The orientation of vascular canals in primary bone may reflect differences in growth rate and/or adaptation to biomechanical loads. Previous studies link specific canal orientations to bone growth rates, but results between different taxa are contradictory. Circumferential vascular canals (forming laminar bone) have been hypothesized to reflect either (or both) rapid growth rate or locomotion-induced torsional loading. Previous work on the hindlimb biomechanics in the emu shows that the femur and tibiotarsus experience large shear strains, likely resulting from torsional loads that increase through ontogeny. Here, we test how growth rate and biomechanical loading affect bone laminarity in wing and hindlimb elements from growing emu (2 - 60 wks). If laminar bone is an adaptation to torsion-induced shear strains, it should increase from juveniles to adults. Alternatively, if bone laminarity reflects rapid growth, as has been shown previously in emu, it should be abundant in fast-growing juveniles and decrease with age. Transverse mid-shaft histological sections from the limb bones (femur, tibiotarsus, humerus, ulna, and radius) were prepared and imaged. Growth rates were measured using fluorescent bone labels. Vascular canal orientation was quantified using laminarity index (proportion of circumferential canals). Principal components analysis was performed to convert highly correlated variables (i.e., mass, age, growth rate, and shear strain) into principal components. Random-intercept beta regression modeling determined which principal components best explained laminarity. The fastest growth rates were found in young individuals for all five skeletal elements. Maximum growth rate did not coincide with peak laminarity. Instead, in the femur and tibiotarsus, elevated laminarity is strongly correlated with adult features such as large size, old age, and modest growth rate. This result is contrary to predictions made based on a previous study of emu but is consistent with results observed in some other avian species (penguin, chicken). Shear strain in the caudal

octant of the femur and tibiotarsus is positively correlated with laminarity but has a weaker effect on laminarity relative to mass, age, and growth rate. Laminarity in the wing elements is variable and does not correlate with ontogenetic factors (including mass, age, and growth rate). Its presence may relate to relaxed developmental canalization or a retained ancestral feature. In conclusion, ontogeny (including growth rate) is the dominant influence on vascular canal orientation at least in the hindlimb of the emu.

24 **ABSTRACT**

25 The orientation of vascular canals in primary bone may reflect differences in growth rate
26 and/or adaptation to biomechanical loads. Previous studies link specific canal orientations to
27 bone growth rates, but results between different taxa are contradictory. Circumferential vascular
28 canals (forming laminar bone) have been hypothesized to reflect either (or both) rapid growth
29 rate or locomotion-induced torsional loading. Previous work on the hindlimb biomechanics in
30 the emu shows that the femur and tibiotarsus experience large shear strains, likely resulting from
31 torsional loads that increase through ontogeny. Here, we test how growth rate and biomechanical
32 loading affect bone laminarity in wing and hindlimb elements from growing emu (2 - 60 wks). If
33 laminar bone is an adaptation to torsion-induced shear strains, it should increase from juveniles
34 to adults. Alternatively, if bone laminarity reflects rapid growth, as has been shown previously in
35 emu, it should be abundant in fast-growing juveniles and decrease with age. Transverse mid-
36 shaft histological sections from the limb bones (femur, tibiotarsus, humerus, ulna, and radius)
37 were prepared and imaged. Growth rates were measured using fluorescent bone labels. Vascular
38 canal orientation was quantified using laminarity index (proportion of circumferential canals).
39 Principal components analysis was performed to convert highly correlated variables (i.e., mass,
40 age, growth rate, and shear strain) into principal components. Random-intercept beta regression
41 modeling determined which principal components best explained laminarity. The fastest growth
42 rates were found in young individuals for all five skeletal elements. Maximum growth rate did
43 not coincide with peak laminarity. Instead, in the femur and tibiotarsus, elevated laminarity is
44 strongly correlated with adult features such as large size, old age, and modest growth rate. This
45 result is contrary to predictions made based on a previous study of emu but is consistent with
46 results observed in some other avian species (penguin, chicken). Shear strain in the caudal octant

47 of the femur and tibiotarsus is positively correlated with laminarity but has a weaker effect on
48 laminarity relative to mass, age, and growth rate. Laminarity in the wing elements is variable and
49 does not correlate with ontogenetic factors (including mass, age, and growth rate). Its presence
50 may relate to relaxed developmental canalization or a retained ancestral feature. In conclusion,
51 ontogeny (including growth rate) is the dominant influence on vascular canal orientation at least
52 in the hindlimb of the emu.

