was the most common sign of impaired health
562 among coral taxa, most commonly observed in *Pachyseris*, *Porites*, *Montipora*, *Dipsastrea* and
563 *Acropora* spp. (in declining order). A comprehensive study by Marshall and Baird (2000) of 40
564 coral taxa on the GBR found the same coral taxa were highly (>50% bleached or dead) or
565 severely (>15% dead) susceptible to thermal stress. In contrast, the other five most abundant
566 corals at the Miri reefs (*Diploastrea*, *Favites*, *Galaxea*, *Echinopora*, *Merulina* spp.) are
567 considered to be less sensitive to rising SST's (Marshall and Baird, 2000; Guest et al., 2016).
568 However, bleaching susceptibility does vary considerably according to the thermal history of a
569 region. For example, *Acropora* sp. is susceptible to bleaching on some reefs (Marshall and Baird,

570 2000; Pratchett et al., 2013; Hoogenboom et al., 2017), but was less susceptible on other reefs
571 (e.g. Singapore following the 2010 bleaching event: Guest et al., 2012). Only ~5% of *Acropora*
572 sp. colonies in Miri showed signs of thermal stress, which suggests moderate thermal tolerance
573 to high SST's. High levels of algal density in coral tissue are linked to higher thermal stress
574 resistance (Glynn, 1993; Stimson et al., 2002) due to the symbionts providing a greater
575 concentration of mycosporine-like amino acids that protect corals from UV radiation (Xu et al.,
576 2017). Symbiont densities measured at Miri were high (mean = 2.4×10^6 cells per cm^2) but
577 comparable to corals on other turbid reefs like those from Singapore (e.g. 0.5 to 3×10^6 cells per
578 cm^2 ; (Browne et al., 2015). However, it was *Acropora* sp. that had significantly higher symbiont
579 density than the more frequently bleached *Montipora* sp. and *Pachyseris* sp. Our results suggest
580 that resilience to stress for these corals is a complex, but synergistic relationship between level
581 and frequency of environmental stressors, community composition and a coral's adaptability to
582 increased SST.

583

584 In 2016, a severe coral bleaching event occurred throughout the Indo-Pacific region. The
585 impacts of this event were thoroughly assessed on the GBR, where over 90% of reefs bleached
586 resulting in the loss of 29% of shallow water coral cover (Great Barrier Reef Marine Park
587 Authority, 2016). In January to March 2016, SST along the northern shore of Borneo were in the
588 highest 10% of global records since 1990 (Great Barrier Reef Marine Park Authority, 2016). SST
589 reported by NOAA for Brunei peaked in May to June 2016 at 31°C (the bleaching threshold
590 temperature; Fig. 12). During this time there was 1 to 2.5 Degree Heating Weeks (DHW) and
591 mid-level bleaching warnings. SST remained at $\sim 30^\circ\text{C}$ until January 2017 (National Oceanic &
592 Atmospheric Administration, 2018), which agree with our in-water assessment of SST during
593 September 2016 to early 2017 (sup Fig. 2). This suggests that while corals at Miri were subject
594 to elevated SST's for 5 or more months our surveys revealed low bleaching rates ($\sim 10\%$ of
595 colonies bleached), and high recovery rates (as suggested by the tagged corals; $>90\%$). This
596 suggests these nearshore turbid water reefs are resilient to high SST's supporting the growing
597 body of evidence that turbid reefs bleach less severely and frequently than their clear-water
598 counterparts (Marshall and Baird, 2000; Heintz et al., 2015; Morgan et al., 2017). Low
599 bleaching and high recovery rates of Miri reefs is possibly due to nearshore coral assemblages
600 more frequent exposure to higher temperatures than their offshore deeper conspecifics, resulting

601 in the development of adaptive mechanisms (Marshall and Baird, 2000; Guinotte et al., 2003;
602 Guest et al., 2016; Morgan et al., 2017). It may also be due to lower UV light penetration that
603 can exacerbate temperature stress (Courtial et al., 2017), or potentially from higher heterotrophy,
604 which increases the supply of essential metals to the symbionts thus sustaining them through
605 elevated temperatures (Ferrier-Pagès et al., 2018). This study further suggests that while turbid
606 reefs are more potentially more resilient to elevated SST, the mechanism/s responsible for this
607 resilience remain unclear.

608

609 **CONCLUSIONS**

610 In conclusion, the MSCRNP reefs are characterized by relatively high coral cover, low
611 prevalence of impaired health and are composed of a few but tolerant coral taxa. Low recently
612 dead coral cover and almost no decline in coral cover over the last two decades indicates these
613 reefs are stable despite elevated sediment inputs and regular exposure to thermal stress events.
614 There are, however, potential risks from proposed coastal and in-land developments given we
615 found that sediment related parameters have resulted in an on- to offshore gradient in coral
616 cover, diversity and health. Furthermore, high bioerosion and algae cover indirectly suggests
617 high nutrient influx, most likely from the Baram River. The high prevalence of bioerosion
618 observed in *Porites* sp. colonies is a concern given that this coral is a key reef framework
619 builder, and any notable declines in *Porites* sp. health will reduce coral reef complexity and
620 habitat availability for other invertebrate and fish species. Currently, there is no baseline data on
621 spatial and temporal changes in river outputs and sediment plume dynamics within the
622 MSCRNP, which is crucial in evaluating future threats to these reefs. Local management
623 agencies will need to address this knowledge gap if they plan to develop strategies that address
624 the potential impacts of changing land use on MSCRNP. The reefs current health state and
625 elevated stress tolerance does, however give hope that these reefs could be resilient to future
626 climate change but only if local water quality does not deteriorate.

627

628

629 **ACKNOWLEDGEMENTS**

630 We would like to thank the Curtin Sarawak Research Institute for facilitating this research,
631 especially Prof Clem Kuek and Ms Daisy Saban who worked tirelessly to make sure our research
632 trips went to plan. We thank our volunteers Amitay Moody, Hedwig Krawczyk (who also

633 produced Figures 1 and 12), Paula Cartwright, Toloy Keripin Munsang, Valentino Anak Jempo,
634 Sun Veer and the numerous volunteers from the Curtin Sarawak Dive Club for their assistance
635 with field work. Thanks also to the captains and crew from Coco Dive Centre and Hoopa Dive.

Figure 1

Map of south China Sea with enlarged map of study area, showing locations of the three reefs, Miri city and the closest rivers.

