Background. Inclusion of forage into the orchard is of great help to promote the use efficiency of resources, while shading from trees restricts forage growth and production in the Loess Plateau of China. This study was aimed to investigate how tree shading affected leaf trait, photosynthetic gas exchange and chlorophyll feature of forages under the tree in the orchard-forage system.

Methods. The shading treatments were set as partially cutting branches (reduced shading), normal fruit tree shading (normal shading) and normal tree shading plus sun-shading net (enhanced shading) in an apple orchard. Leaf trait, photosynthesis, chlorophyll component and fluorescence related parameters were measured with lucerne (*Medicago sativa*), white clover (*Trifolium repens*) and cocksfoot (*Dactylis glomerata*) which were sown under apple trees.

Results. Shading imposed significant impacts on the growth and leaf photosynthetic characteristics, while there were differences among species. Enhanced shading decreased leaf thickness, leaf dry matter content (LDMC) and leaf mass per unit area (LMA). Biomass accumulation decreased with enhanced shading in cocksfoot, but did not change in white clover and lucerne which had much lower biomass accumulation than cocksfoot. Enhanced shading reduced net photosynthetic rate (Pn) of white clover and lucerne, but rarely affected cocksfoot, while it decreased instantaneous water use efficiency (WUEi) of cocksfoot but had few effects on the other forages. Enhanced shading reduced leaf dark respiration rate (Rd), light compensation point (LCP) and maximum assimilation rate. The Rd and LCP of cocksfoot were much lower than those of white clover and lucerne. Chlorophyll contents and chlorophyll a/b changed little with shading. Cocksfoot had the highest contents but lowest ratio. Maximum photochemical rate of photosystem II increased and non-photochemical quenching decreased with enhanced shading in cocksfoot, while did not change in the other forages.

Discussion. Leaf trait, photosynthetic gas exchange and chlorophyll feature were variously affected by species, shading and their interaction. Cocksfoot was more efficient than the other two forages in use of weakened light and more tolerant to tree shading. In the apple orchard, we recommend that reducing the density of apple tree or partially cutting branches together with selecting some shading-tolerant forages, i.e. cocksfoot, would be a practical option for the orchard-forage system in the Loess Plateau of China.

15 **Abstract**

16 **Background.** Inclusion of forage into the orchard is of great help to promote the use efficiency
17 of resources, while shading from trees restricts forage growth and production in the Loess
18 Plateau of China. This study was aimed to investigate how tree shading affected leaf trait,
19 photosynthetic gas exchange and chlorophyll feature of forages under the tree in the orchard-
20 forage system.

21 **Methods.** The shading treatments were set as partially cutting branches (reduced shading),
22 normal fruit tree shading (normal shading) and normal tree shading plus sun-shading net
23 (enhanced shading) in an apple orchard. Leaf trait, photosynthesis, chlorophyll component and
24 fluorescence related parameters were measured with lucerne (*Medicago sativa*), white clover
25 (*Trifolium repens*) and cocksfoot (*Dactylis glomerata*) which were sown under apple trees.

26 **Results.** Shading imposed significant impacts on the growth and leaf photosynthetic
27 characteristics, while there were differences among species. Enhanced shading decreased leaf
28 thickness, leaf dry matter content (LDMC) and leaf mass per unit area (LMA). Biomass
29 accumulation decreased with enhanced shading in cocksfoot, but did not change in white clover
30 and lucerne which had much lower biomass accumulation than cocksfoot. Enhanced shading
31 reduced net photosynthetic rate (Pn) of white clover and lucerne, but rarely affected cocksfoot,
32 while it decreased instantaneous water use efficiency (WUEi) of cocksfoot but had few effects
33 on the other forages. Enhanced shading reduced leaf dark respiration rate (Rd), light
34 compensation point (LCP) and maximum assimilation rate. The Rd and LCP of cocksfoot were
35 much lower than those of white clover and lucerne. Chlorophyll contents and chlorophyll a/b
36 changed little with shading. Cocksfoot had the highest contents but lowest ratio. Maximum
37 photochemical rate of photosystem II increased and non-photochemical quenching decreased
38 with enhanced shading in cocksfoot, while did not change in the other forages.

