

The effects of island forest restoration on open habitat specialists: the endangered weevil *Hadramphus spinipennis* Broun and its host-plant *Aciphylla dieffenbachii* Kirk

Emily D Fountain, Jagoba Malumbres-Olarte, Robert H Cruickshank, Adrian M Paterson

Human alteration of islands has made restoration a key part of conservation management. As islands are restored to their original state, species interactions change and some populations may be impacted. In this study we examine the coxella weevil, (*Hadramphus spinipennis* Broun) and its host-plant Dieffenbach's speargrass (*Aciphylla dieffenbachii* Kirk), which are both open habitat specialists with populations on Mangere and Rangatira Islands, Chathams, New Zealand. Both of these islands were heavily impacted by the introduction of livestock; the majority of the forest was removed and the weevil populations declined due to the palatability of their host-plant to livestock. An intensive reforestation program was established on both islands over 50 years ago but the potential impacts of this restoration project on the already endangered *H. spinipennis* are poorly understood. We combined genetic and population data from 1995 and 2010-2011 to determine the health and status of these species on both islands. There was some genetic variation between the weevil populations on each island but little variation within the species as a whole. The interactions between the weevil and its host-plant populations appear to remain intact on Mangere, despite forest regeneration. A decline in weevils and host-plant on Rangatira does not appear to be caused by canopy regrowth. We recommend that (1) these populations be monitored for ongoing effects of long-term reforestation, (2) the cause of the decline on Rangatira be investigated, and (3) the two populations of weevils be conserved as separate evolutionarily significant units.

10 Introduction

11 Island restoration is a key focus of conservation biology. Often islands are home to endemic flora and
 12 fauna which may be heavily impacted by human modification and introduced species (Hutton et al.
 13 2007). Although restoring an island to a pre-human state is ideal, its restoration is not straightforward
 14 (Lawton 1997) given a lack of information on species interactions and pre-human community
 15 composition and ecosystem conditions. Islands are unlikely to ever be fully restored to their previous
 16 ‘pristine’ states (Atkinson 1990). The dynamic nature of colonization from the mainland (Sinclair &
 17 Byrom 2006) and a relative lack of literature regarding long-term management also hinder island
 18 restoration (Simberloff 1990).

19 Despite these constraints, successful restoration has been achieved on small scales (Simberloff 1990).
 20 Extensive ecological research is necessary for restoration efforts to be successful, and also competent
 21 genetic management of island species is pivotal for long-term success (Jamieson et al. 2006). Genetics
 22 plays an important role in ecology and conservation (Frankham et al. 2002). The loss of genetic
 23 variation, common among island populations with low effective population sizes (N_e), can decrease
 24 fitness and lower ability to adapt to changing environments (Pertoldi et al. 2007). Island restoration
 25 often involves the translocation or captive rearing of organisms that are already genetically depauperate
 26 (Jamieson et al. 2006). Understanding of the genetic characteristics of species involved in island
 27 restorations is vital for long-term viability of the species, and the success of a restoration project.

28 Islands within the New Zealand archipelago have been actively restored for many years, using pest
 29 eradication, replanting, translocation, captive rearing and reintroductions (Towns et al. 2012). One
 30 group of such islands is the Chatham Islands (Chathams), which is approximately 800 km east of New

Zealand's South Island and consists of two large populated islands (Chatham and Pitt) and a series of smaller, uninhabited islands. The Chathams have a history of intense geological activity that resulted in frequent submerging and re-emerging of the islands (Heenan et al. 2010). The most recent emergence of the smaller islands, such as Mangere, is thought to have been between 3.0 and 2.0 Ma (Heenan et al. 2010). Two of the Chatham islands, Rangatira and Mangere, have been under restoration since 1961 and 1968, respectively. The two islands are home to several rare birds [e.g. *Petroica traverse* (Chatham Island black robin)], plants [e.g. *Myosotidium hortensia* (Chatham Island forget-me-not)] and invertebrates [e.g. *Amychus* spp. (Chatham's giant click beetle)].