(Image credit Hedwig Krawczyk modified from Natural Earth - Free vector and raster map data).

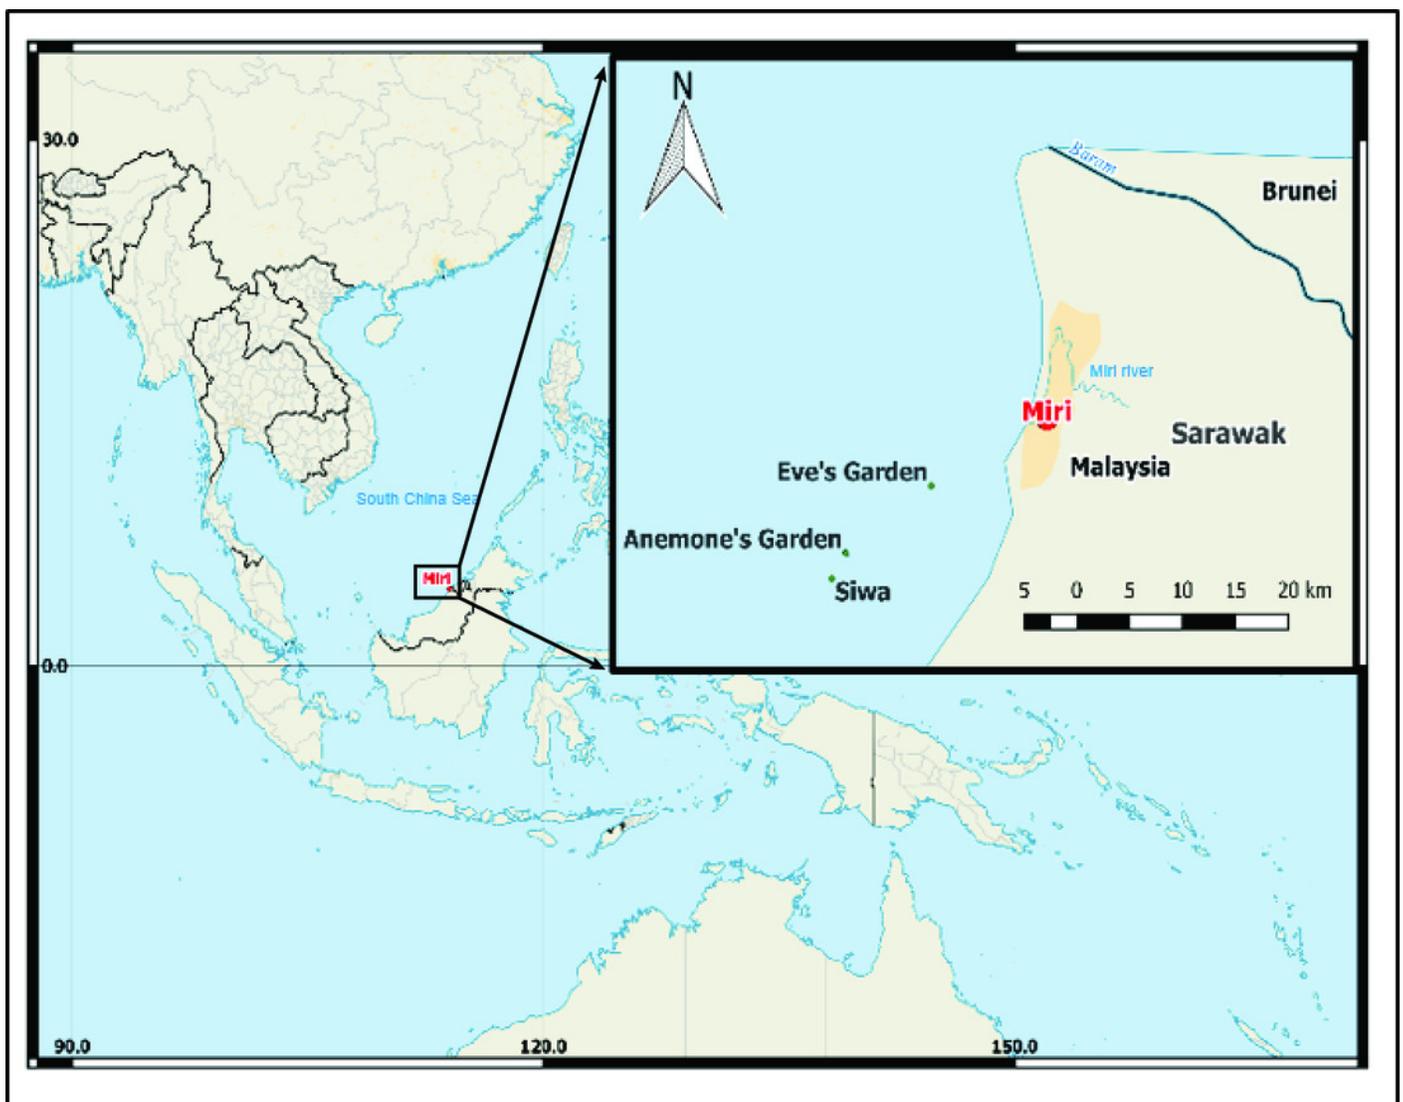

Figure 2

Average monthly data for A. light, B. wind speeds, C. cloud cover, and D. rain fall.

Light data was collected at EG as part of this study whereas wind, cloud and cover data was taken from the worldwideweatheronline.com website (error bars = SE).