39 **Discussion.** Leaf trait, photosynthetic gas exchange and chlorophyll feature were variously
40 affected by species, shading and their interaction. Cocksfoot was more efficient than the other
41 two forages in use of weakened light and more tolerant to tree shading. In the apple orchard, we
42 recommend that reducing the density of apple tree or partially cutting branches together with
43 selecting some shading-tolerant forages, i.e. cocksfoot, would be a practical option for the
44 orchard-forage system in the Loess Plateau of China.

45

46 **Introduction**

47 Traditional orchard performance with bare ground or simple tillage to the soil has led to serious
48 soil erosion and low use efficiency of resources, such as light, soil water and nutrients (*Shui et al.*,
49 2008). Inclusion of grass (and/or forage) into the orchard is an advanced management mode for
50 orchard soil (*Skroch & Shribbs, 1986*), offering a solution to deal with such issues, and has been
51 widely used as an efficient conservation tillage in the orchard (*Neves et al., 2010*). However, the
52 possible competition on soil water and nutrient between tree and grass under the tree has lit up
53 some worries that sowing grass in the orchard might result in loss of fruit yield and quality,
54 especially in some areas where water deficit and soil infertility happen a lot (*Monteiro & Lopes,*
55 2007; *Teravest et al., 2010*), an example being the Loess Plateau of China. So how the grass
56 roles in such an integrative system have attracted wide attention.

57 The inclusion of grass into the orchard can modulate soil features like water and fertility.
58 Sowing grass may potentially adjust the enrichment and paucity of soil water content to keep it
59 relatively stable (*Liu et al., 2013*). It can reduce surface runoff and enhance infiltration,
60 alleviating soil erosion (*Fourie et al., 2007*). Moreover, with the increase of grass age, soil
61 infiltration and water holding capacity will be greatly improved (*Palese et al., 2014*). There is
62 competition for water between grass and tree, which varies with plant species and the amount of
63 rainfall. The competition can be weak under suitable species combination and system
64 management. Inclusion of grass can also be beneficial to improve the contents of organic matter
65 (*Sánchez et al., 2007*), nitrogen (N), phosphorus (P) and potassium in soils (*Shui et al., 2008*).
66 For instance, some legume species may potentially improve soil N availability as they have
67 strong capacity to biologically fix atmospheric N (*Yang et al., 2011*). Additionally, soil microbial
68 diversity and activity also increase in the orchard after sowing grass (*Whitelaw-Weckert et al.,*
69 2007), which may be helpful for the decomposition of soil organism humus (*Wardle et al., 2001*).
70 Therefore under this system the competition for soil nutrient is relatively subtle due to the
71 improvement of soil fertility by grasses and artificial fertilization. In addition, as the pattern of
72 orchard-grass performance is continuously improved, transforming from firstly a single mode
73 (ground cover) to the complex three-dimensional mode (combination of cover, farming and
74 animal husbandry), the role of grass in the system is diversified. The grasses sown in the orchard
75 may also be used as forages for feeding animals with countable amount of biomass accumulation
76 in certain areas. So inclusion of grass into the orchard shows advantages both at ecological and
77 economic scales.

78 The inclusion of grass has broken the water and heat exchange in soil – fruit tree – air
79 continuum and has transformed into soil – fruit tree + grass – air continuum (Bing *et al.*, 2002).
80 In this way, water and heat can be more fully utilized in the system, which requires a balance
81 between the growths of tree and grass to maximum their functions in the system. However, tree
82 shading may be a problem for the growth of grass under the tree as insufficient light causes
83 adverse effects on grass growth and production. Generally, leaf net photosynthetic rate (Pn) may
84 fall under shading and rapid stomatal closure occurs (Kim *et al.*, 2016), while appropriate
85 shading can improve water use efficiency (WUE) of plants, which varies with plant species.
86 Delucia *et al.* (1998) found that the plants usually increased photosynthetic efficiency to improve
87 light utilization by increasing leaf area under shading. With shading, leaf chlorophyll content
88 increases and chlorophyll a/b value decreases to improve plant photosynthetic activity (Abrams,
89 1987; Lambers & Poorter, 1992). Singhakumara *et al.* (2003) found that the shade-tolerant
90 plants generally had larger leaf area, higher chlorophyll content and lower leaf mass per unit area
91 (LMA) than the shade-sensitive ones. These aforementioned traits are important measures in
92 plant adaptation to adverse light environments (Grassi & Bagnaresi, 2001) and thus may be
93 helpful in selecting suitable grasses for the orchard. However, little knowledge has been
94 achieved on how these traits of grass under the tree respond to shading in the orchard.