The coxella weevil (*Hadramphus spinipennis* Broun 1911) is a large, flightless weevil endemic to the Chatham Islands. There are four species in the genus *Hadramphus* (Craw 1999), all endemic to New Zealand, three of which are listed as threatened or vulnerable, including *H. spinipennis* (Hitchmough et al. 2007). The extant populations of this species are found on Rangatira, Little Mangere and Mangere Islands, but the weevil was also historically recorded on Pitt Island in 1900 (Emberson et al. 1996). Surveys of Mangere and Rangatira Islands (Schöps 1998) suggested that the weevil was thriving with an estimate of over 10,000 weevils found in the 1995/1996 summer on Mangere Island (Schöps 2002). The weevil is associated with the plant Dieffenbach's speargrass (*Aciphylla dieffenbachii*), which is found in open habitats on the islands. However, it has also been sighted on *Pseudopanax chathamicum* Kirk (Araliaceae) several hundred meters away from *A. dieffenbachii* (A.Liddy, G. Taylor pers. comm.; Emberson et al., 1996). Choice tests between *A. dieffenbachii* and *P. chathamicum* suggest that *Pseudopanax* is most likely not a viable host plant for this weevil (Schöps et al. 1999). *Hadramphus spinipennis* is often found during September to February, feeding and mating on its host plant on warm, humid nights (Schöps et al. 1999).

Schöps (2000) performed behavioral and ecological studies on *H. spinipennis* and its host plant, *A. dieffenbachii*, on Mangere Island between 1993 and 1997, and on Rangatira Island in the summer of 1995/6. The main driver for this study was the observation of local extinctions of the host-plant on Mangere, which were thought to be caused by the weevil. Local extinctions of the host-plant was caused by the weevils before relocating to a new patch of *A. dieffenbachii* (Schöps 1998). Schöps (2000) recommended, as part of the conservation management strategy (Department of Conservation 1999), that *H. spinipennis* and *A. dieffenbachii* should be monitored every three to four years on Mangere and Rangatira to ensure that the regenerating forests do not affect the population dynamics and survival of the weevil and its host-plant.

Our study was conducted 13 years after the initial research by Schöps (2000) and has two main aims: (1) to measure the genetic similarity between the two populations and the genetic diversity within the species as a whole, and (2) determine if the current population dynamics are consistent with those found by Schöps and whether they support her original prediction of stable metapopulation dynamics. We hypothesize that (1) geographic isolation inhibits gene flow between weevil populations and (2) loss of open-habitat has caused a decline in the *A. dieffenbachii* populations defined by Schöps over a decade ago. We performed DNA analysis on weevils from both islands and repeated the surveys conducted on Mangere and Rangatira Island. Our study explores the possible negative impacts of restoration on an endangered invertebrate by incorporating a genetic and ecological approach.

Methods

Site descriptions

Rangatira (South East) Island is 219 ha and was heavily farmed until its purchase by the New Zealand government in 1953, after which all livestock were removed in 1961 (Department of Conservation

2012) (Fig. 1). Much of the original forest was destroyed for farming and many of the native plants that remained were grazed by livestock. Currently, the island is mostly covered by remnant or regenerating forest and *A. dieffenbachii* is limited to the coastal cliffs and rocky shores.

Mangere Island is 113 ha and surrounded by cliffs, with the highest cliff reaching 286 m (Fig. 1). The island was once covered with native forest but 90% of the forest was burned for sheep farming and many of the native vascular plants and megaherbs were suppressed by heavy grazing (Ritchie 1970). Several plants, such as *A. dieffenbachii*, started to regenerate with the removal of livestock in 1968 and an intensive forest planting program was implemented in 1974 (Butler & Merton 1992). *Aciphylla dieffenbachii* grows along the steep, rocky cliffs of Mangere and in the open grasslands. The plant has a patchy distribution over the whole island.

