There is currently enormous interest in how morphological and physiological responses of herbaceous plants may be affected by changing elevational gradient. Mountain regions provide an excellent opportunity to understand how closely related species may adapt to the conditions that rapidly change with elevation. We investigated the morphological and physiological responses of two Himalayan alpine gingers (*Roscoea alpina* and *R. purpurea*) along two different vertical transects of 400 m, *R. purpurea* between 2174- 2574 m a.s.l and *R. alpina* between 2675-3079 m a.s.l . We measured the variables of plant height, leaf length, leaf area, specific leaf area, and stomata density at five plots, along the vertical transect at an elevational gap of ca. 100 m. Results revealed that with increased elevation plant height, and leaf area decreased while stomata density increased, whereas changes in specific leaf area, were not correlated with the elevation. Our results reveal that these alpine gingers undergo local adaptation by modifying their plant height, leaf area and stomata density in response to the varying selection pressure associated with the elevational gradient. Thus, the findings of this research provide valuable information on how a narrow range of elevational gradient affects the herbaceous plants at the alpine habitat of the Himalayas.

26 [Abstract](#)

27 There is currently enormous interest in how morphological and physiological responses of  
28 herbaceous plants may be affected by changing elevational gradient. Mountain regions provide  
29 an excellent opportunity to understand how closely related species may adapt to the conditions  
30 that rapidly change with elevation. We investigated the morphological and physiological  
31 responses of two Himalayan alpine gingers (*Roscoea alpina* and *R. purpurea*) along two  
32 different vertical transects of 400 m, *R. purpurea* between 2174- 2574 m a.s.l and *R. alpina*  
33 between 2675-3079 m a.s.l. We measured the variables of plant height, leaf length, leaf area,  
34 specific leaf area, and stomata density at five plots, along the vertical transect at an elevational  
35 gap of ca. 100 m. Results revealed that with increased elevation plant height, and leaf area  
36 decreased while stomata density increased, whereas changes in specific leaf area, were not  
37 correlated with the elevation. Our results reveal that these alpine gingers undergo local  
38 adaptation by modifying their plant height, leaf area and stomata density in response to the  
39 varying selection pressure associated with the elevational gradient. Thus, the findings of this  
40 research provide valuable information on how a narrow range of elevational gradient affects the  
41 herbaceous plants at the alpine habitat of the Himalayas.

44

45 [Short title](#): Response of alpine gingers with the elevational gradient in the Himalayas

46

## 47 Introduction

48           The elevational gradient is one of the key environmental factors that affect growth,  
49 morphology and physiology of plants (Cordell et al., 1998; Hultine & Marshall, 2000; Qiang et  
50 al., 2003). The elevational gradient in alpine regions provides a sharp environmental change across  
51 relatively short spatial distances because small changes in elevation can lead to a large shift in  
52 temperature, humidity, exposure, and concentration of atmospheric gases (Hovenden & Vander  
53 Schoor, 2004). Thus, alpine environments can provide useful natural avenues to investigate the  
54 response of plants to a suite of climatic conditions that are representative of the broader latitudinal  
55 range (Montesinos-Navarro et al., 2011). With the increase in elevation, there is typically an  
56 increase in both precipitation and light intensity including changes in distributions of short  
57 wavelength UV-A (315-400 nm) and UV-B (280-315 nm) radiation (Diffey, 1991; Rozema et al.,  
58 1997) whilst temperature and concentration of carbon dioxide and oxygen decrease (Friend &  
59 Woodward, 1990). These environmental variations may potentially alter the morphology and  
60 physiology of plants to endure the different stresses linked with changing elevation (Hovenden &  
61 Brodribb, 2000; Körner, 2007).

62           The alpine environment is potentially affected by climate change associated with global  
63 warming, and thus alpine plants may face rapidly changing environmental conditions that likely  
64 impose different stress levels on plants (Beniston, 2003; Byars, Papst & Hoffmann, 2007). Thus,  
65 based on the adaptative plasticity, the plant species exhibit local adaptation by altering the  
66 morphological and/or physiological traits over the range of elevational gradient (Hirano,  
67 Sakaguchi & Takahashi, 2017). For example, local adaptations of plants in response to variable

68 climatic conditions at different elevations may result in variation of plant height and leaf length  
69 (Wang & Gao, 2004). Variation in carbon assimilation, energy balance and water relations along  
70 the elevational gradient could result in variation of leaf morphological and physiological traits  
71 such as leaf area, specific leaf area (SLA) and stomata density (Ackerly et al., 2002). Therefore,  
72 the study of the variation in the growth forms, morphology and physiology of a plant species along  
73 an elevational gradient could provide valuable insights on how plants may respond to  
74 environmental stress imposed by rapid changes in climatic conditions (Premoli & Brewer, 2007;  
75 Körner, 2007; Bresson et al., 2011).

76         Although several previous studies have documented the effects of elevational gradient on  
77 the growth, morphology and physiology of the plants, most of the studies are focused on tree  
78 species (Cordell et al., 1998; Hultine & Marshall, 2000; Li et al., 2008). Recently a few studies  
79 have been conducted to understand how the elevational gradients affect the herbaceous plants  
80 (Gonzalo-Turpin & Hazard, 2009; Scheepens, Frei & Stöcklin, 2010; Hulshof et al., 2013; Bastida,  
81 Rey & Alcántara, 2015; Takahashi & Matsuki, 2017; Kiełtyk, 2018). These studies particularly  
82 focused on the variation of a specific trait, such as vegetative trait, reproductive trait or leaf trait.  
83 Currently however, there is a lack of empirical evidence on the adaptative potential of herbaceous  
84 plants along the elevational gradient in steep environments such as the Himalayas. As the alpine  
85 ecosystem in the Himalayas is likely to experience the adverse effects of the changing climate  
86 associated with global warming and anthropogenic disturbances (Beniston, 2003; Byars, Papst &  
87 Hoffmann, 2007), understanding the performance of herbaceous plants along the elevational  
88 gradient provides important insights for the enhanced prediction of the response of herbaceous  
89 plants under altered climatic conditions.