95 On the Loess Plateau of eastern Gansu, China, apple orchard is widely established as a
96 profitable option in this arid and infertile area. There was approximately 1.02×10^5 ha apple
97 orchard established in this area with apple yield of 6.7×10^8 kg per year. The existing orchards are
98 mostly lightly tilled, which is unfavorable for controlling soil and water loss (Wang *et al.*, 2015).
99 Some traditional thoughts, i.e. grass and tree fight for water and nutrient in soils, and thus sowing
100 grass may increase the costs of money and labour, have retarded the performance of grass
101 sowing in the orchards of this area. Appropriate grass species are essential for the establishment
102 of a sustainable orchard-grass system (Wang *et al.*, 2015) but there was still rare species suitable
103 for the system in this region. The lucerne (*Medicago sativa*), white clover (*Trifolium repens*) and
104 cocksfoot (*Dactylis glomerata*) are common forage crops widely sown and used to feed domestic
105 animals in this region. However, it was not clear how they can be better used in the orchard.

106 We proposed a hypothesis that tree shading would impose heavy impacts on grass species
107 included in the orchard in some species-specific way. In this study, biomass, leaf trait,
108 photosynthetic gas exchange and chlorophyll feature of three forages (grasses) were measured
109 under three shading treatments in an apple orchard. The objectives were to find out: 1) how tree
110 shading affects biomass accumulation, leaf trait, photosynthetic gas exchange and chlorophyll
111 feature of the forages? 2) Which of the three species is more tolerant to shading in the orchard?

112

113 **Materials & Methods**

114 **Plant material and experimental design**

115 The experiment was conducted in a 7 year–old apple orchard at Qingyang Loess Plateau Pastoral
116 Agriculture Station of Lanzhou University (35°40' N, 107°51' E), which locates in Qingyang,
117 eastern Gansu of China with a typical continental climate. The mean annual precipitation is 543

118 mm and 70% of this total usually falls in July to September. The mean annual temperature is
119 9.3°C with the lowest in January (-21.3°C) and the highest in July (40°C). The annual frost-free
120 duration is 255 d in average. The soil is Heilu soil with 70% silt and 23% clay, representing the
121 main cropping soil in this area.

122 In the intervals between tree lines (4 m wide), three forages were broadcast sown, which are
123 lucerne (*Medicago sativa*), white clover (*Trifolium repens*) and cocksfoot (*Dactylis glomerata*)
124 in July 4, 2014. The sowing rates were 22.5, 15.0 and 15.0 kg ha⁻¹ for lucerne, white clover and
125 cocksfoot respectively. For this test, 6 m long (×4 m wide) plots were chosen and for each
126 treatment, four replicates were set. All plots were broadcast applied with 300 kg ha⁻¹ N fertilizer
127 in the form of urea before sowing. The forage was supposed to be cut and the shoot was removed
128 out so that great amount of nutrient (especially N) would be lost from the system, so N fertilizer
129 was applied, even to legume species. Soil P in the orchard was excessive due to long term P
130 fertilization and slow release of soil P source. And the inclusion of forages would benefit the
131 release of soil residual P in the orchard. So P fertilizer was not applied. No irrigation and
132 pesticide spraying were performed. All the forages were cut to feed domestic animals after plant
133 samples taken. Notably, no treatment and measurement were conducted in the first year in order
134 to favour the establishment of grasslands under the trees.

135 The shading treatments were started in April 12 before the forages were reviving in the
136 second year. Three shading treatments were set as reduced shading (partially cutting branches),
137 normal shading (normal tree shading) and enhanced shading (normal tree shading plus sun-
138 shading net), and these treatments made the light intensity equal to about 70%–80%, 40%–50%
139 and 10%–20% photosynthetically active radiation (PAR) above the canopy, which we measured
140 every 2 weeks on sunny days using a portable photosynthesis system (LI-6400, Li-Cor, USA).
141 All measurements were conducted at about two months later after shading treatment when
142 lucerne and white clover were at early flowering stage and cocksfoot was at late heading stage.
143 Due to budgetary limit, all measurement was only conducted in this year. Considering all three
144 species are perennials and the second year is very close to the stabilized ages of artificial
145 grassland in this area, the data we obtained should show the characteristics of the second year's
146 forages.