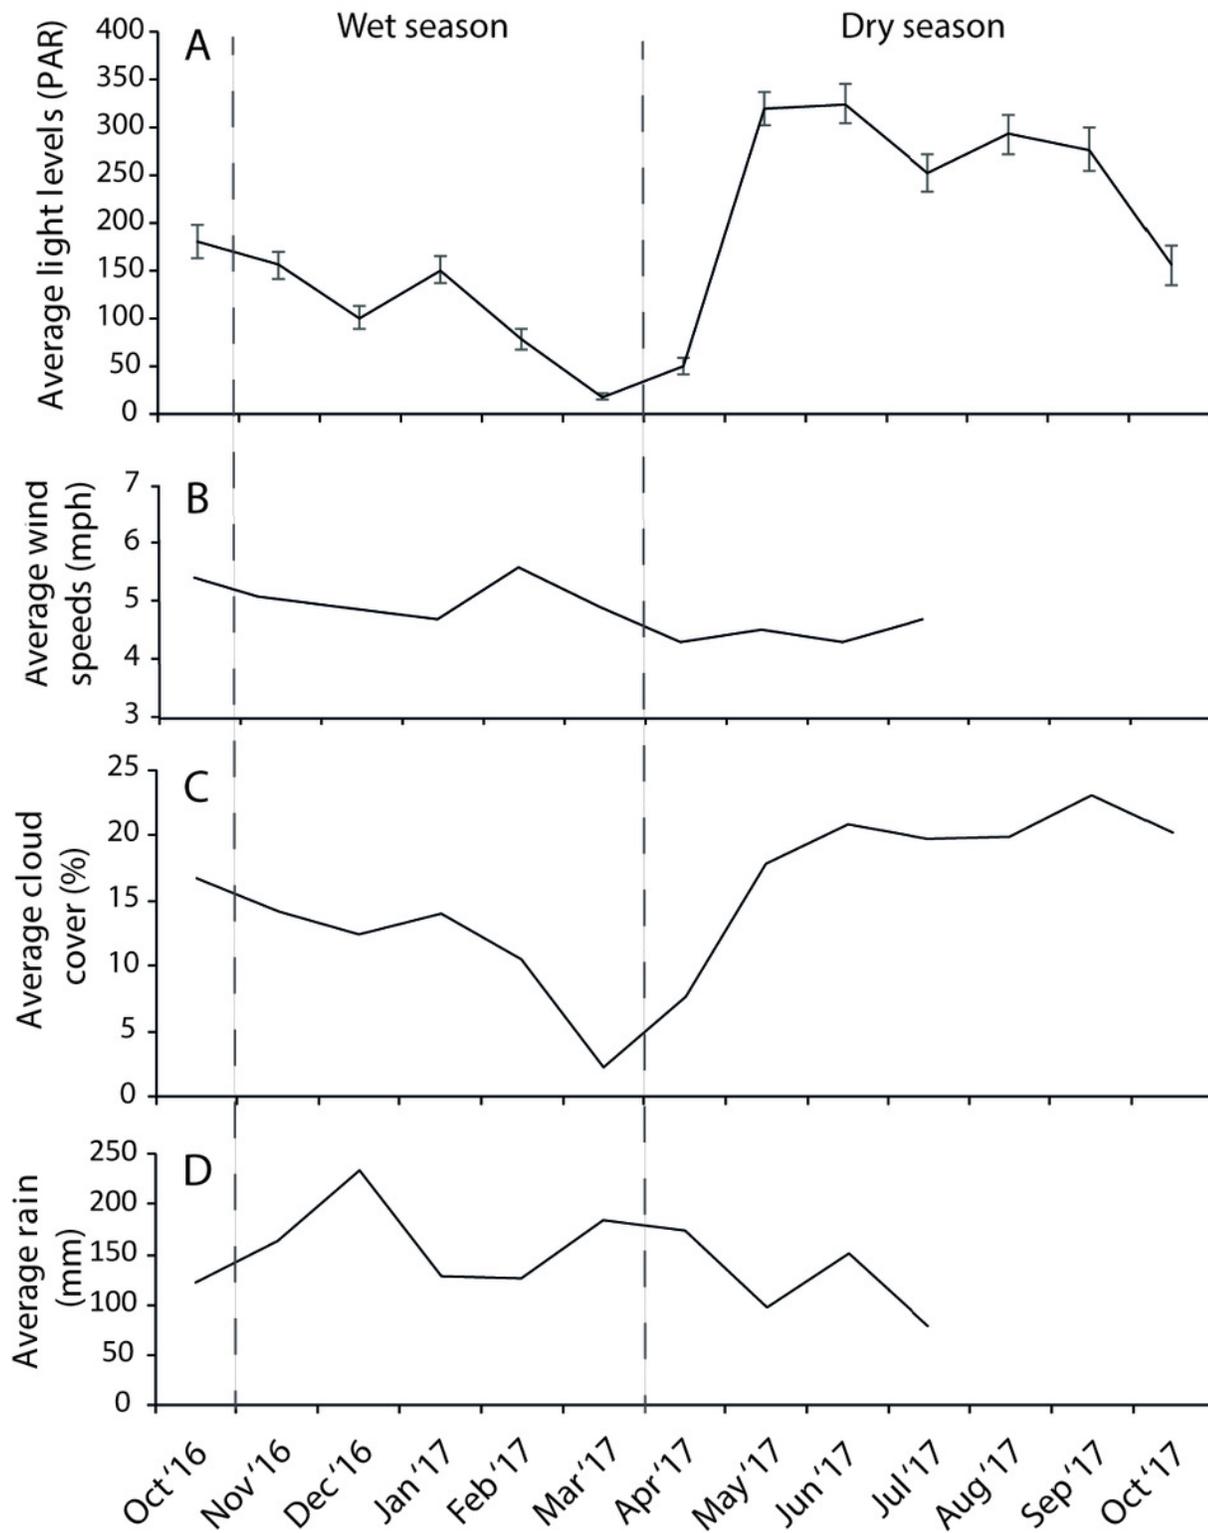

Figure 3

Average sedimentation rates at the three surveyed sites (error bars = SE).

