Abstract

The Katalalixar National Reserve (KNR) lies in an isolated marine protected area of Magellan Sub-Antarctic channels, which represent an important area for marine biodiversity and macroalgal conservation. The present study is the first report of the species *Lessonia spicata*, “huir negro”, in the Magellan Sub-Antarctic channels. This finding has implications for macroalgal biogeography and conservation concerns in the Chilean coast. In the ecological assessments of the KNR in 2018 we found populations of *L. spicata*, specifically on rocky shores of Torpedo Island and Castillo Channel. The morphological identification and molecular phylogeny based on nuclear (ITS1) sequences revealed that these populations of *Lessonia* are within the lineage of *L. spicata* of central Chile. This report increases the species richness of kelps for the Magellan Sub-Antarctic Channels from 2 to 3 confirmed species (*L. flavicans*, *L. searlesiana* and *L. spicata*), and it also extends the southern distribution range of *L. spicata*. This species has high harvest demand which is moving towards southern Chile, thus these populations should be considered as essential for macroalgal conservation in high latitudes of South America.

Key words: biogeography, conservation, extension, kelp, Magellan, Sub-Antarctic

Introduction

Lessonia Bory (Laminariales, Phaeophyceae) is one of the most conspicuous brown macroalgal genera that inhabit the littoral to sublittoral zone of rocky coasts (~ 20 m depth) in temperate-cool waters of the South Pacific Ocean (Cho *et al.*, 2006; Martin & Zuccarello, 2012). There are currently records of 11 species of the genus *Lessonia* that are taxonomically accepted, distributed along the coasts of South America, New Zealand, Tasmania, and Sub-Antarctic islands (Cho *et al.*, 2006). These species have major ecological roles in the structure of benthic marine communities (Villouta & Santelices, 1984; Vásquez & Santelices, 1984), and are commercially exploited for the extraction of alginic acid (Steneck *et al.*, 2002). *Lessonia* species are one of the most characteristic and abundant macroalgae (12°S to 56°S) that inhabit the rocky shores of the Chilean coast (17° to 56° S) (Searles, 1978; Avila *et al.*, 1985; Villouta & Santelices, 1986; Vasquez *et al.*, 1998; Tellier *et al.*, 2011; Martin & Zucarello, 2012; Mansilla *et al.*, 2014). Currently, six species have been recorded in Chile: *Lessonia nigrescens* Bory, *Lessonia berteriana* Montagne, *Lessonia. spicata* Suhr, *Lessonia trabeculata* Villouta & Santelices, *Lessonia searlesiana* Asensi & De Reviers and *Lessonia flavicans* Bory (Guiry & Guiry, 2018). A recent morphological and molecular analysis showed that the species distributed from Peru (17°) to Puerto Montt (41°), commonly known as *L. nigrescens*, is actually two cryptic species; the populations distributed from Peru (17°S) to central Chile (30°S) correspond to *L. berteriana* Montagne, and those occurring from central Chile (29°S) to Puerto Montt (41°S) correspond to *L. spicata* (Suhr) Santelices (González *et al.*, 2012; Vega, 2016). However, *L. nigrescens* is still a valid species, because no material of the referred species has been found near its type locality, Cape Horn.

The huiro negro kelps, which include *L. berteriana* and *L. spicata*, are heavily exploited and represent almost 70% of the kelp biomass landed annually (Vega *et al.*, 2014). This economic activity is mainly practiced in northern Chile (18-32°S), through a complex productive chain with high social impact and low added value (Vásquez, 2008). *L. berteriana* and *L. spicata* are exported as a natural commodity to more than 20 countries mainly due to their alginate, which has high economic value (Westermeyer *et al.*, 2019). Thus populations of huiro negro have economic interest along Chilean coasts, being essential to generate a stewardship from a local and large scale.