90           The genus *Roscoea*, with 22 known species, is a Himalayan endemic alpine perennial herb  
91 and the only alpine member of the predominately-tropical family Zingiberaceae (Cowley, 1982,  
92 2007). The genus is distributed between the elevations of ca 1500 to 4500 m a.s.l (Cowley, 2007),  
93 thus serving as a key model for how herbaceous plants respond to the potentially stressful  
94 environmental conditions associated with increasing elevation. All *Roscoea* species are small  
95 herbs with annual leafy shoots produced from a reduced erect rhizome (Cowley, 1982, 2007).  
96 Among the *Roscoea* species, *R. alpina* Royle and *R. purpurea* Smith are widely distributed in the  
97 Himalayan Mountains from Kashmir (Pakistan) in the west through Nepal, India, Bhutan and  
98 Tibet. As these two *Roscoea* species are widely distributed from low to high elevations,  
99 characterization of the variation in morphological and physiological traits along the elevational  
100 gradient will help to understand how these alpine gingers respond to changes in climatic conditions  
101 associated with elevation. In this study, we explore the changes in the morphological (plant height  
102 and leaf length) and physiological variables (leaf area, SLA and stomata density) of these alpine  
103 gingers along the well-defined elevational gradient in the Himalayan mountain range.

## 104 [Materials and Methods](#)

### 105 [Study species](#)

106           The two widespread *Roscoea* species used in this study were *R. alpina* and *R. purpurea*  
107 (Fig. 1). *Roscoea alpina* is a common species with a wide distribution between the elevations  
108 2130-4270 m a.s.l in the Himalayan range from Kashmir (Pakistan) in the west through Bhutan in  
109 the east. The annual pseudostem may grow up to 12-20 cm high and presents flowers from the end  
110 of May to mid-August (Cowley, 2007). It has 2-3 obtuse sheathing leaves. Leaves are usually 1-2  
111 in number and underdeveloped; occasionally the plant may bear up to four well-developed leaves.  
112 Leaves are linear, broadly elliptic or lanceolate. Only the first leaf is slightly auriculate and widest

113 at the base while rest of the leaves are widest at the middle, with 17- 25 cm in length. Leaves are  
114 usually glabrous but young leaves are occasionally hairy at acute apex. Inflorescences are without  
115 exerted peduncle. Flowers are deep purple to white in appearance for a human observer (Fig. 1).  
116 A single plant can develop up to five flowers, however only one flower blooms at a time. Obtuse  
117 to almost truncate bracts are shorter than the ovary. The calyx is much longer than the bract and  
118 bluntly bi-dentate. A long corolla tube is exerted from the calyx (Cowley, 2007).

119 *Roscoea purpurea* is also a widespread member of the Himalayan *Roscoea*, distributed  
120 between the elevations 1520-3100 m a.s.l. from Himachal Pradesh (India) in the west through  
121 Assam/Bhutan in the east. The annual erect pseudostem is most variable in habit and form and  
122 may grow up to 25-38 cm high, bearing 0-2 obtuse to truncate sheathing leaves. Leaves are usually  
123 4-8 in number, lanceolate to oblong-ovate and 14-20 cm long with acuminate and sometimes with  
124 ciliated apex. Lower leaves are slightly auriculate at the base. The plant flowers from the end of  
125 June to early September (Cowley, 2007). The inflorescence is enclosed in upper leaf sheaths with  
126 only the upper part of bracts and flowers visible. Flowers are light purple or white with purple  
127 markings. Usually, 1-2 flowers open at a time. Bracts longer than calyx with acute apex which is  
128 pale green. The sharply bi-dentate and apiculate calyx is usually pale green and sometimes marked  
129 with pink. The corolla tube has a mauve or white colouration and is hardly exerted from the calyx  
130 (Cowley, 2007).

### 131 [Study sites](#)

132 The research was conducted along an elevational gradient at two sites, Daman and  
133 Ghorepani, Central Nepal (Fig. 2). Daman is located in Makawanpur district and forms a part of  
134 the Mahabharat mountain range (mountains lower than the Himalayas). This site lies about 70 km  
135 south-west of Kathmandu and is midway between Kathmandu and Hetauda. The vegetation type

136 of this site typically comprises a mixed forest of *Pinus* (*Pinus roxburghii*), *Rhododendron* (*R.*  
137 *arboreum*, *R. campanulatum*) and *Quercus* (*Q. semecarpifolia*, *Q. lanata*). The site experiences  
138 cool temperate to subalpine climate with warm summers and cold winters that typically incur mild  
139 to heavy snowfall from November to February (Pers. Obs. BRP). Ghorepani, located in Myagdi  
140 district, is about 270 km west of Kathmandu. The vegetation type of this site comprises a mixed  
141 forest of *Pinus* (*P. wallichiana*), *Abies* (*A. spectabilis*) and *Rhododendron* (*R. arboretum*, *R.*  
142 *barbatum*, *R. campanulatum*, *R. antohopogon* at upper limit). The site has a subalpine climate and  
143 cool weather throughout the year, and heavy snowfall from November to February (Pers. Obs.  
144 BRP). The geographical coordinates and the elevations of the study sites are presented in Table  
145 1.