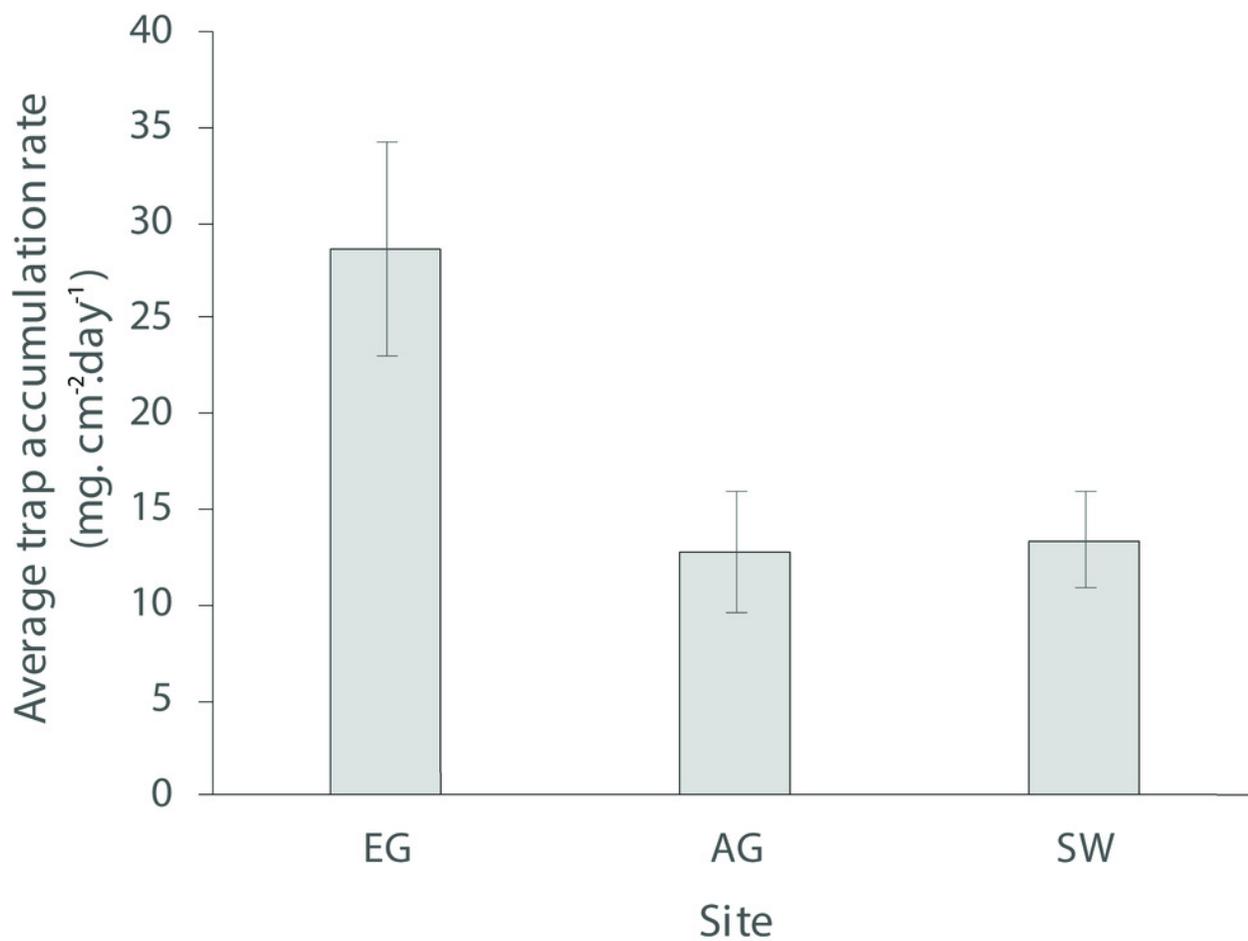

Figure 4

Particle size data from the sediment traps and the benthos at EG, AG and SW.

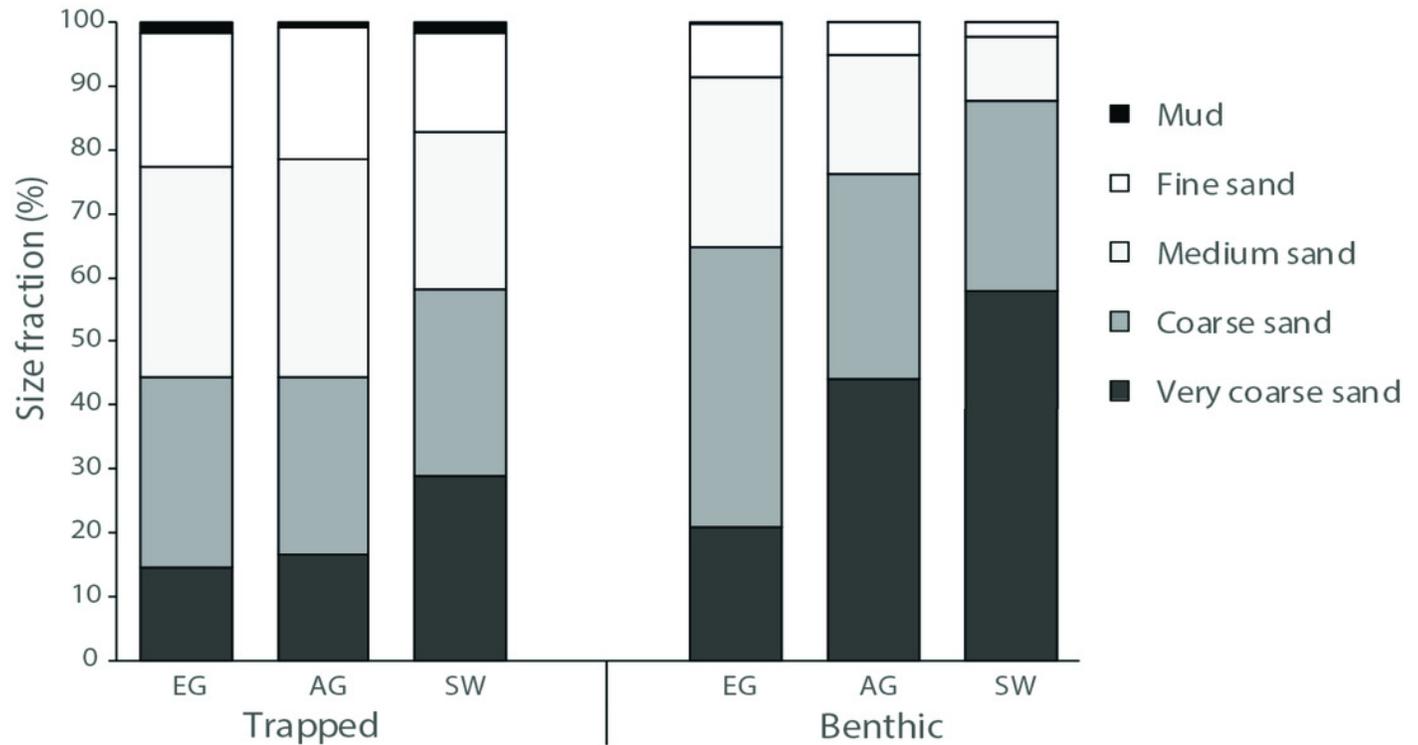

Figure 5

Average percentage benthic cover at EG, AG and SW. Sites are organised from inshore to offshore (error bars = SE).