Survey of Hadramphus spinipennis and Aciphylla dieffenbachii

Rangatira (South East) Island (14-19 February 2010) and Mangere Island (17-23 February 2011) were surveyed for *A. dieffenbachii* during the day. The search was restricted to coastal and open areas where *A. dieffenbachii* has been documented to grow (Schöps 2000). Due to adverse weather conditions, the high cliffs of both islands could not be surveyed although on Rangatira, although there had been reports of a large *A. dieffenbachii* population on North Summit.

When plants were found, the quantity and state of flowering and a visual assessment of plant size were made. Plants were searched for signs of weevil feeding and activity, in particular the characteristic margin feeding of *H. spinipennis* (Schöps 2000). Although other herbivores can be found on *A. dieffenbachii*, the feeding pattern of *H. spinipennis* is distinctly different and well documented by photograph making feeding signs easily observable (Fig. 2). Each plant was photographed and the surrounding area was searched for new seedlings. GPS coordinates of major plant clusters were

recorded (Table S1). At night, starting at 22:00, known *A. dieffenbachii* populations were visually searched for *H. spinipennis* individuals. Data collection on Mangere was conducted in the same manner as on Rangatira. All locations where *A. dieffenbachia* and *H. spinipennis* had previously been recorded were visited and surveyed.

DNA collection and PCR

Due to collection restrictions of protected species by the Department of Conservation and also local imi/iwi, weevils for DNA analysis were limited to 15 individuals captured per island. Adult *H. spinipennis* range from 18-22 mm in length. Individuals were randomly selected from different subpopulations on the islands; the tarsal claw and the first two segments of the tarsus were removed using ethanol-cleaned scissors and the weevil was then released. Previous work has shown that a tarsal clip has no known negative impacts on the weevils (Fountain et al. 2013). Clips were stored in propylene glycol and, when returned to the laboratory, were washed with 95% ethanol and then stored at -20°C in 95% ethanol. Each tarsal clip was cut into several pieces using a sterile scalpel blade and then transferred into a 1.7mL Eppendorf tube. A QIAmp DNA Investigator Kit (Qiagen, Auckland, catalog # 56504) was used for DNA extraction following the manufacturer's protocol for tissue samples.

Two mitochondrial genes, cytochrome *c* oxidase subunit I (COI) and cytochrome b (cytb), and one nuclear gene, internal transcribed spacer 2 (ITS2), were amplified by polymerase chain reaction (PCR). For all PCRs, 2.5 µl of the DNA extraction was added to the following: 2.5µL of 0.25 mM of dNTPs, .2µl of polymerase, 1µL of 20 µM for each primer, 2.5µL of 10x PCR buffer (*i*-taq, iNtRON Biotechnologies) and deionized water to bring the total reaction volume to 25 µl.

COI was amplified using the primers LCO1490 and HCO2198 (656 base pair fragment) (Folmer et al. 1994). The PCR cycle was 94°C for 3 min followed by 35 cycles of 94°C for 45 s, 45°C for 45 s and 72°C for 1 min 20 s, with a final extension at 72°C for 5 min. The primers CB1 and CB2 (432 base pair fragment) (Simon et al. 1994) were used to amplify cytb. The PCR cycle was 94°C for 3 min followed by 40 cycles of 94°C for 30 s, 49°C for 45 s and 72°C for 1 min, with a final extension at 72°C for 5 min.

Due to the difficulty in amplifying a large fragment of ITS2 using the original primer set, a new genus-specific primer set was developed for a 450 base pair fragment of ITS2 (Table 1) (See Appendix S1 for primer design details). The PCR mixture and cycle for these primers were the same as those for ITS3 and ITS4, except that the annealing temperature was decreased to 54°C. Every PCR reaction included a negative (water) control with no DNA.