#### 146 [Measurement of traits](#)

147 The field sampling was conducted from May to August 2014 and repeated the sampling  
148 again in 2017 (May to August). Five sampling plots were selected along a vertical transect from  
149 2174 to 2574 m a.s.l. for *R. purpurea* and from 2675 to 3079 m a.s.l. for *R. alpina*. The sampling  
150 was done in a counterbalanced random fashion such that two adjacent sampling plots were at an  
151 elevation gap of ca 100 m. Plant height and leaf length were measured to examine the  
152 morphological variables. Physiological variables included leaf area, specific leaf area (SLA) and  
153 stomata density. At each sampling plot, a horizontal transect of 100 m length was laid down and  
154 twenty plants were randomly selected along the horizontal transect in such a way that the distance  
155 between the adjacent sampling plant was at least 5 m. A standard metric ruler was used to measure  
156 plant height (the distance from the ground to the topmost part of the stem). The largest leaf of  
157 every sampled plant was removed and leaf length was measured with a ruler. We used a graph  
158 paper to trace and quantify the area of each leaf, enabling robust repeatable measurements in

159 remote locations. Specifically, two alternative methods were used to measure the area of the leaf.  
160 In 2014, the area of the leaf was measured after wet storage, while in 2017 the area was measured  
161 on the freshly plucked leaf. To prevent the leaves from possible shrinkage during wet storage, the  
162 leaves were first flattened if necessary and carefully placed in between the folds of a paper.  
163 Resulting samples were then placed in a sample box to avoid the external light and heat sources.  
164 For both respective leaf collection methods, the leaf (either wet stored or freshly plucked) was  
165 placed on a graph paper, its outline was sketched and the number of squares enclosed within the  
166 leaf-outline were counted. Complete and greater than half squares were scored, whilst squares less  
167 than half a square were excluded. The measurements were repeated several times for each leaf to  
168 enable a robust field measurement of leaf area. Twenty leaves at each sampling plot were measured  
169 to assess variability. The area of leaf as measured by two alternative methods did not differ  
170 significantly ( $t$  test,  $P>0.05$ ), thus data generated from the freshly removed leaf were used for  
171 further analysis. All collected leaves were gently pressed between the folds of an absorbent paper  
172 for five days to flatten the leaf surface and to absorb any excess moisture. The pressed leaves were  
173 subsequently oven dried at the university laboratory for 48 hours at  $70^{\circ}$  C. Dry leaf weight was  
174 measured using a digital electronic balance (Fameway International (HK) Limited; accuracy  
175 0.001g). Specific leaf area (SLA) of a leaf was calculated as the ratio of the area of a fresh leaf and  
176 its dry weight and expressed in  $\text{cm}^2/\text{g}$ .

177 To determine the stomatal count, transparent nail polish was applied on the middle dorsal  
178 surface of a fresh leaf. After a few minutes, when nail polish had dried, a thin layer was peeled  
179 from the middle dorsal surface of a leaf. The peeled layers were separately preserved in a 10%  
180 glycerine solution for about 72 hours. In the laboratory, the temporary slide of each layer was  
181 prepared using safranin as a staining agent. The stained layers were individually mounted on

182 microscope slides, and all stomata observed under a 10-x magnification microscopic field were  
183 counted. The stomata counts were repeated at three different microscopic fields to ensure the exact  
184 measurement of the stomata density. Area of the microscopic field was calculated using the  
185 formula  $A = \pi r^2$  where  $r$  is the radius of microscopic field and density of stomata was calculated as  
186 the number of stomata under a microscopic field divided by the area of the microscopic field. The  
187 stomata density was expressed in terms of number per square millimetre.

## 188 [Statistical Analyses](#)

189 An independent sample  $t$  test was used to test the variation in measured traits between the  
190 years. Data from each of the measured morphological variables were summarized as Q-Q plots  
191 and tested for normality. Exploratory data analyses revealed that some of the response variables  
192 were not normally distributed and were better described by a Gamma distribution as most data  
193 consisted of positive values larger than zero (Zuur, Hilbe & Ieno, 2013). Consequently, non-  
194 parametric correlation analyses were performed among the five different traits measured for each  
195 species implementing Kendall's tau statistic ( $\tau$ ). This coefficient was chosen as it has a known  
196 standard error and provides a better estimate with low sample size. After the exploratory  
197 analyses, generalised linear regression models (GLM) were applied to test for the potential  
198 effects of elevation on the different traits measured for each species. For the five regression  
199 models, elevation was used as a predictor and it was assumed that the response variable followed  
200 a Gamma distribution. Link function for each model was selected based on a comparison of AIC  
201 scores obtained after fitting models implementing different link functions (Zuur, Hilbe & Ieno,  
202 2013). Regression analyses were performed using the routine *glm* available as part of the base  
203 distribution of the R language and environment for statistical computing (version 3.3.1) (R Core  
204 Team, 2015).

## 205 Results

### 206 Correlation analyses

207 Our results indicated that all the measured variables did not differ significantly between  
208 years ( $P > 0.05$ ), thus only 2017 data were used for further analyses. For *R. purpurea*, there was a  
209 significant correlation between stomata density and the variables of leaf area ( $P < 0.001$ ) and  
210 specific leaf area (SLA) ( $P = 0.020$ ) (Fig. 3). In *R. alpina*, leaf length was correlated with all  
211 remaining variables (Fig. 4). Consequently, we separately performed the regression analyses for  
212 the two species for each of the measured response variables.

### 213 Variations of traits with elevation

214 Leaf length of *R. alpina* and plant height significantly decreased with increasing elevation  
215 ( $P = 0.001$  for leaf length and  $P = 0.017$  for plant height). The same trend was observed for leaf  
216 area ( $P < 0.001$ ), while stomata density increased with elevation ( $P = 0.005$ ). SLA values for this  
217 species were not significantly correlated with elevation ( $P = 0.114$ ) (Fig. 5).

218 Plant height and leaf area significantly decreased, while stomata density increased, with  
219 increasing elevation in *R. purpurea* ( $P = 0.044$ ,  $P = 0.001$  and,  $P = 0.002$  for plant height, leaf area  
220 and stomata density respectively). However, we did not find a significant relationship of elevation  
221 either with leaf length ( $P = 0.471$ ) or with SLA ( $P = 0.555$ ) (Fig. 5). Details on the regression  
222 analysis including coefficients and associated 95% confidence intervals are provided in Table 2  
223 and Table 3.