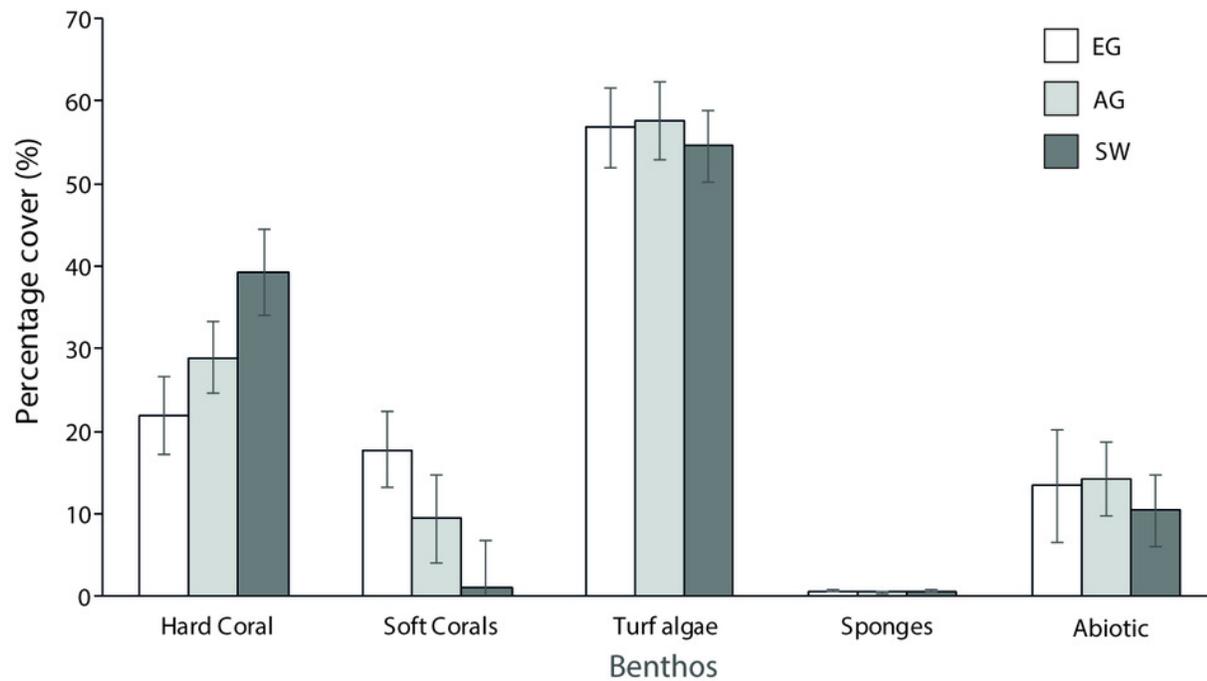

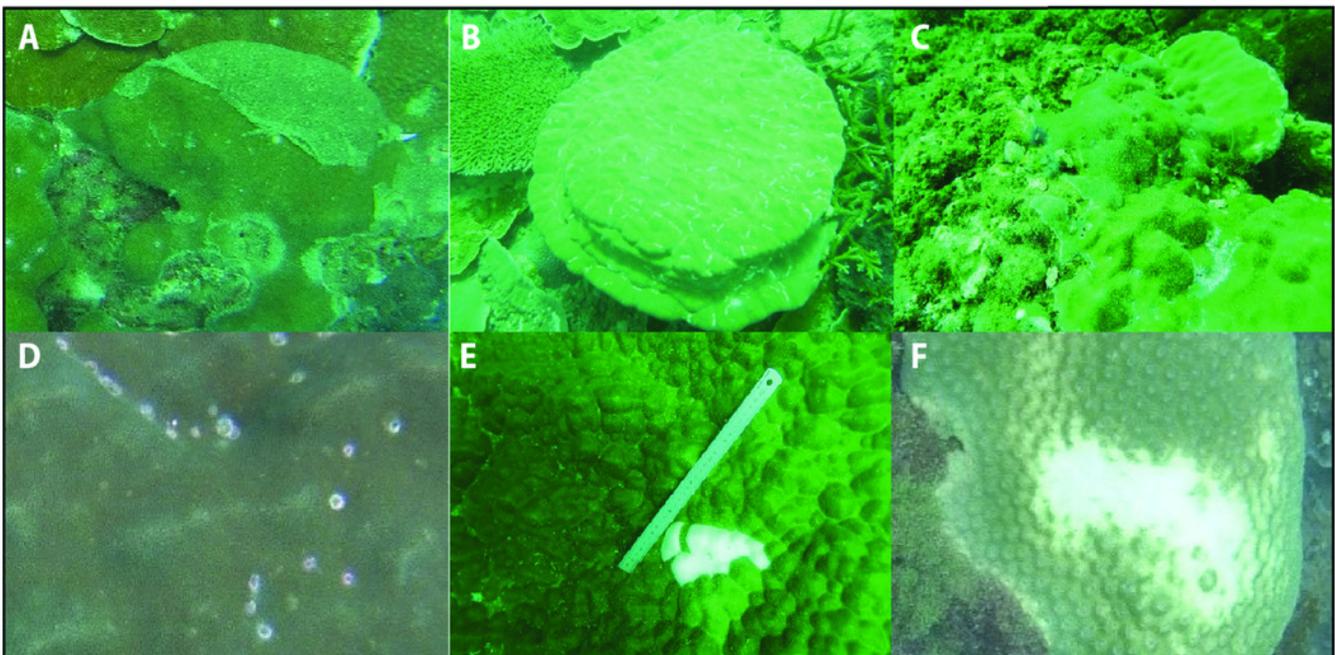

Figure 6

Signs of impaired health

A. Mucus, B. Feeding scars, C. Christmas tree worms and bivalves, D. pigmentation response in *Porites* sp. E. Non-focal bleaching, and F. Partial bleaching.

▪

Figure 7

Average prevalence of the dominant signs of impaired health across all three surveyed sites (EG, AG, SW) following the 2016 dry season and 2017 wet season (error bars = SE).