Molecular Data Analysis

Sequence chromatograms for 30 COI, 16 cytb and 25 ITS2 sequences were visualized using FinchTV 1.4 (Geospiza) and forward and reverse sequences were manually aligned in Mega 5.05 (Tamura et al. 2011). No insertions, deletions or stop codons were found for COI or cytb. Within ITS2 a variable AT short tandem repeat (STR) was found in the middle of the sequences. Short tandem repeats may have higher mutation rates compared to the flanking regions which may interfere with the phylogenetic signal (Selkoe & Toonen 2006) so we conducted preliminary analysis on the ITS2 data set with and without the STR. Preliminary phylogenies were constructed in MEGA from a Kimura two-parameter (K2P) distance matrix (Kimura 1980) using neighbor joining (NJ) with 1,000 bootstrap replicates. No differences were found in the ITS2 analysis when the STR was removed; we chose to use the dataset

139 without the STR for additional analysis to be confident the STR would not interfere with the
140 phylogenetic inference.

141 For Bayesian analysis, the COI data set was reduced to 16 sequences to match them with the cytb
142 sequences. Sequences of the two genes were then concatenated in R 2.13.2 (R Development Core
143 Team 2011). The concatenated mitochondrial sequence data were analyzed separately from the ITS2
144 data because they are independently evolving loci and also have differences in mutational rates. The
145 ITS2 analysis was performed on the full set of 25 sequences. Bayesian analyses were performed using
146 Beast 1.7.1 (Drummond et al. 2012). The best partitioning scheme and evolutionary model were found
147 with PartitionFinder (Lanfear et al. 2012) using the corrected Akaike Information Criterion (AICc) for
148 COI and cytb. The Kimura three-parameter (K81) model (Kimura 1981) was chosen with no
149 partitioning between the concatenated genes (known collectively below as mtDNA). Since ITS2 is not
150 a protein coding gene it was not considered for partitioning and the best fit evolutionary model was
151 found using the AICc with jModeltest 2.1.1 (Darriba et al. 2012), which identified the symmetrical
152 (SYM+G) model (Zharkikh 1994) with gamma distribution as the optimal model.

153 The mtDNA and ITS2 data were analyzed under a strict molecular clock with a coalescent (constant
154 population size) tree prior. For each gene, four replicate runs of a chain run for 50 million generations
155 were performed, sampling every 2000 generations. Convergence and effective sample size of each
156 parameter was assessed in Tracer 1.5 and samples from the four runs were pooled using Log Combiner
157 1.7.2. After discarding the initial 10% as burn-in, a maximum clade credibility tree was compiled in
158 TreeAnnotator 1.7.1 (Drummond et al. 2012).

159 For the mitochondrial data, two Bayesian analyses were conducted to provide estimates of divergence
160 time using (i) the geological evidence and the timing of the volcanic emergence of Mangere, 3-2

million years ago (Heenan et al. 2010), and (ii) the standard invertebrate mitochondrial rate of 0.0115 substitutions/site/million years (Brower 1994). For geological dating, priors were set to allow tree calibration using direct input of a fixed date for specific nodes; the root of the tree was constrained to no older than 3 million years with uniform prior. Since we aim to estimate the split between the Rangatira and Mangere populations a distribution of dates was not used as Mangere did not emerge until 3 million years ago at the earliest. All analyses were performed in BEAST 1.7.2 (Drummond et al. 2012) using the same model and partitioning scheme employed in the previous analysis. Four independent runs consisting of a chain run for 50 million generations were conducted, sampling every 2000 generations. Maximum clade credibility trees were generated in the same manner as in the previous analysis.

Pairwise genetic distances for mtDNA were taken from the Bayesian maximum clade credibility tree using PASSaGE 2.0 (Rosenberg & Anderson 2011). A Neighbor-Net network of ITS2 haplotypes was generated using SplitsTrees 4.12.3 (Huson & Bryant 2006) to visualize conflicting patterns in the phylogenetic signal. Distances for the Neighbor-Net network were calculated under the generalized time reversible (GTR) model and no rate heterogeneity among sites.

Results

Survey

Rangatira

Three locations were found to have subpopulations of *A. dieffenbachii*: East Clears, West Clears, and West Landing (subpopulations A, B, C in Fig. 3). Subpopulation A showed signs of heavy weevil herbivory on all plants. In subpopulation B only a few plants showed signs of weevil damage, whereas

subpopulation C had no weevil feeding damage. Table 3 provides a detailed description of the number of plants, size of plants, and flowering state for the *A. dieffenbachii* populations.