The Katalalixar National Reserve (KNR) is a national reserve area created in 1983. KNR comprises 674,500 ha and is located in a remote zone next to the village of Tortel. This area includes a wilderness temperate rainforest with a complex ecosystem of islands and fjords (Bell *et al.*, 2007). The offshore area (western side) of the Magellan Sub-Antarctic Channels is one of the few places of the Magellan Biogeographic Province (MBP) (43°-56°S; Camus, 2001) that has not been explored systematically by scientific expeditions (Gorny & Zapata, 2018) (Fig. 1a, b). KNR is located at the southern limit of the Humboldt Current System (HCS). The HCS is a key component of the general oceanic circulation in the eastern South Pacific, being one of the most productive marine ecosystems on the earth (Thiel *et al.*, 2007). HCS is originated in southern Chile between 42-48°S and is characterized by a northward flow in front of South American coasts with a strong upwelling of cool nutrient-rich waters (Silva *et al.*, 2009). The origin of the HCS induced a large-scale redistribution of biota, and nowadays plays a key role in the biogeography of the South Pacific (Camus, 2001). Thus KNR provides an enormous opportunity to understand the taxonomic composition and biogeography of macroalgae that inhabit the southern boundary of the Humboldt Current (Camus, 2001; Thiel *et al.*, 2007).

The present study contributes the first report of the species *L. spicata* in the Magellan Sub-Antarctic Channels. The distribution of this was thought to be limited to 41°S, but appears to be extended south of the Golfo de Penas (46° 59'-47° 40'S). Continuing survey studies will be necessary to understand the occurrence patterns of populations of *L. spicata* in the MBP.

Materials & Methods

Three individuals of *Lessonia spicata* were collected in the intertidal zone of Torpedo Island and Castillo Channel (Fig. 1a, b) in July, 2018. The specimens were air-dried and then pressed on herbarium sheets for morphological observation and molecular analysis. The Chilean Hydrographic and Oceanographic Service of the Navy (N° 13270/24/337), approved field sampling.

External and internal morphological observations were made. The anatomical observations were performed by sectioning with a razor and staining with 1% aqueous aniline blue acidified with 1% diluted HCl, and mounted in 70% glycerin. Photomicrographs were taken with a Canon Powershot S5 IS camera attached to a BX 51 Olympus microscope (Canon USA, Melville, New York, USA; Olympus Corp., Tokyo, Japan, respectively). A total of 15 replicates from the three

individuals were selected for measurement of cortical cell diameter following Gonzalez *et al.*, (2012); means and standard deviations were calculated. Samples of other species occurring in the Sub-Antarctic region (*L. flavicans* and *L. searlesiana*) were also analyzed for comparative purposes. Voucher specimens were deposited in the herbarium of University of Magallanes, Punta Arenas, Chile.

Molecular analyses

Genomic DNA was extracted from ~ 5 mg of dried thallus ground in liquid nitrogen using a NucleoSpin Plant II Kit (Macherey-Nagel, Düren, Germany) according to the manufacturer's protocol. The PCR primers for the ITS were ITSP1-ITSRi (Tai *et al.*, 2001; Martin & Zucarello, 2012) and KP5- KG4 (Lane *et al.*, 2006). Polymerase chain reaction products were purified using a NucleoSpin Gel and PCR Clean-up (Macherey-Nagel, Düren, Germany) and commercially sequenced (Macrogen, Seoul, South Korea). The electropherograms were edited using the Chromas v1.45 software (McCarthy, 1998) and the new generated sequences were deposited in GenBank (www.ncbi.nlm.nih.gov/genbank/).

A total of 34 ITS sequences (731bp) were included in the construction of the phylogeny: 31 sequences belonging to the genus *Lessonia* and three outgroups, *Cymathaere triplicata* (Postels & Ruprecht) J. Agardh, *Ecklonia cava* Kjellman and *Macrocystis pyrifera* (Linnaeus) C. Agardh (Table 1). Sequences were aligned using the MUSCLE algorithm in MEGA5 v.6.06 software using the default settings (Tamura *et al.*, 2013).

The phylogenetic analysis was constructed using Maximum likelihood (ML) and Bayesian inference (BI) analyses. The program PartitionFinder (Lanfear *et al.*, 2012) were used to choose the best-fitting nucleotide substitution model under the Bayesian Information Criterion. The general time reversible nucleotide substitution model with a gamma distribution and a proportion of invariable sites (GTR + Γ + I) was selected as the best substitution model. ML analysis was performed with the RAxML HPC-AVX program (Stamatakis, 2014) implemented in the raxmlGUI 1.3.1 interface (Silvestro & Michalak, 2012) with the statistical support obtained by 1000 bootstrap replications. BI was performed with the MrBayes v. 3.2.5 software (Ronquist *et al.*, 2012) using Metropolis-coupled Markov Chain Monte Carlo (MC³). The inference of Bayesian posterior probability (BPP) was inferred following Calderon & Boo (2017).