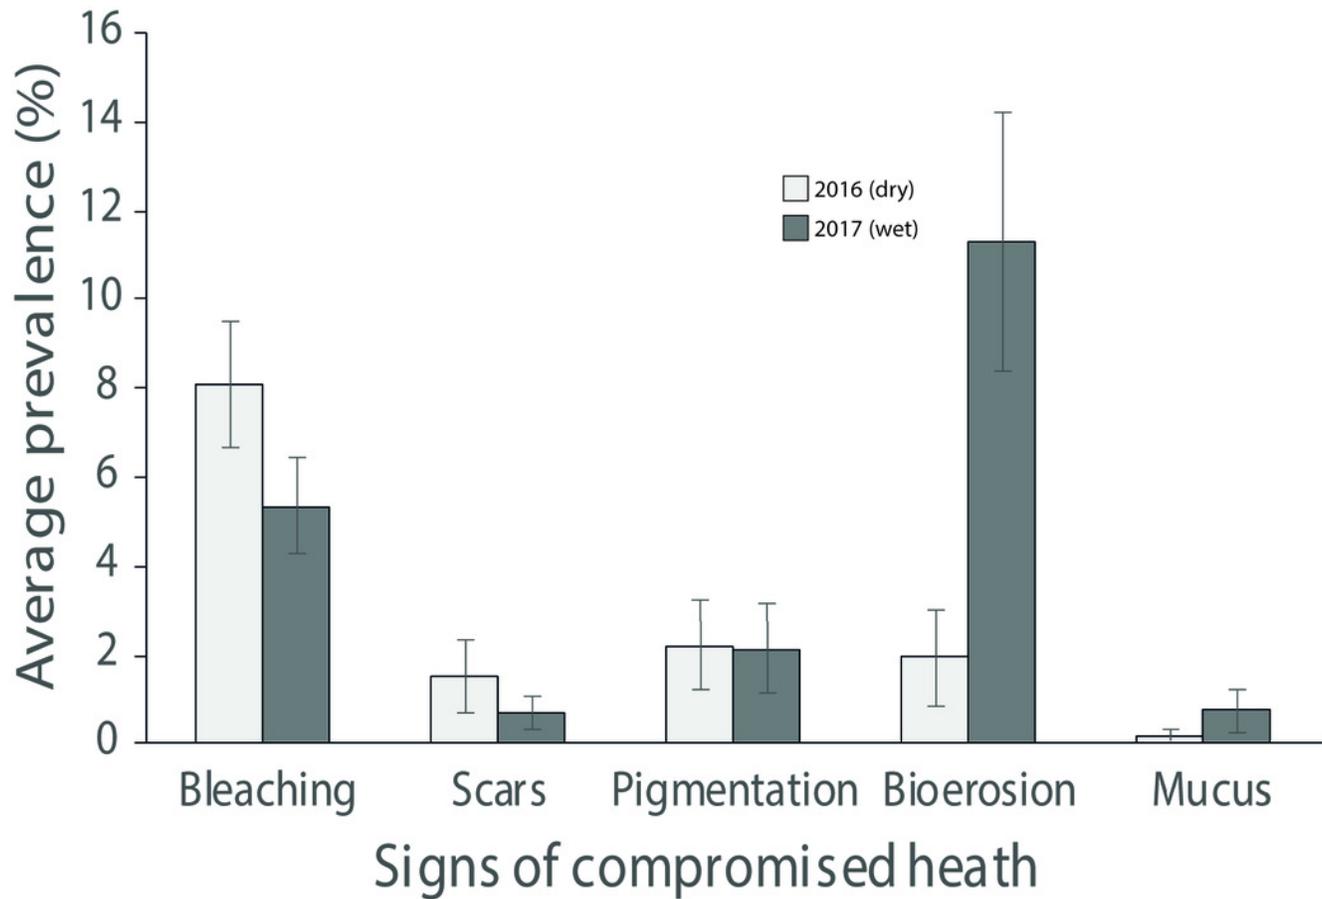

Figure 8

Average bleaching scale for the three coral genus across the three survey sites (EG, AG, SW) that were tagged in September 2016 following the warm dry season and cooler wet season (error bars = SE).

(1=normal, 2=pale, 3=0-20% bleached, 3=21-50% bleached, 4=51-80% bleached, 5=81-100% bleached)

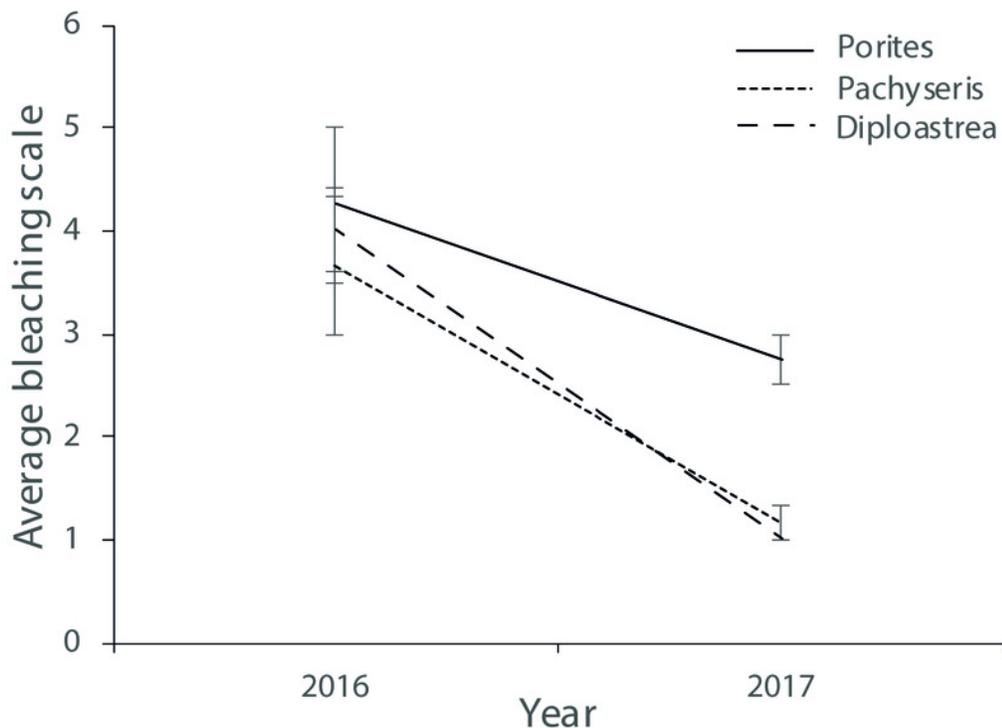

Figure 9

Prevalence of the most common impaired health signs following the 2016 dry season and the 2017 wet season for the five most common observed coral genus across all three sites surveyed (EG, AG < SW).