In subpopulation A, 29 *H. spinipennis* were found feeding and mating on the plants. The male: female sex ratio of the weevils was 15:14. In subpopulation B, three out of the nine major *A. dieffenbachii* groups had weevils. Group 1 had two males and two females: one pair breeding and the other two feeding. Group 4 had one breeding pair, and group 9 had one male feeding.

West Landing was searched for two nights but no weevils were found (Fig. 3). One male *H. spinipennis* was found on *Pseudopanax chathamicus*, approximately 250 meters from the nearest *A. dieffenbachii* at West Landing.

Mangere

Seven subpopulations of *A. dieffenbachii* were identified on Mangere (Fig. 4). Feeding signs were observed in plants from all subpopulations. In addition to the plants found in the seven subpopulations, a few individual plants were also found scattered along the south-east coast of the island but had no evidence of weevil feeding damage (Fig. 4). A detailed description of the *A. dieffenbachii* populations, including number of plants, size of plants and flowering state, is provided in Table 4.

Individuals of *H. spinipennis* were found in five of the seven *A. dieffenbachii* subpopulations. The observed number of weevils reached 26 in location 1, which corresponded to subpopulation 1 of *A. dieffenbachii*. Ten specimens were counted in locations 4, 6 and 3, and only two in location 2. The male: female sex ratio ranged from 19:7 in location 1, through 8:6 in location 4, to 1:1 in locations 3 and 2. Weevils were observed feeding and mating in all locations except for location 2, where the two individuals were feeding on separate plants.

203 *Molecular analysis*

204 In total, 30 specimens of *H. spinipennis* were successfully sequenced for COI, 16 for cytb and 25 for
 205 ITS2. For COI, a 656 bp fragment was obtained, which had three variable sites, two of which were
 206 parsimony informative. Base frequency means for COI were unequal and AT-rich (T=35.0%,
 207 C=19.6%, A=30.3% and G=15.1%); a chi-square test confirmed heterogeneity of base frequencies
 208 across all taxa (d.f. =87, $p=1.00$). For cytb, a 432 bp fragment was obtained, which had one variable
 209 site, which was parsimony informative. Base frequency means for cytb were unequal and AT-rich
 210 (T=36.6%, C=22.2%, A=29.3%, and G=11.9%); a chi-square test confirmed heterogeneity of base
 211 frequencies across all taxa (d.f. =45, $p=1.00$). The 30 COI sequences showed little variation with only
 212 two individuals sharing a single nucleotide difference between themselves and the rest of the samples.
 213 However, for cytb there was a clear difference at one nucleotide in all samples between individuals
 214 from each of the two islands. The pairwise genetic distances in the concatenated mitochondrial genes
 215 were low with a mean of 0.002 (max 0.003) substitutions/site between the two island populations. The
 216 maximum P-distance within each island was 0.001 substitutions/site.

217 After the removal of the AT variable repeat, a 428 bp fragment was obtained for ITS2, which contained
 218 24 variable sites, 17 of which were parsimony informative. Four indels were found in the sequences,
 219 two from an individual on Rangatira and two from an individual on Mangere. The Neighbor-Net
 220 network does not show strong genetic structure within or between the islands (Fig. 5). The results of
 221 the Neighbor-Net network (Fig. 5) suggest that there may be a complicated signal between the two
 222 islands represented by the network separating the two groups.

223 The maximum clade credibility trees were very similar in topology to the NJ trees; due to the splitting
 224 of zero-length branches in the maximum clade credibility trees we opted to display the NJ trees. The

mitochondrial tree shows a weakly-supported split between the two islands (Fig. 6a), and the branch length separating the two islands is extremely small at 0.002 substitutions/site. The universal mitochondrial rate for invertebrates of 0.0115 substitutions/site/million years places the origin of this split around 1,300 BP (95% HPD 0.000-0.0139 BP) and the geological time calibration of 4 million years places it around 600 BP (95% HPD 0.0001-0.0016 BP) (Fig. 6a, Table 2). The ITS2 tree shows a lack of resolution and does not support any split between the two islands (Fig. 6b). There is no evidence for genetic differentiation in COI and ITS2 among the subpopulations for each island [subpopulations A, B, C for Rangatira and subpopulations 1-7 for Mangere (Figs. 3 and 4)].