224

## 225 Discussion

## 226 Variations of morphological traits with elevation

227 In the current study, we found a significant decrease in plant height of both species of  
228 *Roscoea* (*R. alpina* and *R. purpurea*) with increased elevation. Reduction of plant height in these  
229 alpine gingers with increased elevation is consistent with several previous findings reported for  
230 tree species (Körner, 1998; Cordell et al., 1998; Kronfus & Havranek, 1999; Paulsen, Weber &  
231 Korner, 2000; Kogami et al., 2001; Li, Yang & Kräuchi, 2003; Shi et al., 2006) and herbaceous  
232 species (Takahashi & Matsuki, 2017; Kiełtyk, 2018). Similarly, a decrease of leaf length of *R.*  
233 *alpina* with the increased elevation in the current study is consistent with the previous findings  
234 (Hansen-Bristow, 1986; Schoettle, 1990; Kajimoto, 1993; Kao & Chang, 2001; Kiełtyk, 2018).  
235 Based on the present result, we conclude that the elevational gradient has a significant effect on  
236 the growth form of these alpine gingers. At the lower elevation, environmental conditions are  
237 likely to be more favourable for optimum plant growth. The reduction of plant height and leaf  
238 length of these two alpine gingers with increasing elevation reflects the morphological adaptation  
239 to increased environmental stresses such as low concentration of carbon dioxide, decreased  
240 temperature, higher solar radiation and/or low water availability (Wang & Gao, 2004; Davis, Shaw  
241 & Etterson, 2005; Guerin, Wen & Lowe, 2012). The observed relatively smaller plants with shorter  
242 leaf characteristics of these gingers at higher elevation thus may reflect local adaptation at a higher  
243 altitude to enable reduction of transpiration and maintain efficient utilization of water (Ackerly et  
244 al., 2002; Royer et al., 2008; Peppe et al., 2011; Guerin, Wen & Lowe, 2012).

245 [Variation of physiological traits with Elevation](#)246 [Leaf traits variation with elevation:](#)

247           Our findings revealed that variation in leaf area showed a significant but negative  
248 correlation with elevation, while the correlation between SLA and elevation was non-significant.  
249 Consistent with our result, Kouwenberg, Kurschner and McElwain (2007) found a decreasing  
250 trend in the leaf area of *Quercus kelloggii* with increasing elevation. Our result on the variation of  
251 leaf characters (leaf area and SLA) with the elevation is partially consistent with the previous  
252 findings reported by Hultine and Marshall (2000); Scheepens, Frei and Stöcklin (2010); Hulshof  
253 et al., (2013); Bastida, Rey and Alcántara, (2015), while the findings of Gonzalo-Turpin and  
254 Hazard (2009) indicate a different effect. Previous studies have suggested that the environment at  
255 higher elevations is characterized by higher solar radiation, lower water availability and lower  
256 stomatal conductance (Parkhurst & Loucks, 1972; Givnish & Vermeij, 1976; Ackerly et al., 2002).  
257 Under such potentially stressful environmental conditions, small leaf size provides optimum  
258 adaptation to the plants by reducing boundary layer resistance and maintaining favorable leaf  
259 temperature and high photosynthetic water use efficiency (Renzhong et al., 2001). Thus, decreased  
260 leaf area of these alpine gingers with increased elevation may reflect an adaptation for the  
261 increased environmental stress and may be favourable to reduce water loss and maintain efficient  
262 use of absorbed water (Renzhong et al., 2001). In addition, some authors have implicated  
263 increasing UVB radiation levels as having a damaging effect on certain plant structures (Jansen,  
264 Gaba & Greenberg, 1998; Rozema, Aerts & Cornelissen, 2002); and there is some evidence of this  
265 affecting plant growth in some lowland terrestrial species (Rozema, Aerts & Cornelissen, 2002).  
266 These topics may be of high value to explore in alpine environments where there are likely large  
267 changes in UV levels. SLA is closely associated with leaf thickness, which mediates the trade-off

268 between light capture, water loss and diffusion of carbon dioxide (Oberle & Schaal, 2011). Higher  
269 SLA leaves are thicker and contain more photosynthetic enzymes and there is more demand for  
270 carbon dioxide per unit area. Thus, stomata density increases to supply the higher demand for  
271 carbon dioxide. Consequently, the increase in SLA may be an advantage for carbon dioxide uptake.  
272 Non-linear change of SLA of both species along the elevational gradient may indicate that  
273 environmental factors associated with altitude alone cannot regulate the trade –off between light  
274 capture, water loss and diffusion of carbon dioxide in these alpine gingers. The smallest SLA of  
275 *R. alpina* at 2674 m a.s.l and *R. purpurea* at 2374 m a.s.l may indicate limited carbon gain and  
276 supply due to poor availability of resources and may be associated with the least productive zone  
277 of these species where retention of captured resources and protection from desiccation is of high  
278 priority (Wilson, Thompson & Hodgson, 1999).

#### 279 Variation in Stomata density with Elevation

280 We found a significant increase in stomata density of both species (*R. alpina* and *R.*  
281 *purpurea*) with increased elevation. Many authors have made comprehensive efforts to relate the  
282 variation in stomata density along elevation gradients and have obtained different results.  
283 Consistent to our current results, Körner and Cochrane (1985); Friend and Woodward (1990);  
284 Hovenden and Brodribb (2000); and Kouwenberg, Kurschner and McElwain (2007) have found  
285 that stomata density increased linearly with elevation. Li et al. (2006) found that stomata density  
286 of *Quercus aquifolioides* increased linearly up to the height of 2800 m a.s.l., whilst above that  
287 height, it decreased linearly. Schoettle and Rochelle (2000) found that the stomata density of *Pinus*  
288 *flexilis* decreased linearly with altitude whilst Woodward (1986) did not observe any significant  
289 change in stomata density of *Vaccinium myrtillis* considering altitudes from 200 to 1100 m asl. The  
290 significant increase in stomata density with increasing elevation in our findings may be associated

291 with lower availability of carbon dioxide, higher UV-B and long wave radiation, all reducing  
292 photosynthetic efficiency by decreasing stomatal absorption and conductance (Kouwenberg,  
293 Kurschner & McElwain, 2007; Körner, 2007). To adapt to such a harsh environmental conditions  
294 and maintain vitalities, stomata density of these gingers may have increased. The increase in  
295 stomata density provides compensation against the reduced stomatal conductance and carbon  
296 dioxide partial pressure to maintain photosynthetic efficiency (Kao & Chang, 2001; Kouwenberg,  
297 Kurschner & McElwain, 2007; Körner, 2007).