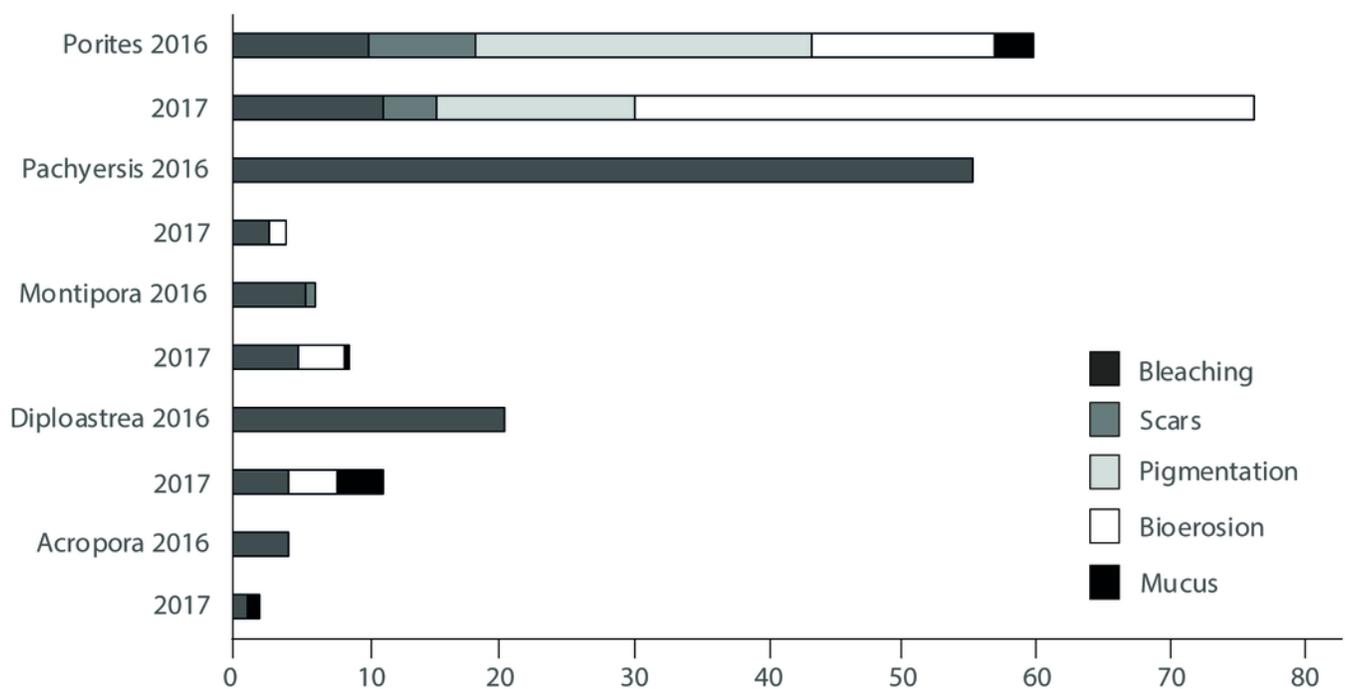

Figure 10

Average symbiont density (A) and chlorophyll a pigment density (B) across the three coral species assessed (*Acropora*, *Montipora* and *Pachyseris*) at EG, AG and SW (error bars = SE).

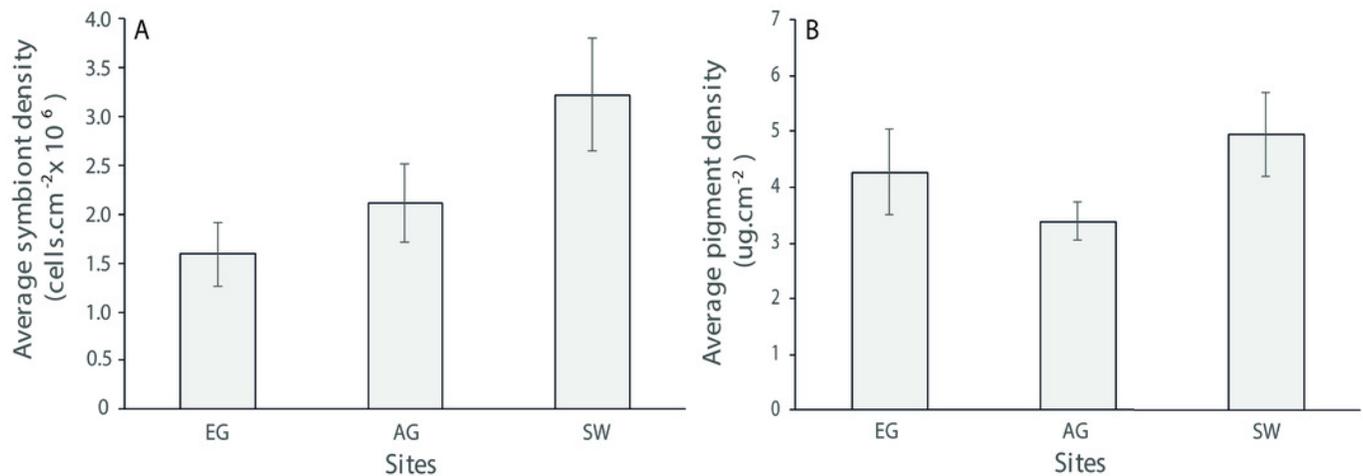

Figure 11

Distance-based redundancy analysis (dbRDA) plot with an AIC criterion selection illustrating the significant environmental factors ($p < 0.05$) that influence community composition at EG, AG and SW.

The length and direction of the vectors represent the strength of the correlation (circle denotes a correlation of 1) and direction (+/-) of the relationship with transects (points plotted) at each site.