Discussion

The genetic analysis shows a population of weevils that is highly similar across the islands with only a small amount of difference between the two islands in the mitochondrial genes. A genetic difference between the weevil populations of Mangere and Rangatira has been previously reported for a different section of the COI gene (Goldberg & Trewick 2011). The analysis with the two concatenated mitochondrial genes showed a strong support for a split between the two islands. This difference is not seen in the nuclear gene ITS2; however, due to the longer coalescent times of nuclear genes compared to mitochondrial genes, there may have been insufficient time for ITS2 to achieve reciprocal monophyly. Although some signal interference in the ITS2 gene caused by incomplete lineage sorting and recent divergence can skew the resulting phylogeny, there is still strong support for a group that includes two individuals, one from each island. Further molecular work should be conducted on more nuclear genes to discover a clearer signal of genetic differentiation between the two islands.

The difference in the mitochondrial and nuclear gene trees can be explained by the four times faster coalescence time in mitochondrial genes compared to nuclear genes (Ballard & Whitlock 2004). The

island split in the mitochondrial gene tree may be the result of the two populations having no gene flow. Given the faster mutation rate of mitochondrial genes versus the nuclear genes (Moriyama & Powell 1997), reproductive isolation is likely to lead to faster differentiation of the mitochondrial genes. In the future, this split may become evident in the slower evolving nuclear genes if the populations remain genetically isolated. Currently the populations of the weevil and its host plant on Rangatira are not as heavily monitored as they are on Mangere. If the Rangatira and Mangere populations are confirmed to be genetically isolated, it is of utmost importance to take conservation measures to make sure that both populations have similar chances of survival.

Both methods of dating the separation between individuals on the two islands using the mitochondrial genes date the mean time for this split as rather recent, in the last few thousand years. This timing approximately coincides with the arrival of humans and introduced mammals, particularly Polynesian rats, which are known to predate *Hadramphus* weevils (Towns 2009). Calibrating the molecular clock using the geological age of 4 million years as the last emergence of the islands gave a smaller 95% confidence interval. Given that using a universal mitochondrial rate is fraught with problems, such as variation between genes, differences depending on substitution model used and the universal rate does not account for variance in coalescent times (Papadopoulou et al. 2010), geological dating can offer a better estimation of the time of separation between the two islands when applying the correct distribution to account for dating uncertainty (Ho 2007).

The lack of genetic diversity found within *H. spinipennis* may be a result of population decline in the weevils. A likelihood of population decline is supported by the extinction of populations of *H. spinipennis* from Pitt Island in the late 1800s due to the loss of habitat and habitat modification from humans. Loss in genetic variation and extinction of populations points directly to a population bottleneck in *H. spinipennis*.

270 The results of this study suggest that there has been no decline in the number of the *H. spinipennis* and
271 *A. dieffenbachii* populations surveyed on Mangere and population numbers have not been affected by
272 the forest regeneration. The weevil has a consumer-resource metapopulation relationship with its host
273 plant and will decimate populations of *A. dieffenbachii* before moving onto another population of
274 plants (Schöps 1998). Metapopulation theory suggests that as long as recolonization by the consumer
275 exceeds or equals the extinction rate of the resource, the metapopulation will persist (Taylor 1990). On
276 Mangere, there is evidence for subpopulations going extinct while new *A. dieffenbachii* populations
277 have arisen which suggests a dynamic system of localized host-plant exploitation, extinction, and
278 weevil dispersal.