298         Our results indicate two major patterns in the vegetative traits of these alpine gingers with  
299 increased elevation: a significant decrease of leaf area and a significant increase of stomata density.  
300 These variations provide compensation to cope with the change in the concentration of  
301 atmospheric carbon dioxide, temperature, humidity and light at higher altitudes (Van de Water,  
302 Leavitt & Betancourt, 1994; Hultine & Marshall, 2000; Qiang et al., 2003). A non-significant  
303 correlation between SLA and stomata density may suggest that leaf thickness have little role in  
304 regulating the carbon dioxide uptake and transpiration in these two alpine gingers. A negative  
305 correlation of stomata density with leaf area has previously indicated that with the increase of  
306 stomata density at a higher elevation, narrowing of leaves may reduce excess transpiration (Herms  
307 & Mattson, 1992; Etterson & Shaw, 2001). The closely correlated variation in these two traits thus  
308 maintains a likely trade-off between photosynthesis and transpiration and provides local adaptation  
309 to the specific conditions, at different elevations.

## 310 Conclusions

311         Growth, morphology and physiology of *R. alpina* and *R. purpurea* were found to have a  
312 significant association with altitude. These alpine gingers exhibit optimum growth at their  
313 respective lowermost distribution range, and their growth response retards with increasing

314 elevation. Based on the present result, it can be concluded that these alpine gingers favour shorter  
315 height, smaller leaf and higher stomata density at a higher elevation to adapt with the stressful  
316 factors associated with the change in elevational gradients. Variation in those traits at different  
317 elevations may reflect the response to the combined selection pressure of different abiotic and  
318 biotic factors that may generate different micro-environmental conditions at the respective  
319 elevation. Decreased growth forms and leaf area of these alpine gingers at a higher altitude may  
320 indicate a selection response to reduce water loss from the plant body during transpiration while  
321 increased stomata density may indicate the adaptation to cope with the decreased concentration of  
322 carbon dioxide. The closely correlated modification of these traits at different elevations may have  
323 played a significant role in providing local adaptation to these alpine gingers.