The neighbor joining analysis was performed in MEGA5 v.6.06 with the default settings software, using 1000 bootstrap replicates.

Results

This is the first confirmed report of *L. spicata* in the Sub-Antarctic region, extending its distribution to the south by seven degrees of latitude (Fig. 2a). The sporophytes collected in the two localities have cylindrical stipes, flattened toward the beginning of the blades, with a regular, almost dichotomous long lanceolate blade with a spike (Fig. 2b-e).

Internal anatomy

Our specimens showed several layers of cortical tissue with cells of smaller diameter compared to *L. searlesiana* (Fig. 3b, e, h) and *L. flavicans* (Fig. 3c, f, i), moreover no lacunas were observed in our samples, unlike *L. flavicans* (Fig. 3c, h). The medulla was composed of elongated medullary cells with filamentous elements (Fig. 3g). The internal anatomy was composed of a narrow cortex (Fig. 3a), with cortical cell diameter of 25.91 ± 2.90 for the individual 1, 28.22 ± 2.10 for individual 2, and 27.02 ± 2.27 for the individual 3 (Table 2).

Phylogenetic analysis

The ITS phylogeny placed our specimens within the lineage of *L. spicata* of central Chile (Fig. 4a). The phylogenetic trees constructed by ML and BI had the same topology except for the phylogenetic position of *L. corrugata* and *L. variegata* from northeastern South Is. The three specimens analyzed consistently formed a strongly supported clade with sequences of *L. spicata* (97% for ML and 0.96 for BPP) collected in Chile; having to *L. berteriana* and *L. trabeculata* as sister taxa. The cladogram was consistent with the phylogenetic tree (Fig 4b). Variable sites occurred at 201 positions (27.5%), and 123 positions (16.8%) were parsimoniously informative. Intraspecific divergence of *L. spicata* from three different populations ranged between 0.0% and 0.2% (0–3 bp). *L. spicata* differed by 0.8%–1.0% from *L. berteriana* and by 1.1%–1.3% from *L. trabeculata*. *L. variegata* is a non-monophyletic species complex of four different species.

Discussion

We confirm here the presence of *L. spicata* both morphologically and genetically, whose individuals correspond to the central Chile lineage described by González *et al.*, (2012). Morphologically these features correspond to those described for *L. spicata* by Suhr (1839) and González *et al.*, (2012). These values also agree with those mentioned by González *et al.*, (2012) for *L. spicata*. Genetically our phylogeny is consistent with those of previous studies that show *Lessonia* as a monophyletic lineage (Lane *et al.*, 2006, Martin & Zucarello, 2012).

Lessonia species are a characteristic component of benthic ecosystems in this region (Searles, 1978; Martin & Zucarello, 2011). We highlight two aspects about the importance of this report of *L. spicata* for this area: a) we increase the knowledge of the species richness of kelps for the Sub-Antarctic Channels, and (b) this species has a strong extraction activity which we hypothesize that will move southward in the near future, therefore these populations should be properly preserved in order to prevent high risk of human impact.

The name *L. spicata* was proposed because it was the oldest name available to assign the lineage of central Chile, populations between 29° and 43°S. However, *L. spicata* would be a provisional name mainly because no representative specimens of *L. nigrescens* have been found near the type locality Cape Horn. Therefore, if the true *L. nigrescens* belongs to one of the lineages already described or to a new one, this name would have priority (González *et al.*, 2012). In the MBP *L. nigrescens* has been recorded not only for Cape Horn; Searles (1978) reported a population in the Trinidad Channel (Puerto Alert 49° 53.6 'S), and two others in the Aysén region (Searles, 1978). Puerto Alert is 126 km south of Castillo Channel where we found the population of *L. spicata*. Therefore, it is likely that Searles' records (1978) correspond to populations of *L. spicata*. Finally, it is important to mention that, like González *et al.*, (2012), in recent expeditions to the Diego Ramirez and Cape Horn archipelago—which are related to the characterization of the Diego Ramírez-Drake Passage Marine Park (Rozzi *et al.*, 2017)—we have not found populations of *L. nigrescens*, only individuals of *L. flavicans* (Rozzi *et al.*, 2017). Therefore, in the absence of biological material from the type locality the status of *L. nigrescens* is still in doubt, and the lineage of central Chile that now extends south of 43°S should continue to be named as *L. spicata*.