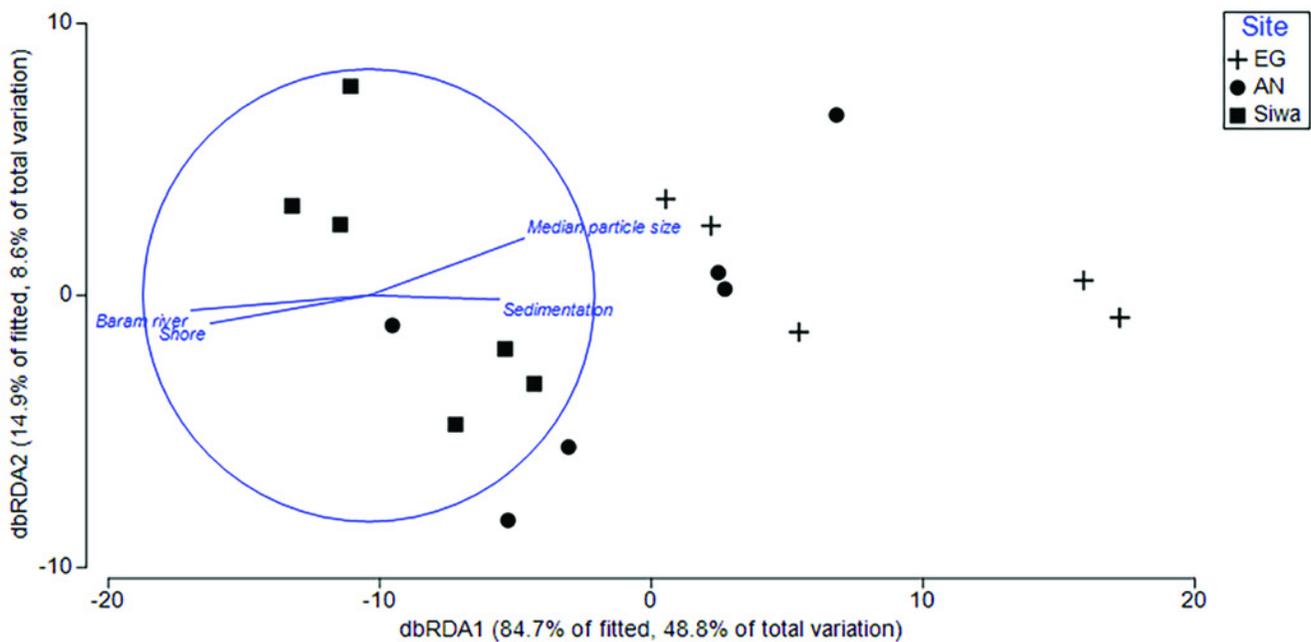

Figure 12

Distance-based redundancy analysis (dbRDA) plot with an AIC criterion selection illustrating the that influence coral health at at EG, AG and SW.

Significant explanatory variables ($p < 0.05$; HCC = hard coral cover, diversity = coral diversity, year = Sept 2016 and May 2017). The length and direction of the vectors represent the strength and direction (+/-) of the relationship with transects (points plotted) at each site. (Image credit: Amitay Moody).

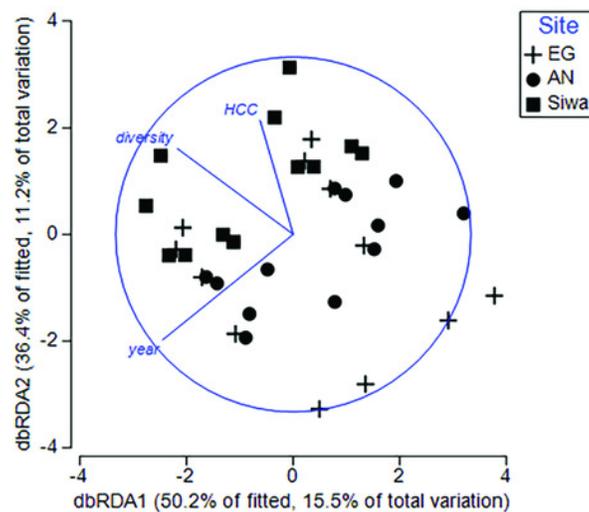

Table 1 (on next page)

Average (%) coral cover of the 28 genera observed at the three surveyed reefs illustrating the 10 most dominant coral genus.

Genus	Eve's Garden	Anemone's Garden	Siwa reef
Acropora (branching)	0.07 ± 0.07		2.60 ± 0.40
Diploastrea (massive)	14.80 ± 1.60	10.60 ± 3.70	0.40 ± 0.10
Echinopora (encrusting)		0.50 ± 0.14	1.90 ± 1.60
Dipsastrea	0.90 ± 0.30	3.44 ± 0.40	3.60 ± 2.00
Favites (massive)	1.70 ± 0.80	2.40 ± 0.86	5.10 ± 1.60
Galaxea	3.00 ± 1	0.62 ± 0.20	0.90 ± 0.30
Merulina	1.60 ± 1.5	0.10 ± 0.03	1.33 ± 0.80
Montipora (plate)	1.30 ± 100	2.09 ± 1.10	8.60 ± 3.00
Pachyseris (plate)	2.10 ± 1.10	0.50 ± 0.30	2.00 ± 1.30
Porites (massive/plate)	5.70 ± 2.80	7.30 ± 1.50	7.30 ± 2.30
Astreopora			0.90 ± 0.60
Caulastrea		0.07 ± 0.19	0.04 ± 0.04
Ctenactis (solitary)	0.07 ± 0.07	0.62 ± 0.15	0.14 ± 0.09
Echinophyllia	0.30 ± 0.30		0.06 ± 0.06
Fungia			0.10 ± 0.01
Goniastrea		0.10 ± 0.03	0.04 ± 0.04
Goniopora	0.03 ± 0.03		
Heliofungia	0.10 ± 0.10		
Leptoria	0.03 ± 0.03		0.08 ± 0.08
Leptoseris	0.17 ± 0.17		1.60 ± 1.50
Montastrea			0.04 ± 0.04
Oxypora	0.03 ± 0.03		0.17 ± 0.17
Pectinia			0.08 ± 0.08
Physogyra			0.17 ± 0.17
Platygyra (massive)	0.90 ± 0.80	1.79 ± 1.60	0.60 ± 0.40
Psammocora	0.10 ± 0.10		
Symphyllia		0.40 ± 0.20	0.69 ± 0.30
Turbinaria			0.68 ± 0.68

Table 2 (on next page)

Statistical results from two-way ANOVA of the total impaired health and each impaired health indicator with site (EG = Eves Garden, AG = Anenomes Garden, SW = Siwa) and season (2016, 2017), and the interaction.

Health sign	Factor	df	F value	p value	Post hoc
Total impaired health	Site	2	0.25	0.780	
	Season	1	1.11	0.300	
	Site*Season	2	0.15	0.860	
Bleaching	Site	2	0.19	0.830	
	Season	1	3.30	0.080	
	Site*Season	2	0.69	0.510	
Mucus	Site	2	3.60	0.040	EG<AG,SW
	Season	1	0.15	0.700	
	Site*Season	2	7.20	0.003	
Bioerosion	Site	2	0.87	0.430	
	Season	1	20.20	<0.001	2017>2016
	Site*Season	2	3.80	0.040	
Pimentation	Site	2	5.30	0.010	AG>SW
	Season	1	1.00	0.320