Figure 1

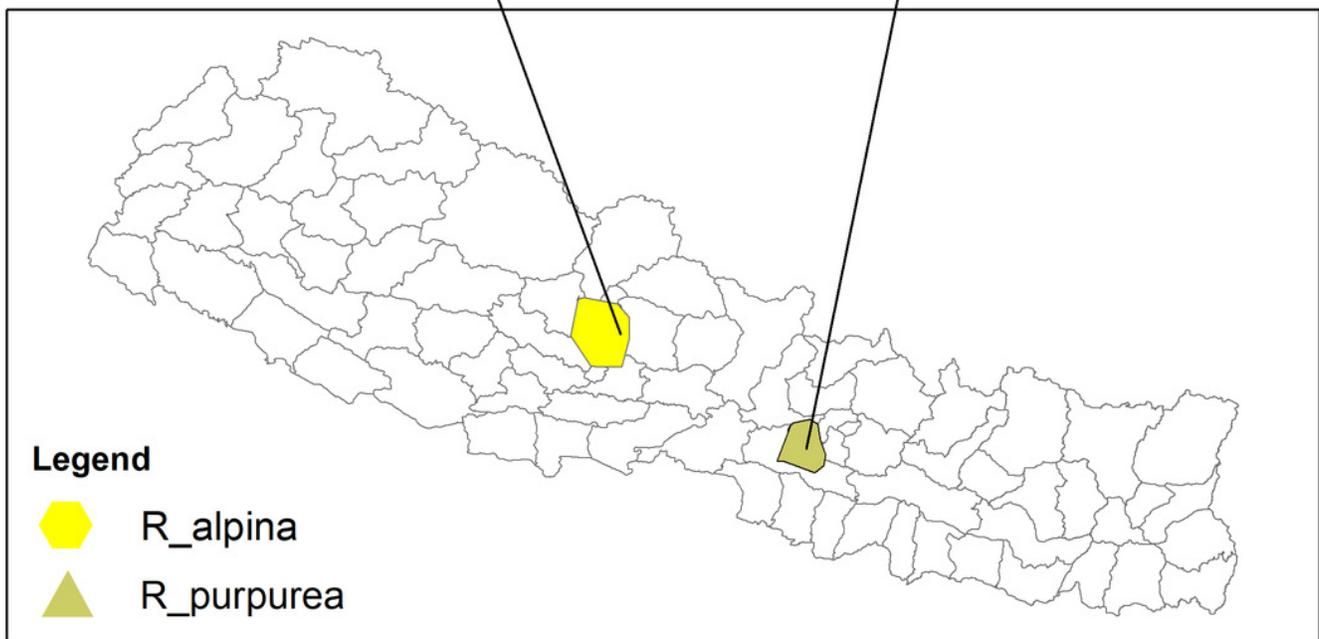

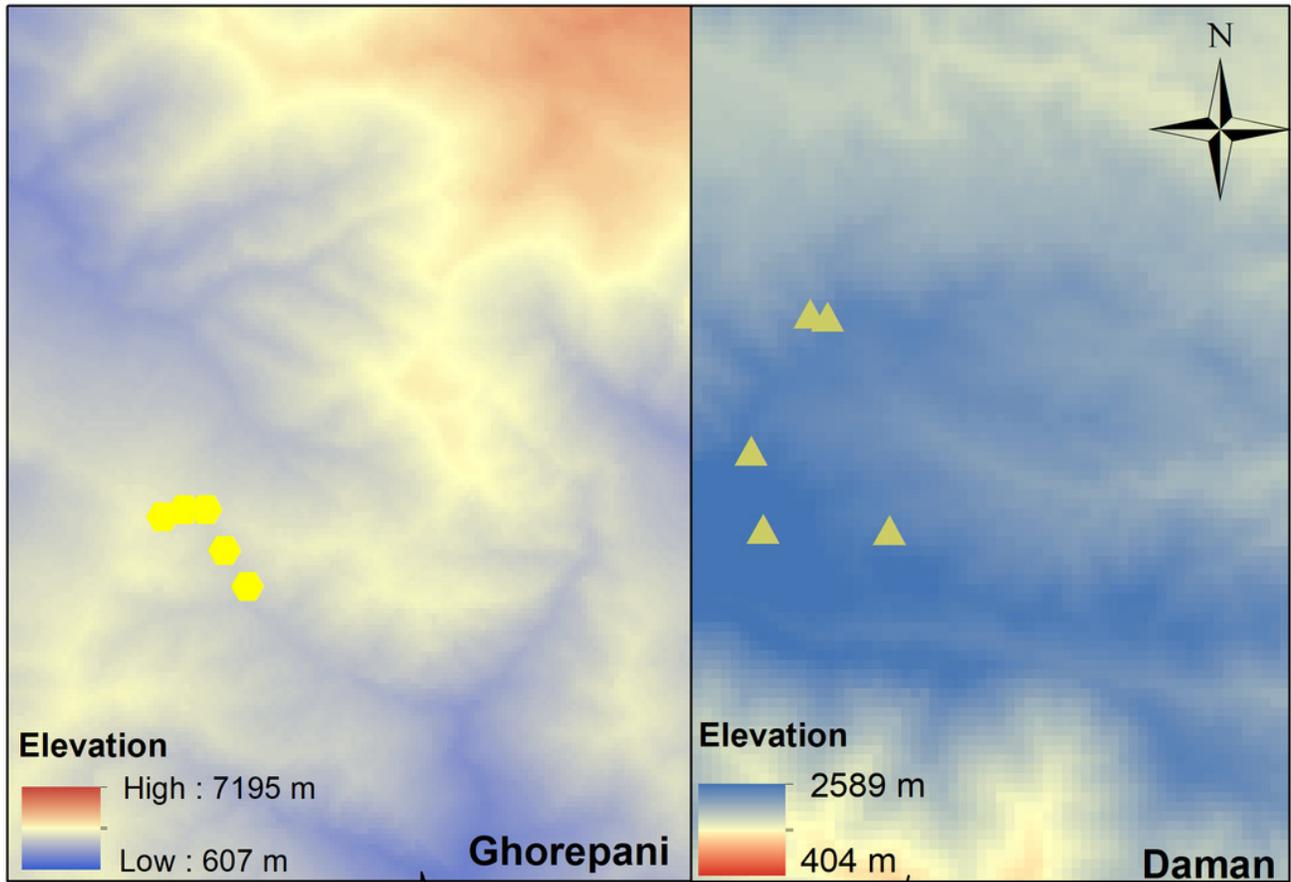

Study species *Roscoea purpurea* (A) and *R. alpina* (B) in their natural habitat.