Several bio-geographical breaks have been described along the coast of Chile (Santelices & Menesses, 2000; Tellier *et al.*, 2009; Fraser *et al.*, 2010); one of the most relevant for many taxa is at 42°S (Brattström & Johansen, 1983; Lancellotti & Vázquez, 1999; Valdovinos *et al.*, 2003). For macroalgae and particularly for kelp species such as *Durvillaea antarctica*, a marked

divergence is present south of 43°S, where populations between 49° and 55°S are genetically different from the rest of the populations occurring in the Chilean coast (32°S and 43°S) (Fraser *et al.*, 2010). These authors suggested that although *D. Antarctica* has a high dispersion capacity due to its buoyancy (rafting), it could only colonize free coasts, since it would have limited potential to increase gene flow between established populations. Therefore, it is interesting that although *L. spicata* has a low dispersal capacity in comparison to *D. antarctica* (Oppliger *et al.*, 2012), since it does not have the buoyancy capacity, there is a single genetic unit in the individuals collected in this study and individuals from the central zone of Chile. *L. spicata* must have some physiological adaptations which allowed it to colonize and inhabit areas of high latitudes. In this sense, this species has been described as a perennial seaweed and has not been found in the "bank of microscopic forms" in the Chilean central coast (boulders and water from tidal pools) (Santelices *et al.*, 1995; Santelices *et al.*, 2002). However, it has been observed that microscopic form of *L. spicata* can survive up to 90 days in total darkness and propagules can germinate in total absence of light (Santelices *et al.*, 2002). This high capacity for tolerance to darkness could be a key strategy to colonize new areas with a significant seasonal changes in daylight hours and luminosity (Photosynthetically Active Radiation) during the winter period (Ojeda *et al.*, 2019). Nevertheless, future studies and a greater number of samples along the Chilean coast (mainly the area between 41° - 48°S) will help to elucidate its biogeographic history and how much structure and connectivity the populations of *L. spicata* present throughout their distribution (29°S to 48°S).

The harvesting pressure on the genus *Lessonia* has increased alarmingly along the Chilean coast, so we should take a precautionary approach to potential harvesting of *L. spicata* in its austral distribution range. *L. berteriana* (sister species of *L. spicata*) is currently the most exploited seaweed in South America; the main landings are in northern Chile (Westermeier *et al.*, 2019). *Lessonia* is socially important in this region because many artisanal fishers depend directly or indirectly on its harvest (Vega *et al.*, 2014). However, high demand, lack of oversight and harvest methods have created a concerning scenario for kelp forests (Vega *et al.*, 2014; Westermeier *et al.*, 2019). The extraction of *L. spicata* in southern Chile began in 2012, and its extractive pressure has been moving southward, mainly between 33° and 41°S (SERNAPESCA, 2019). In the Chilean Los Lagos Region (41°S), between 2014 and 2017 landing increased from 494 to 747 dry tons of *L. spicata* (SERNAPESCA, 2019). This gradual increase should draw attention to kelp forest conservation, since there is evidence on sustainability problems that *Lessonia* populations have

experimented and their biodiversity in northern Chile (Vega *et al.*, 2016). This concern acquires significant relevance if we consider that the Magellan Sub-Antarctic Channels are the austral distribution range of *L. spicata*, -where kelp forest populations are important for sustainability of small-scale fisheries (e.g. king crab; Cárdenas *et al.*, 2007), indigenous traditions (Ojeda *et al.*, 2018) and terrestrial and marine biodiversity (Darwin, 1839; Rosenfeld *et al.*, 2014).

Conclusion

Despite the geographical distance and the presence of important biogeographic breaks (41° and 46°S), our results confirm that the individuals collected in the coastal zone of the Katalalixar Reserve are the species *Lessonia spicata*. The strong morphological and genetic evidence are indicating that the individuals analyzed are associated with the lineage of central Chile, and the populations of *L. spicata* would inhabit the area exposed to the Pacific.

With diverse industrial uses, including providing phycocolloids in the form of alginate *L. spicata* is a potentially important economic resource in the Chilean coast. However, with extractive pressure moving to the south, caution is needed given that this kelp serves not only as a habitat for many animals but also as a spawning ground for some benthic (e.g., gastropods) species.

Figure 1

Collection points of *Lessonia spicata*. Map showing the location of Katalalixar National Reserve (KNR) in central Patagonia in the oceanic margin of the Campana Archipelago

Collection points of *Lessonia spicata*. a) Map showing the location of Katalalixar National Reserve (KNR) in central Patagonia, (b) Collection sites of *Lessonia spicata*, Torpedo Island (red circle) and Castillo Channel (blue circle) in the oceanic margin of the Campana Archipelago (KNR).