53

54 INTRODUCTION

55 Avian bone tissue is highly vascularized with a fibrolamellar structure, which allows for
56 rapid growth by depositing randomly arranged spicules of woven bone initially, followed by in-
57 filling of the cancellous spaces with centripetal lamellar bone, forming primary osteons
58 (Francillon-Vieillot et al., 1990; de Ricqlès et al., 1991; Curry, 2002). Each primary osteon
59 contains a central canal that houses blood vessels and nerves. These vascular canals vary in
60 orientation and bones can be classified based on the predominant canal orientation. Laminar
61 bone typically has a higher proportion of canals with circumferential orientation (parallel to the
62 periosteal surface of the bone) relative to other orientations. Additional canal orientations
63 include: radial, those orthogonal to the periosteal surface; longitudinal, those running parallel to
64 the long axis of the bone; and oblique, all other orientations (de Ricqlès et al., 1991).

65 It has been hypothesized that differences in primary vascular canal orientation might be a
66 reflection of growth rate, biomechanical loads, or phylogenetic relationships (Padian, 2013).

67 Amprino (1947) first suggested that the organization of bone microstructure may be influenced
68 by bone growth rate, such that woven bone is deposited during rapid growth and lamellar bone
69 during slow growth (de Ricqlès et al., 1991). Further studies have investigated whether specific

70 primary vascular canal orientations in fibrolamellar bone are also associated with slow or fast
71 growth by directly comparing microstructure with bone growth rates measured through the use
72 of injectable fluorochromes (Castanet et al., 2000; de Margerie et al., 2002; de Margerie et al.,
73 2004). Rapidly growing hindlimb bones of ratites have been found to exhibit structure that is
74 laminar and reticular (bone with numerous obliquely-oriented canals), whereas the more modest-
75 growing wing elements of ratites exhibit reticular and longitudinal canal structure (Castanet et
76 al., 2000). This suggests that laminar bone, in part, may reflect faster growth rates. This result
77 was supported in a recent study of pigeon wing elements, which showed that peak laminarity
78 (proportion of laminar bone) coincides roughly with the growth spurt in each element (Ourfalian,
79 Ezell & Lee, 2016). However, work on mallard long bones showed no relationship between
80 growth rate and predominant vascular canal orientation (de Margerie et al., 2002). Additionally,
81 in the king penguin, radially-oriented canals dominated in the fastest growing sections, not
82 circumferential canals (laminar bone) (de Margerie et al., 2004). Likewise, chickens selected for
83 fast growth showed limb bones with predominantly radial canals (Williams et al., 2004; Pratt and
84 Cooper, 2018).

85 Laminar bone has been hypothesized to better resist torsional loading. In laminar bone,
86 the bone tissue is arranged in ‘sheets’ or ‘plates’ between layers of circumferential canals. Shear
87 strain is thought to flow continuously within these ‘sheets’, and thus the concentrated stresses on
88 the bone tissue surrounding the canals is reduced (de Margerie et al., 2004). Indeed, bone
89 elements that are hypothesized to predominantly experience torsional loads have been found to
90 exhibit laminar bone. Laminar bone is found to be most abundant in the humerus, ulna, and
91 femur in a large sample of flighted bird species (de Margerie, 2002; de Margerie et al., 2005). *In*
92 *vivo* strain gauge studies have shown that these elements experience predominantly torsional

93 loads in at least some species: the humerus in the pigeon during flapping flight, the ulna in the
94 turkey during wing flapping while on the ground, and the femur in the chicken and emu during
95 terrestrial running, (Rubin and Lanyon, 1985; Biewener and Dial, 1995; Carrano and Biewener,
96 1999; Main and Biewener, 2007).

97 A limitation of previous studies of laminar bone is the indirect comparison of bone
98 histology in one species with bone growth rates and/or *in vivo* strain gauge measures taken from
99 different species. In this study, we present an analysis of laminar bone in a species in which bone
100 growth rate and *in vivo* bone strain data were directly measured. The emu (*Dromaius*
101 *novaehollandiae*, Order Struthioniformes, Family Dromaiidae) is a flightless bird endemic to
102 Australia, but widely farmed in the US. The individuals included in this study comprise a growth
103 series that were previously injected with fluorescent bone labels and surgically implanted with
104 gauges to measure *in vivo* locomotor strains in the femur and tibiotarsus (Main and Biewener,
105 2007). Shear strains, produced by torsional loads about the long axes of the bones, were the
106 predominant type of strain in the two bones and increased from juveniles to adults (Main and
107 Biewener, 2007). Bone strains were not measured in the wing elements of these individuals.
108 Presumably, shear strains are negligible in the wing elements because emus have extremely
109 reduced wings, which have no known function other than occasionally being raised to aid
110 thermoregulation (del Hoyo et al., 1992; Maxwell and Larsson, 2007).