## Figure 2

### Figure 2

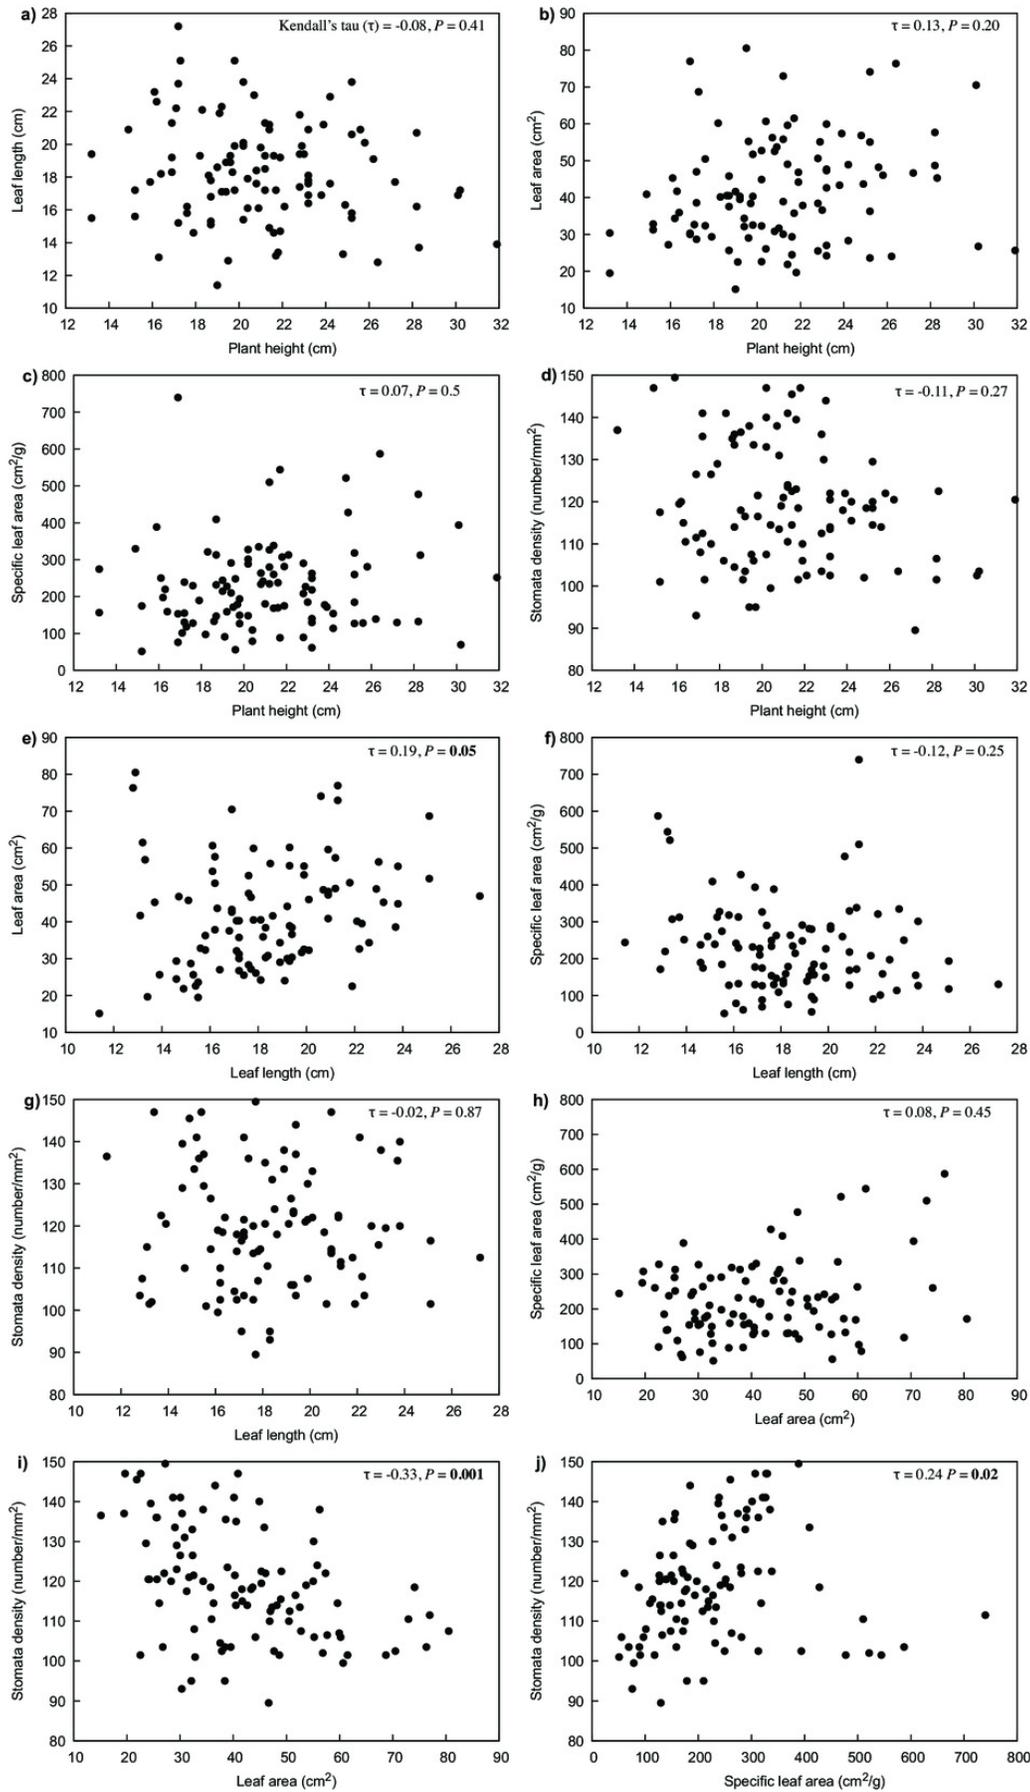

Map of the study area: Yellow hexagons represent the study site (Ghorepani ) of *Roscoea alpina* whereas Light-Oliventine triangles represent the study site (Daman) of *R. purpurea* (See Table 1 for detail). The top map represents the elevational gradient of study locations.