279 On Rangatira, there has been a decline in both *H. spinipennis* and *A. dieffenbachii* populations.
280 Although two of the populations (A & B) of *A. dieffenbachii* were found in 1995 and 2010, the plants
281 were in decline in 2010 with no flowering and no large-sized plants. One population of *A. dieffenbachii*
282 that was found in 1995 was longer in existence, not even as seedlings, in 2010. The newly discovered
283 population of plants on the West Clears contained mainly small plants and seedlings, with only one
284 plant that flowered, and may not be able to support a large weevil population. The decline on Rangatira
285 does not seem to be the result of forest regeneration as the locations of all *A. dieffenbachii* populations
286 are on open grasslands and cliffs where no forest has regenerated. Modeling suggests that if the
287 distance between host-plant populations is great enough to not be easily traversed, but not so far that it
288 is unreachable by the weevils, then the consumer-resource dynamic could persist for the long-term
289 (Johst & Schöps 2003). The host-plant populations on Rangatira were separated by several hundred
290 meters and the weevil is known to travel up to 500 m to a new plant resource (Schöps 1998).
291 Therefore, distance between populations does not appear to be the cause of its decline. More intensive

292 monitoring should be conducted on Rangatira to determine the cause of the host-plant decline and
 293 whether the metapopulation dynamic between *H. spinipennis* and *A. dieffenbachii* has been altered.

294 *Hadramphus spinipennis* is listed as endangered by the New Zealand Department of Conservation and
 295 is considered a species of concern due to its very restricted range. Although spatial models have shown
 296 that the weevil population is in equilibrium, and could possibly be classified as “common” (Kean
 297 2006), combining genetics with longer-term ecological data does not completely support the notion
 298 that *H. spinipennis* is common on both Mangere and Rangatira. In regards to the number of weevils
 299 and host-plant populations on Mangere, the weevil seems relatively abundant; however, on Rangatira
 300 lower weevil numbers were found. Genetic data indicates that both populations do not possess a large
 301 amount of genetic diversity and have most likely undergone a population bottleneck. Population
 302 bottlenecks are related to a loss of genetic diversity which can have significant consequences for long-
 303 term viability of small populations (Grueber et al. 2008). As the forests on Mangere and Rangatira
 304 Islands continue to regenerate, *A. dieffenbachii* may decline due to a loss of open habitat. Although the
 305 population counts suggest no change in *H. spinipennis* on Mangere, the weevil may be unable to adapt
 306 to a possible decline in its host-plant resulting from the loss of open habitat. This is particularly a
 307 concern on Rangatira where a decline in weevil numbers was seen.

308 Conclusions

309 A pattern of genetic structure separating a species by island haplotype is something that has been
 310 reported in other flightless beetles (Sequeira et al. 2012; Stroschio et al. 2011). Between the two islands
 311 there are some genetic differences, which should be preserved if possible, as the *H. spinipennis* on
 312 Rangatira and Mangere Islands are shown to be genetically isolated from each other. The unique
 313 haplotypes from each island adds variation and allows for the possibility of cross-introduction of

weevils to preserve genetic diversity. Our results strongly suggest that forest restoration on Rangatira and Mangere Islands has not had a negative impact on *H. spinipennis* or its host plant; however, a long-term survey, in particular accessing the area on Rangatira that could not be searched in this study, is recommended to confirm small population sizes. Although continued monitoring of the weevil populations is recommended, forest restoration should continue and is not impacting on the conservation of an open habitat specialist.

Acknowledgements

We thank the Chatham Islands Conservation Board, the Chatham Island imi/iwi, and the Department of Conservation (DoC) for the permit (WE-26391-RES) to collect and for access to the island, housing, and general assistance.

Table 1 (on next page)

ITS2 primers

Primers developed to amplify a region of the ITS2 gene in *H. spinipennis*.

| Primer Name | Primer Sequence 5' to 3' |
|--------------|---------------------------------------|
| Had ITS2 For | ATT CTG TTC CCG GAC CAC TCC TGG CTG A |
| Had ITS2 Rev | GCG CGC ACC GTT ACR ATC KGA CGY C |

2

Table 2(on next page)