111 Therefore, if laminarity is an adaptation to torsion-induced shear strains, we predict that
112 hindlimb bone laminarity will increase from juveniles to adults. Consistent with this hypothesis,
113 we expect no trend in laminarity in the vestigial wing elements from juveniles to adults.
114 Alternatively, if bone laminarity reflects rapid growth (as has been shown previously in emu), it
115 should be abundant in juveniles and decrease with age as growth slows in adults for all elements.

116 Incorporating growth rate measurements, direct biomechanical data, and direct histological
117 classification of laminarity makes this study a first of its kind that will be able to clarify the
118 importance of growth and mechanics on vascular canal orientation in emu limbs.

119

120 **MATERIALS & METHODS**

121 This study samples forelimb and hindlimb elements from eight emus ranging in age from
122 2 to 60 weeks (Table 1). Birds used in this study were euthanized as part of a previous study
123 (Main and Biewener, 2007) and the selected elements stored frozen. Emus were originally
124 obtained as hatchlings by R.P. Main (at the time at Harvard University) from commercial farms
125 (Songline Emu Farm, Gill, MA, USA; Scattered Oaks Emu Farm, Iola, TX, USA; Deep Hollow
126 Farm, Oakdale, CT, USA) and raised at Harvard University's Concord Field Station (Bedford,
127 MA, USA) under Harvard FAS IACUC approval AEP 23-15. For the first eight weeks of life the
128 emus were held in large indoor enclosures, and then moved into pasture-sized outdoor
129 enclosures. All birds had free access to commercial ratite diet (Mazuri, PMI Nutrition
130 International, LLC, Brentwood, MO, USA) and water. Male and female birds were included
131 based on availability. Emus exhibit a minor degree of sexual dimorphism, with females being
132 slightly larger on average (del Hoyo et al., 1992). The difference in size is not large enough to be
133 considered a confounding factor for this study.

134 As a part of a previous study (Main and Biewener, 2007), each bird was given a single
135 intramuscular injection of xylenol orange (80mg/kg) followed by calcein (30mg/kg). Injections
136 were given one week apart in birds less than 16 weeks of age and two weeks apart in birds
137 between 16 and 65 weeks of age. Xylenol and calcein are fluorescent labels that are incorporated
138 rapidly into newly mineralizing surfaces of bone at the time of injection (An and Martin, 2003).

139 Thus, the time elapsed and the space between xylenol and calcein labels allows the calculation of
140 periosteal (radial) growth rate. One week after the last injection, surgery was performed to attach
141 strain gauges to the cranial, caudal, and lateral aspects of the left femur and the cranial, caudal,
142 and medial aspects of the left tibiotarsus. Single element strain gauges were used on the lateral
143 femur and cranial and medial tibiotarsus. Rectangular rosette gauges were used on the cranial
144 and caudal femur and caudal tibiotarsus. Rosette strain gauges allow both tensile and
145 compressive principal strains and their orientations to be measured, and were placed so the
146 central element of the gauge was parallel to the long axis of the bone. One day after surgery, the
147 birds were run on a treadmill over a wide range of speeds and gaits. The raw data produced from
148 the strain gauges were converted from voltage to microstrain using a custom MATLAB program.
149 Shear strains were calculated from the rosette strain gauges using standard equations (Biewener
150 and Dial, 1995). High quality shear strain data were most consistently collected from the caudal
151 cortices of the femur and tibiotarsus and that is what is reported here. Trials in which the birds
152 ran with a duty factor near 0.50 are included in the shear strain analysis (mean \pm SD: $0.50 \pm$
153 0.02). Duty factor is the proportion of the time that the animal's foot spends on the ground
154 during a stride relative to the entire stride time. A duty factor of 0.50 represents the point at
155 which the birds transition to a running gait that incorporates an aerial phase. This is a relatively
156 slow run for emu, but represents the duty factor for which we could maximize the number of
157 animals included in this study based upon successful strain gauge function. Each trial was
158 represented by five footfalls and, generally, two trials were collected for each bird. Following
159 bone strain data collection, animals were euthanized. After death, whole wings were removed
160 from the individuals and stored frozen. Histological sections of the femora and tibiotarsi were
161 prepared (see Main and Biewener, 2007 for details) and shipped with the frozen wings to