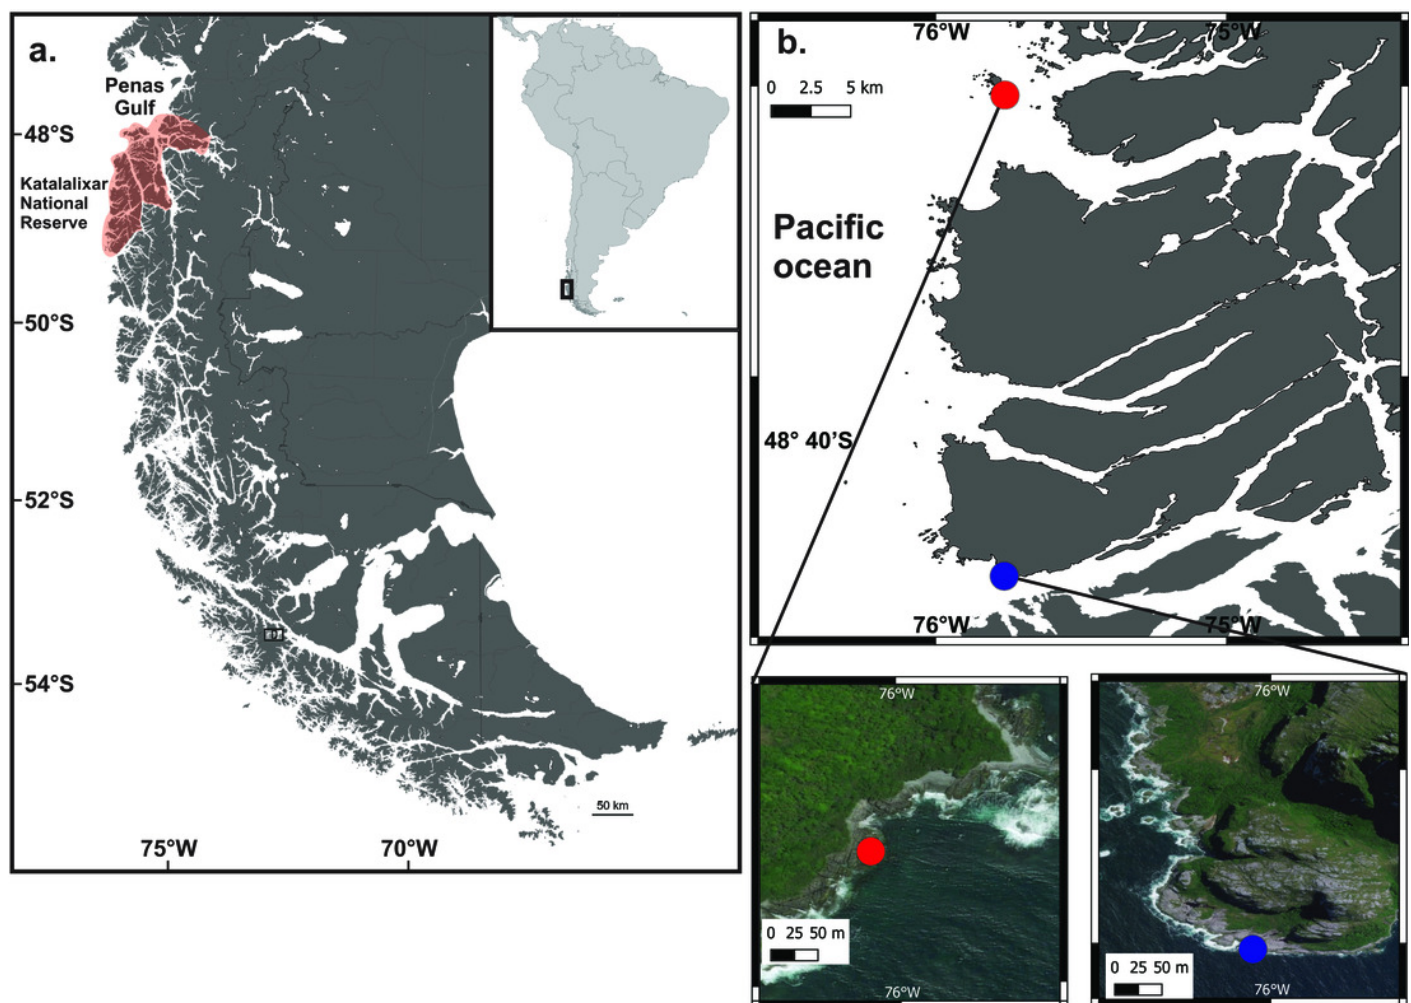

Figure 2

Distribution of *Lessonia spicata* (interspersed bars), showing its previously known distribution (solid bars). Habitat of specimen collected in both sites (Torpedo Island and Castillo Channel)