147

148 **Measurements and calculations**

149 At least 20 youngest fully expanded leaves were sampled for each treatment. The sampled leaves
150 were then brought back to laboratory as soon as possible for further measurements. Leaf biomass
151 at saturated moisture content and dry weight were measured to determine leaf dry matter content
152 (LDMC) (*Garnier et al., 2001*) using the equation: LDMC (mg g⁻¹) = leaf dry weight / leaf
153 saturated fresh biomass. Fresh leaf area (cm²) was scanned with Win FOLIA (LA2400, Canada)
154 and the LMA was determined using the equation: LMA (g m⁻²) = leaf dry weight / leaf area. In
155 addition, leaf thickness (LT) was measured with a vernier caliper. Biomass was measured with
156 drying method. After sampling with quadrat frame of 1m×1m, the samples were dried at 80°C
157 until constant weight and measured the biomass on the ground.

158 Constant photosynthetic gas exchange was measured with a portable photosynthesis system
159 (LI-6400, Li-Cor, USA) at 9:30 – 11:30 am on a clear sunny day during leaf sampling. The CO₂
160 concentration was maintained at 400 μL L⁻¹ using CO₂ supplying cartridge. The Pn (μmol m⁻² s⁻¹)
161 and transpiration rate (E, mmol m⁻² s⁻¹) were recorded and instantaneous WUE (WUEi, μmol
162 mmol⁻¹) was calculated as Pn/E. In each replicate, three plants were selected randomly and at
163 least three healthy and fully expanded leaves were measured. The Pn response to light gradient
164 was measured at 09:00–11:00 on a clear sunny day using the red and blue light source equipped
165 with LI-6400. During the measurements, CO₂ concentration was maintained at 400 μL L⁻¹ using
166 CO₂ supplying cartridge and light intensity was set according to the Equipment Instruction. The
167 curve was then fit with the classic Farquhar model (*Farquhar et al., 2001*) to obtain light
168 compensation point (LCP), light saturation point (LSP), dark respiration rate (Rd), maximum
169 assimilation rate (Amax) and apparent quantum efficiency (Qapp).

170 Chlorophyll a and b was extracted by mixture of propanone and anhydrous ethyl alcohol,
171 and then the contents were determined by spectrophotometer method of *Arnon (1949)*. The
172 contents of chlorophyll a, b and a+b were calculated using the following equations:

$$173 \text{ Chlorophyll a (mg g}^{-1}\text{)} = [(12.7 \times A_{663} - 2.59 \times A_{645})V/W],$$

$$174 \text{ Chlorophyll b (mg g}^{-1}\text{)} = [(22.9 \times A_{645} - 4.67 \times A_{663})V/W],$$

$$175 \text{ Chlorophyll a+b (mg g}^{-1}\text{)} = [(20.3 \times A_{645} + 8.04 \times A_{663})V/W],$$

176 Where A is absorbance at specific wavelengths; V is final volume of chlorophyll extract; W is
177 fresh weight of leaf extracted. In the present experiment, the volume (V) and weight (W) were
178 100 ml and 0.1 g, respectively.

179 Chlorophyll fluorescence was measured at 09:00–11:00 on a clear sunny day to obtain actual
180 photochemical efficiency of photosystem II (ϕPS II), photochemical quenching coefficient (qP)
181 and non-photochemical quenching (NPQ) using fluorescent leaf chamber of LI-6400 with
182 controlled light intensity of 1500 μmol m⁻² s⁻¹. Prior to these measurements, marked leaves were
183 measured in dark to determine maximum photochemical rate (Fv/Fm) at 01:00 deep night. In
184 each replicate, three plants were selected randomly and at least three healthy and fully expanded
185 leaves were measured.