Divergence times for the mitochondrial maximum clade credibility tree

Mean divergence times (Ma) and 95% confidence interval for the two different dating schemes used to date nodes in the mitochondrial maximum clade credibility tree. Dates were estimated in BEAST using a strict molecular clock with fixed mean rate of 0.0115 substitutions/site/my, and a strict molecular clock with a 3 million year age constraint on the tree root.

| | Divergence Times (Ma) | |
|-------------------------|-----------------------|-----------------|
| | Fixed mean rate | Geological date |
| Mean | 0.0013 | 0.0006 |
| 95% confidence interval | 0.0000-0.0139 | 0.0001-0.0016 |

Table 3(on next page)

Aciphylla dieffenbachii populations on Rangatira

Aciphylla dieffenbachii populations found on Rangatira including estimated population size, approximate size of the plants found in the population and whether the plants were in flower.

| Population | A | B | C |
|------------------|--------|---------------------|-------------------------------|
| Number of plants | 10 | 3 to 6 ^a | 2 to 7 and 55 ^a |
| Plant size | medium | Small / medium | Small to large / seedlings |
| Flowering | No | No | Yes ^b |

^aPopulation B had nine groups of plants spread across a cliff face; each group consisted of 3 to 6 plants. Population C had five groups of plants patchily distributed with 2 to 7 plants in each group. A total of 55 seedlings were spread throughout the area. ^bOnly two female plants were flowering.

Table 4(on next page)

Aciphylla dieffenbachii populations on Mangere

Aciphylla dieffenbachii populations found on Mangere including estimated population size, approximate size of the plants found in the population and whether the plants were in flower.

²

| Population | 1 | 2 | 3 | 4 | 5 | 6 | 7 |
|------------------|-------------------|-------------------|-------------------|-------------------|-------|-------------------|-------|
| Number of plants | 410 | 100 | 180 | 330 | 20 | 150 | 17 |
| Plant Size | Small / medium | Small to large | Small to large | Small / medium | Small | Small / medium | Small |
| Flowering | Yes | Yes | Yes | Yes | Yes | Yes | No |

1

Map of Chatham Islands

Map (1:500,000 scale) of the Chatham Islands with Rangatira (South East) and Mangere Islands labeled. Insert map shows the location of the Chatham Islands in relation to New Zealand.

2

Weevil marginal feeding pattern

A photograph depicting the weevil feeding pattern, which is identified by marginal notches.

Photograph by: Jagoba Malumbres-Olarte.

3

Maps of Rangatira survey sites

Rangatira Island with the populations of *A. dieffenbachii* that were recorded in the 1995 survey by Schöps (2000) (white circles) and the *A. dieffenbachii* populations found in the 2010 survey (white circles with letters). Letters were assigned to each site as they were found. The triangle with a question mark on the 2010 map represents the one area that could not be surveyed due to adverse weather conditions. Map image was obtained from Google Earth 2013 image and the same image was used for both maps.

4

Map of Mangere survey sites

Mangere Island with the *A. dieffenbachii* sites that were recorded in the 1995 survey by Schöps (2000) (white areas) and the *A. dieffenbachii* populations found in the 2011 survey (white areas with numbers representing the larger patches of *A. dieffenbachii*). Numbers were assigned to each site as they were found. The entire island was surveyed visually for *A. dieffenbachii*, but some plant patches could not be reached for hand-searching for weevils. Map image was obtained from Google Earth 2013 image and the same image was used for both maps.

5

ITS2 Neighbor-Net network

Neighbor-Net network generated from ITS2 distances. The underlined numbers are individuals from Mangere and the letters are individuals from Rangatira.

6

Neighbor joining trees for mitochondrial genes and ITS2

(A) Neighbor joining (NJ) tree for the concatenated mitochondrial genes COI and cytb. (B) Neighbor joining tree for ITS2. For both trees, individuals from Mangere are underlined (first number of weevil ID is subpopulation and the second number is ID to denote different weevils). The maximum clade credibility tree posterior probabilities higher than 95% are labeled below the branch node and the bootstrap value for the NJ tree are above the branch node. The root that was estimated in Beast for the maximum clade credibility tree and it is represented by the grey root line. The scale bar is in substitutions/site.