Distribution of *Lessonia spicata* (interspersed bars), showing its previously known distribution (solid bars). We included the Chilean biogeographical classification of Camus (2001). b) Habitat of specimen collected in Torpedo Island (LMS000001). c) Discoid holdfasts of specimen collected in Torpedo Island (LMS000001), d) Blades of specimen collected in Torpedo Island (LMS000001), e) Habitat of specimen collected in Castillo Channel (LMS000002, LMS000003).

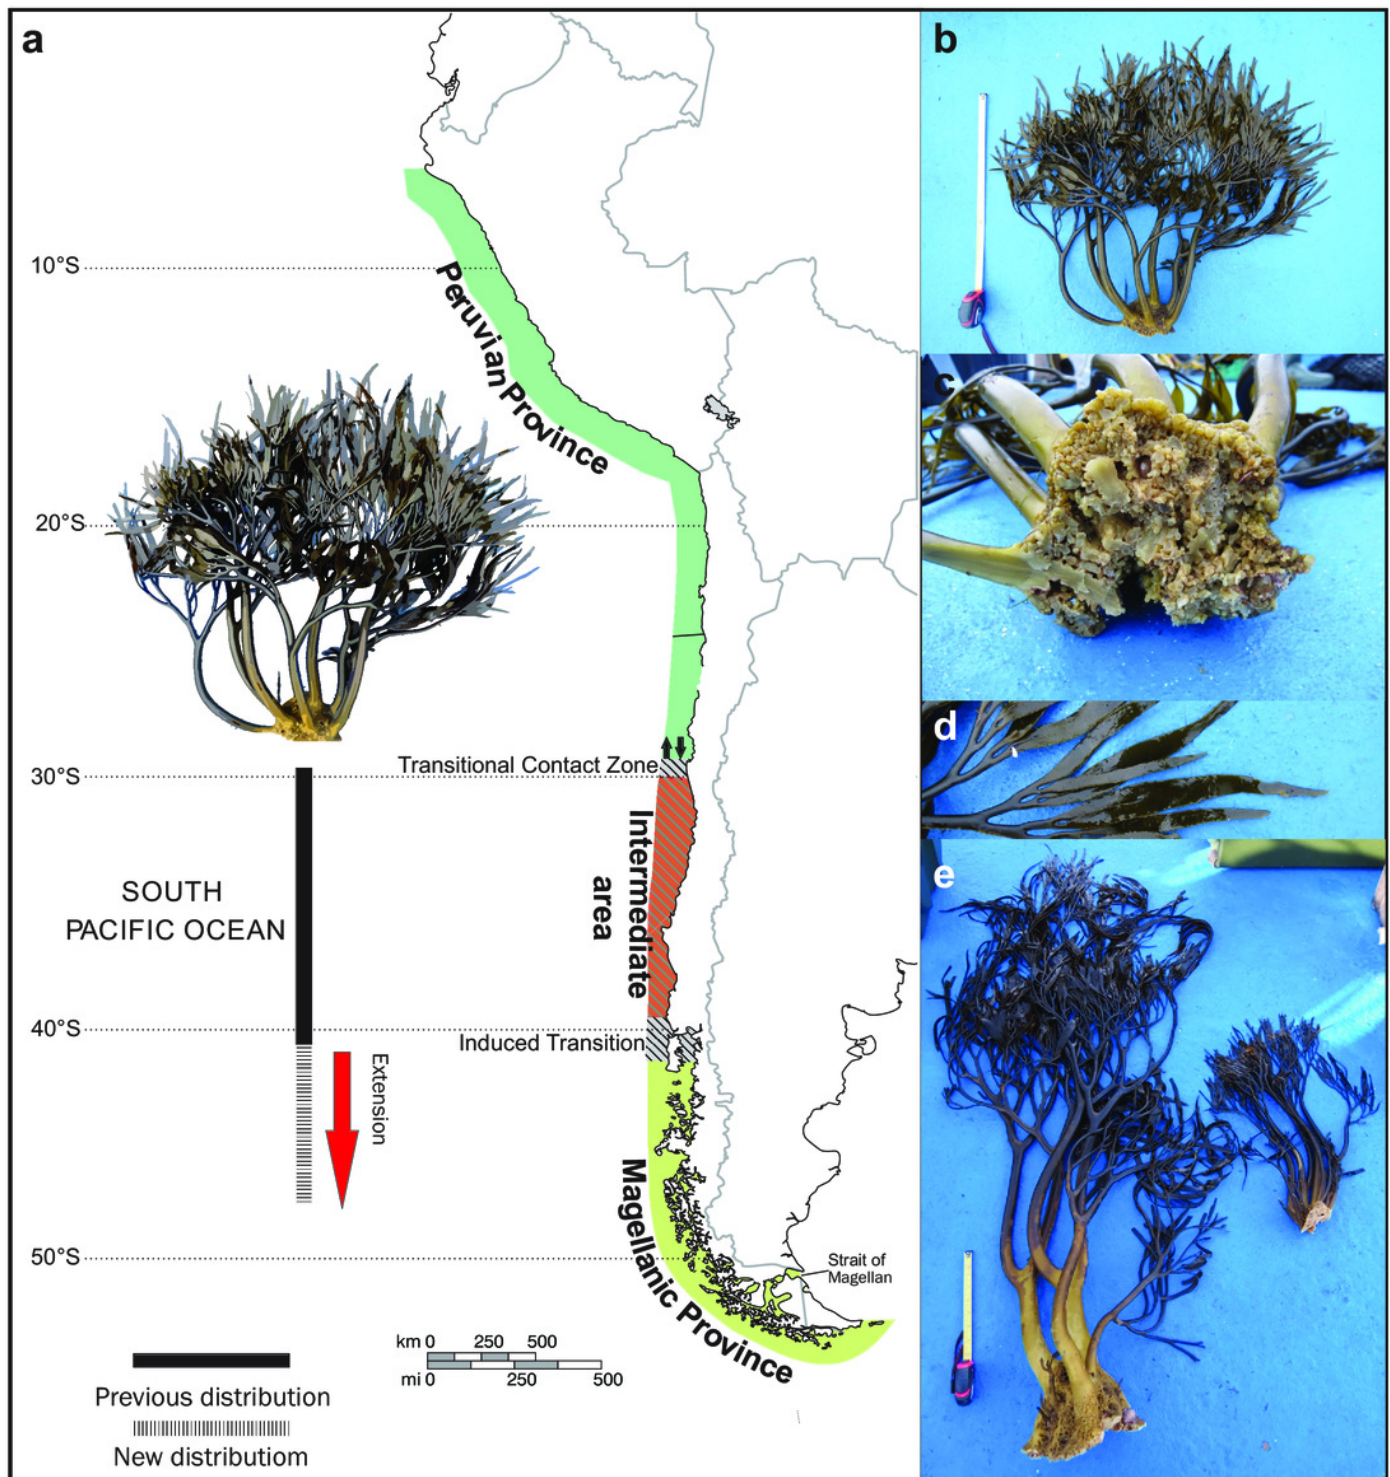

Figure 3

Cross section of the medial part of mature fronds of *Lessonia* species who inhabit the Sub-Antarctic channels

Cross section of the medial part of mature fronds of *Lessonia spicata* collected in the Katalalixar Reserve (Fig. 3a, d and g), of *L. searlesiana* from Fuerte Bulnes (Fig. 3b, e and h) and *L. flavicans* from Horn Island (Fig. 3c, f and i); mer = meristoderm, co = cortex and me = medulla, l= lacuna.

Figure 4

Phylogenetic tree of ITS sequences obtained by maximum likelihood (ML) inference.

a) Phylogenetic tree of ITS sequences obtained by maximum likelihood (ML) inference. ML bootstrap values ($\geq 50\%$) and Bayesian posterior probabilities (≥ 0.90) are indicated next to branches. b) Cladograms of ITS sequences obtained by the neighbor joining (NJ) method. Bootstrap values ($\geq 50\%$) are indicated next to branches. The sequence for taxa in bold was generated in this study.