186

187 **Data analysis**

188 The effects of shading treatment, forage species and their interaction on leaf trait, gas exchange,
189 chlorophyll component and fluorescence were analyzed using factor analysis. The differences in
190 leaf traits, gas exchange parameters and chlorophyll features among forages or shading
191 treatments were analyzed using Two-Way ANOVA. The Pn–PAR curve was fit with the classic
192 Farquhar model to gain related parameters. Correlations among the growth and leaf
193 photosynthetic characteristics of three forages under shading were analyzed using Spearman's
194 rank correlation analysis. The SPSS 17.0 was used for statistical analysis.

195

196 **Results**

197 **Leaf traits and biomass growth under shading**

198 The LDMC and LMA of three forages were affected by shading, species and their interaction,
199 while the LT was only affected by shading and the biomass was only affected by species (Table
200 1). The LT of cocksfoot did not change under all treatments but it tended to decrease with the
201 enhancement of shading. The LT of white clover decreased with the enhancement of shading.
202 For lucerne, LT was reduced by enhanced shading and did not change under reduced shading
203 (Fig. 1A). The LDMC of cocksfoot and lucerne decreased with the enhancement of shading. For
204 white clover, LDMC was reduced by enhanced shading and was not changed by reduced shading
205 (Fig. 1B). The LMA of all three forages decreased with the enhancement of shading (Fig. 1C). In
206 response to the enhancement of shading, LT of cocksfoot did not change, but LDMC and LMA
207 decreased, and its LMA was the lowest among all forages under enhanced shading (Fig. 1). The
208 biomass of cocksfoot was much higher than the other forages, which tended to decrease with
209 enhanced shading. The biomass of white clover and lucerne were not changed by shading (Fig.
210 1D).

211

212 **Leaf photosynthetic gas exchange under shading**

213 The Pn and WUEi were affected by shading, species and their interaction (Table 1). The Pn of
214 cocksfoot was reduced by enhanced shading and did not change under reduced shading. The Pn
215 of white clover and lucerne decreased with the enhancement of shading (Fig. 2A). The WUEi of
216 cocksfoot decreased with the enhancement of shading. For white clover and lucerne, WUEi was
217 elevated by enhanced and reduced shading (Fig. 2B). In response to the enhancement of shading,
218 the Pn of cocksfoot changed little and both Pn and WUEi were not different from those of other
219 two forages under enhanced shading (Fig. 2).

220 The shading imposed various impacts on Pn–PAR curves of different forages (Table 2). The
221 Rd of cocksfoot was elevated by reduced shading but was not impacted by enhanced shading.
222 The Amax and LCP of cocksfoot tended to decrease with the enhancement of shading, while
223 LSP was reduced by enhanced and reduced shading but Qapp was elevated. The Rd of white
224 clover was reduced by enhanced and reduced shading. The Amax, LCP and LSP of white clover
225 tended to decrease with the enhancement of shading. Its Qapp tended to decrease under enhanced
226 and reduced shading. For lucerne, the Rd, Amax and LCP tended to decrease with the
227 enhancement of shading. The LSP tended to decrease under enhanced and reduced shading but
228 the Qapp was elevated. The Rd and LCP of cocksfoot were lower than other forages but the
229 Amax was not different and the Qapp was even higher under enhanced shading.

230

231 **Leaf chlorophyll component and fluorescence under shading**

232 The content and proportion of chlorophyll component were affected by species, but seldom by
233 shading and their interaction (Table 1). For cocksfoot, the contents of all chlorophyll components
234 and chlorophyll a/b were not impacted by enhanced and reduced shading (Fig. 3). For white
235 clover, the contents of chlorophyll a, b and a+b increased with the enhancement of shading,
236 while chlorophyll a/b decreased. For lucerne, the contents of all chlorophyll components and
237 chlorophyll a/b were not changed by enhanced and reduced shading (Fig. 3). The contents of

238 chlorophyll a, b and a+b were highest in cocksfoot, while for chlorophyll a/b, it appeared as
239 white clover > lucerne > cocksfoot (Fig. 3).