## Figure 3

Figure 3

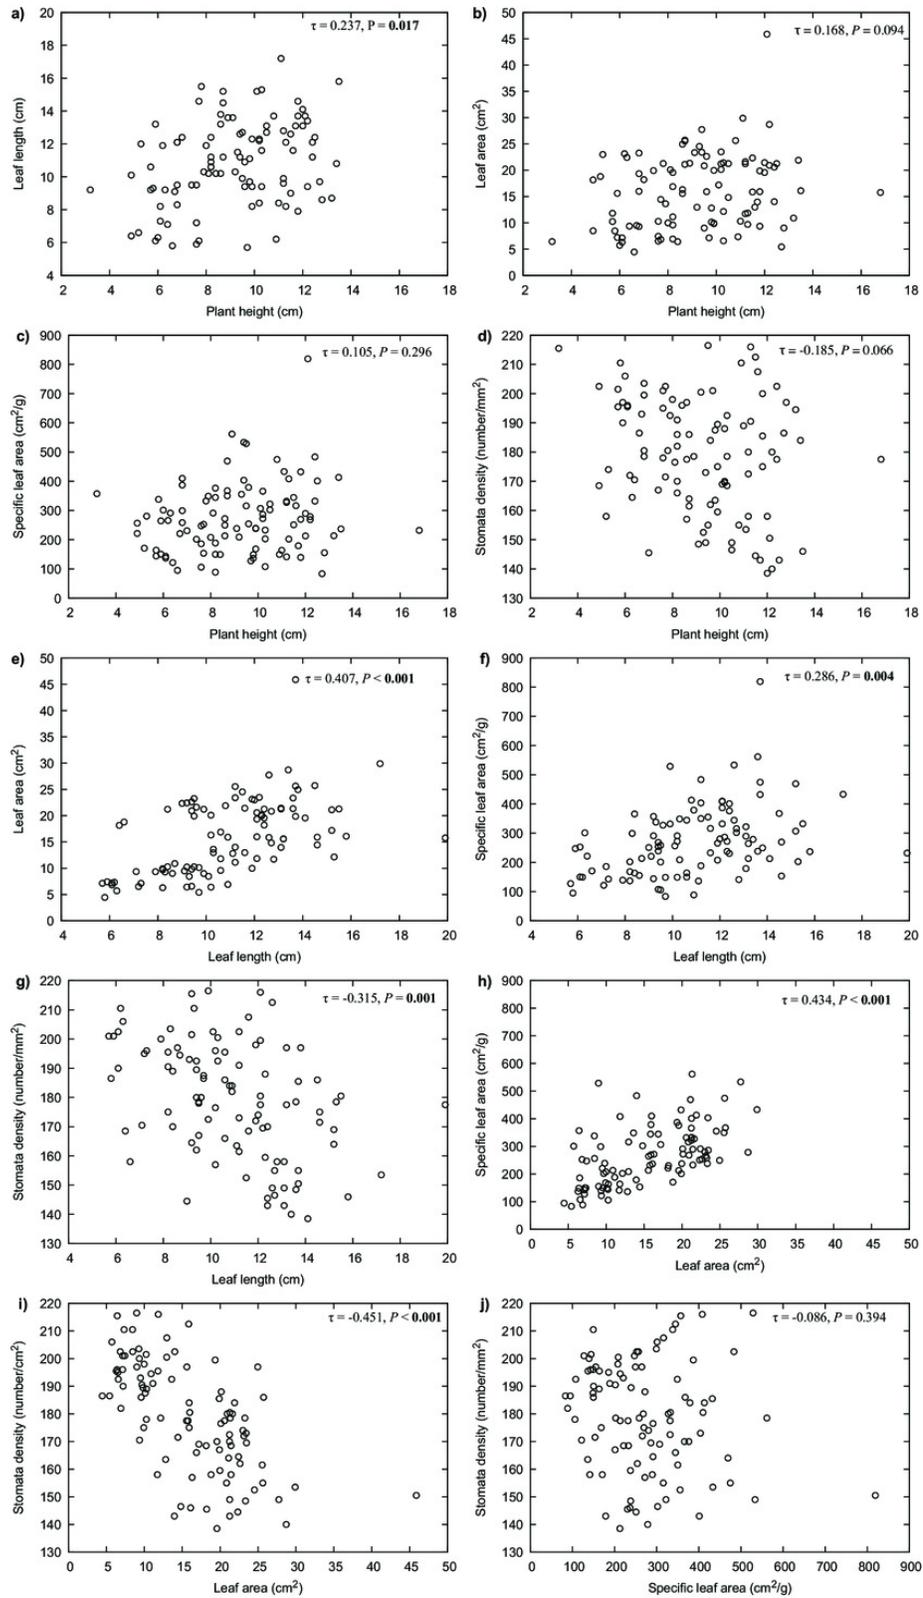

Correlations between the different traits of *R. purpurea* measured at five different elevations.

## Figure 4

Figure 4

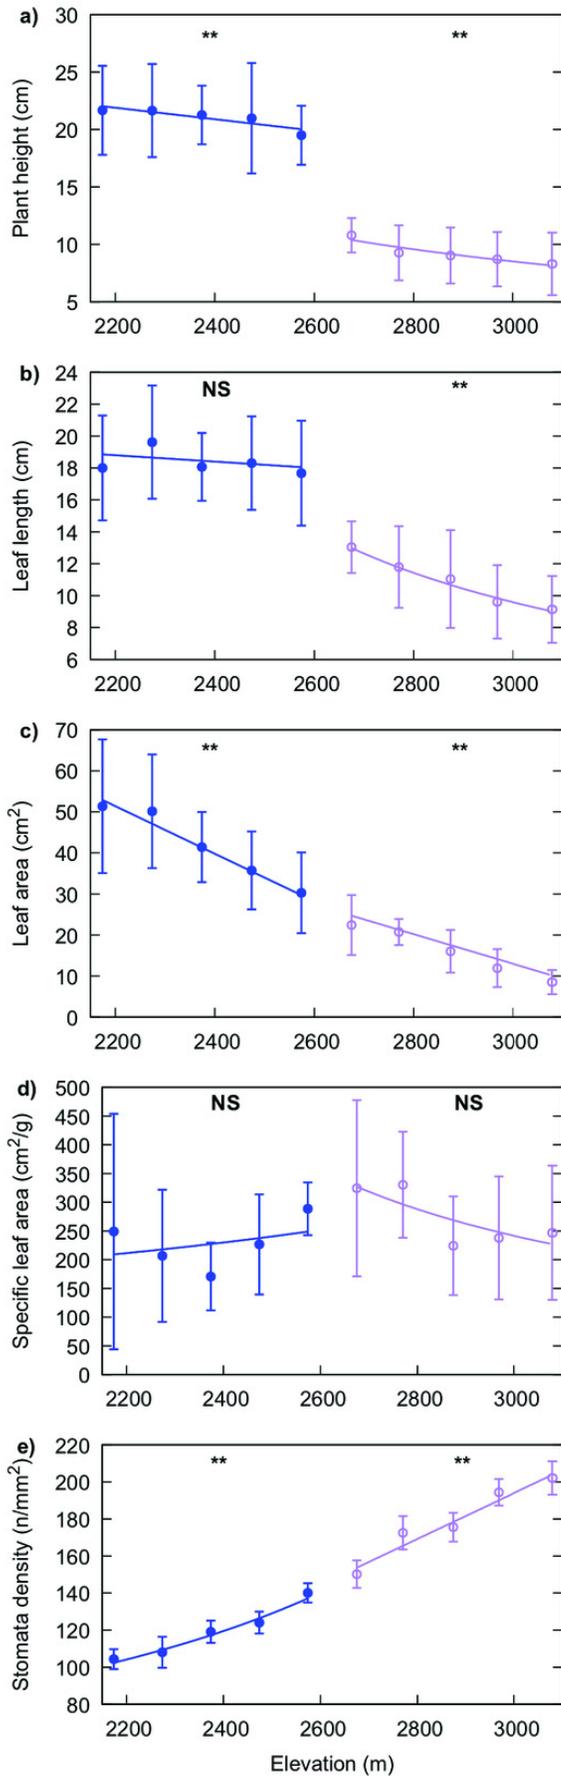

Correlations between the different traits of *R. alpina* measured at five different elevations.

## Figure 5

### Figure 5

Generalised linear regression models showing the effect of elevation on plant height (fig. a), leaf length (fig. b), leaf area (fig. c), specific leaf area (fig. d) and, stomata density (fig. e) for *R. purpurea* (blue line with filled markers) and *R. alpina* (purple line with empty markers). Markers indicate the mean value of the corresponding trait at each elevation and error bars indicate standard deviation. Solid lines represent the regression function for each trait and species. A significant correlation of elevation on the value for each trait is indicated by two asterisks (\*\*) while a non-significant correlation of elevation is indicated by “NS” above the corresponding regression line.