240 Chlorophyll fluorescence was affected by species and their interaction (Table 1). The Fv/Fm
241 increased with the enhancement of shading in cocksfoot and was not changed in white clover,
242 while in lucerne, Fv/Fm was elevated by enhanced and reduced shading, and it was higher under
243 reduced shading than enhanced shading (Fig. 4A). The ϕ PS II and qP of cocksfoot were lowered
244 by enhanced and reduced shading and in white clover they were not impacted, while in lucerne,
245 the ϕ PS II and qP decreased with the enhancement of shading (Fig. 4B and 4C). In cocksfoot, the
246 ϕ PS II and qP were higher under enhanced shading than reduced shading. The NPQ of cocksfoot
247 decreased with the enhancement of shading. For white clover, NPQ was lowered by enhanced
248 and reduced shading, while in lucerne, NPQ was elevated (Fig. 4D). In response to the
249 enhancement of shading, the Fv/Fm increased in cocksfoot and its NPQ was far lower than those
250 in other two forages (Fig. 4A and 4D).

251

252 **Correlations among the growth and leaf photosynthetic characteristics of three forages** 253 **under shading**

254 The biomass was positively correlated with WUEi, chlorophyll a, b and a+b contents, but
255 negatively correlated with chlorophyll a/b, Fv/Fm, ϕ PS II, qP and NPQ (Table 3). The Pn was
256 positively correlated with LDMC, LMA, chlorophyll a/b, Fv/Fm, ϕ PS II and qP, but negatively
257 correlated with chlorophyll a+b content. The WUEi was positively correlated with LDMC, LMA,
258 chlorophyll a, b and a+b contents, but negatively correlated with chlorophyll a/b, Fv/Fm, ϕ PS II,
259 qP and NPQ.

260

261 **Discussion**

262 **Effects of shading on leaf traits of three forages**

263 Leaf trait is partly the consequence that a plant responds to the external environments at leaf
264 scale (*Vendramini et al., 2002*) and its change is one of the most important strategies that the
265 plant has developed to cope with adverse environments. This study showed that species, shading
266 and their interaction imposed significant impacts on leaf traits. Shading reduced LT, LDMC and
267 LMA. Thus, shading may reduce assimilates accumulation but enhance the allocation for
268 potential enhancement of photosynthetic photon capture because lower LT, LDMC and LMA
269 generally indicate more input into photosynthetic area (*Modrzy et al., 2015*). These changes
270 would result in enhanced photosynthesis. In addition, shading may help to maintain soil water
271 status and improve air humidity under the tree, which potentially ameliorate the possible water
272 stress that the forages are encountering, especially in this semi-arid and rainfed region. The LT
273 wasn't affected by species, but it tended to be higher in cocksfoot than other species and did not
274 change with shading, suggesting that cocksfoot may be more tolerant to shading. Much quicker
275 decline in LMA of cocksfoot also proved that this species is more adaptive to shading, as lower
276 LMA shows stronger potential to use weak light under the tree.

277

278 Effects of shading on chlorophyll contents and fluorescence of three forages

279 Generally, a plant with high chlorophyll content and low chlorophyll a/b has stronger resistance
280 to shading (*Boardman, 1977*). In this study, species and its interaction with shading significantly
281 affected chlorophyll a, b, a+b contents and a/b, while shading showed rare effect. Only in white
282 clover, the contents reduced and chlorophyll a/b increased along with the reduction in shading,
283 suggesting that chlorophyll content and ratio weren't influenced by shading in cocksfoot and
284 lucerne. Intriguingly, the contents of chlorophyll component in cocksfoot were highest, but
285 chlorophyll a/b was lowest, indicating that cocksfoot is more efficient in use of weak light
286 because high chlorophyll b content and proportion promise a plant to do so (*Abrams, 1987*;
287 *Threlfall, 1981*).

288 Chlorophyll fluorescence reflects the actual and maximum photosynthesis, the function of
289 reaction center and the heat dissipation of a plant (*Govindjee, 2002*). In this study, all
290 fluorescence was significantly affected only by species. The NPQ tended to be lowest in
291 cocksfoot, and the Fv/Fm increased with the enhancement of shading, suggesting that this
292 species is more tolerant to shading. The increased Fv/Fm reflects the enhancement of potential
293 PSII photochemical efficiency of leaves after a fully dark adaptation (*Demmig & Björkman,*
294 *1987*). The lower NPQ shows less light energy consumption as heat dissipation (*Genty et al.,*
295 *1989*). Compared to lucerne and white clover, cocksfoot showed normal light conversing
296 efficiency and light trapping efficiency under shading, but much lower light energy loss, helping
297 to adapt to weakened light environments.

298

299 Effects of shading on Pn, WUEi and biomass of three forages

300 In this study, constant Pn and WUEi were significantly affected by species, shading and their
301 interaction. The Pn and WUEi tended to decrease with the enhancement of shading. These may
302 suggest that under tree shading, weakened light led to Pn decrease because generally, Pn and
303 light intensity are positively correlated with suitable water supply under natural light. However,
304 improved water status in soils and relative air humidity under the trees would have kept stomata
305 open, consequently leading to great transpiration (rate). Thus, the WUEi would decrease with
306 shading as it was calculated with Pn/E. From another viewpoint, it also proved that shading may
307 improve water supply around the forage and tree. Changes in Pn with shading among species
308 may be due to variations in leaf traits and chlorophyll features as there were positive correlations
309 of Pn with LDMC, LMA and chlorophyll a/b, ϕ PS II and qP, and negative correlation with
310 chlorophyll a+b content. As for WUEi, there were contrasting roles played by chlorophyll
311 features as the WUEi was positively correlated with chlorophyll a, b and a+b contents, but
312 negatively correlated with chlorophyll a/b, Fv/Fm, ϕ PS II, qP and NPQ. Compared with other
313 forages, the Pn of cocksfoot changed little with shading, and both Pn and WUEi were not
314 different from other forages, suggesting that this species was more tolerant to shading.

315 The Pn–PAR curve provides very useful parameters to address photosynthetic responses of a
316 plant to adverse environment, while eliminating much interference, i.e. insufficient light
317 radiation (*Lewis et al., 2000*). In this study, the LCP and Amax decreased with the enhancement

318 of shading, suggesting that all species are acclimating to shading, while the Rd, Qapp and LSP
319 changed in a species-specific way. Compared to white clover and lucerne, the Rd and LCP of
320 cocksfoot were lower, but the Amax was similar, and the Qapp was even higher under shading,
321 indicating that cocksfoot may be more tolerant. The lower LCP indicates that the plant can
322 survive in weakened light environments (*Taiz & Zeiger, 2010*), i.e. tree shading, and generally,
323 shading-tolerant plants have lower Rd (*Lewis et al., 2000*). The greater Qapp reflects stronger
324 photosynthesis to use weak light. Thus, it suggested that cocksfoot could make better use of
325 weak light and adapt to shading, compared to other species.

326 The biomass of cocksfoot was much higher than the other forages, which decreased little
327 under enhanced shading compared to normal shading. Cocksfoot has good adaptability to various
328 environmental conditions, such as drought and restricted light conditions, with good regrowth
329 characteristics (*Sanada et al., 2010*). Change in biomass accumulation with shading among
330 species was more correlated with WUEi, but not Pn in the orchard environment. Therefore,
331 cocksfoot might be more beneficial to provide biomass under tree shading.

332 As known, plant biomass accumulation was not only impacted by light, but also by soil
333 carbon and nutrients. Soil nutrients (such as N and P) can indirectly affect the utilization of light
334 radiation by regulating photosynthesis apparatus (*Arain et al., 2002; Palmroth et al., 2014*). In
335 this study, there were similar basic soil feature and relative enough nutrient supply to soils.
336 Therefore, the difference in effects of soil nutrients on the plant might be negligible. However, it
337 is obliged to admit the fact soil nutrient availability would change after longer time forage
338 growth and this would affect the response of forage to light radiation, so further studies would be
339 required in the future.

340

341 **Conclusions**

342 Shading imposed significant impacts on the growth and leaf photosynthetic characteristics, while
343 there were differences among species. Shading affected chlorophyll content and fluorescence,
344 LDMC and LMA, which finally changed biomass accumulation. Cocksfoot was more efficient
345 than the other two forages in use of weak light and more tolerant to tree shading. In the apple
346 orchard, we recommend that selecting some shading-tolerant grasses, i.e. cocksfoot, or widening
347 the distance between individual apple trees, would be practical options for the orchard-forage
348 system in the Loess Plateau of China.

349