162 Midwestern University.

163 **Histological Preparation**

164 Emu wings were thawed and feathers, skin, muscles, and tendons were reflected to
165 expose the skeletal elements. Both right and left wings were used based on availability. Using
166 digital calipers, total length of each bone was measured and recorded. A 37-mm segment was
167 removed using a Dremel tool from the mid-shaft region of the humerus, ulna, and radius. For two
168 and four week old individuals whole elements were harvested due to their small size. Segments
169 were labeled with permanent marker to maintain orientation. Dissected bone segments were
170 placed in 10% neutral buffered formalin for fixation and then dehydrated in a graded ethanol
171 series (70%, 85%, 100%) under vacuum. Segments were cleared with a xylene-substitute (Histo-
172 clear; National Diagnostics, Atlanta, Georgia, USA). The bone segments were then vacuum-
173 infiltrated and embedded in glass vials using Osteo-Bed Plus Resin, a two-part methyl
174 methacrylate (Polysciences Inc.). Vials were placed in a 32° C bead bath to fully harden.

175 Once the resin hardened, vials were broken and two roughly 800- μ m transverse sections
176 were cut using a diamond blade saw (Isomet 1000; Buehler, Lake Bluff, Illinois, USA). These
177 sections were attached to frosted glass slides using two-ton epoxy (Devcon, Milpitas, California,
178 USA), keeping consistent spatial orientation. Slides were then ground to a thickness of
179 $100\pm 10\mu$ m using a graded scale of grit paper on a stand grinder (Metaserv 250; Buehler, Lake
180 Bluff, Illinois, USA) and coverslipped with Permount (Fisher Scientific). The histological
181 preparation was modified from An and Martin (2003) and closely followed Lee and Simons
182 (2015).

183 **Image Collection**

184 The undecalcified sections contain xylenol (orange) and calcein (green) fluorochromes

185 that were incorporated into newly mineralizing bone at the time of injection (see above for
186 injection schedule). These fluorochromes create stable long lasting tags (van Gaalen et al., 2010)
187 and were examined under bright-field and fluorescent illumination with a motorized
188 epifluorescent microscope (IX73, Olympus). The xylenol (orange) and calcein (green) tags were
189 revealed using TRITC and FITC filter cubes, respectively, and a multichannel (red, green,
190 bright-field) image of each section was generated with imaging software (cellSens, Olympus).
191 Sufficient optical resolution (10X UPlanAPO $\approx 0.84 \mu\text{m}$; 20X UPlan S-APO $\approx 0.45 \mu\text{m}$) allowed
192 a dual color-monochrome camera (DP80, Olympus) to capture high quality images (10X = 1.02
193 $\mu\text{m}/\text{pixel}$; 20X = 0.51 $\mu\text{m}/\text{pixel}$).

194 **Calculating Bone Laminarity and Radial Growth Rates**

195 Bright-field and fluorescent images were obtained from the wing and hindlimb elements
196 (Figs. 1 and 2) and divided into equal octants from the estimated bone centroid. Four octants
197 representing the cardinal anatomical positions (wing elements: cranial, caudal, dorsal, ventral;
198 hindlimb elements: cranial, caudal, lateral, medial) were extracted (Fig. 2). Using ImageJ, each
199 extracted octant was then uncurved using the “Straighten” function. The purpose of straightening
200 was to standardize the periosteal tangent line so that appropriate measurements could be made in
201 classifying the orientation of the vascular canals (Lee and Simons, 2015). To ensure there was
202 minimal deformation of the image during the straightening process, known test angles were
203 placed upon the image and measured in relation to the periosteal surface after the straightening
204 function had been applied. Only those images with an average deformation less than or equal to
205 10° were accepted.

206 Within each of the four octants, the calcein green and xylenol orange tags were outlined
207 with two reference lines. The distance between reference lines was measured at 10 equally

208 spaced points in each octant. Growth rate was measured by taking the mean distance between
209 consecutive fluorescent tags divided by number of days between injections (Fig. 2C).

210 Degree of laminarity (Laminarity Index, LI) was measured in the interval of bone
211 between the fluorochrome reference lines across all four octants. Using ImageJ, an ellipse was
212 drawn within each in-focus primary vascular canal in the measurement interval (Fig. 2D).
213 Branching canals were separated at branch points and counted individually. Sharply curving
214 canals were treated as branching. The aspect ratio and angle at which the ellipse sat in relation to
215 the straightened periosteal surface was measured. We used the criteria set forth by de Margerie
216 (2002) to classify the orientation of the vascular canals: (1) “circular” (circumferential) canals
217 are oriented parallel ($0^\circ \pm 22.5^\circ$) to the periosteal surface of the bone; (2) radial canals are
218 orthogonal ($90 \pm 22.5^\circ$) to the periosteal surface; (3) longitudinal canals run parallel to the long
219 axis of the bone and have ellipses with an aspect ratio of less than 3; (4) oblique canals are all
220 other orientations. Only primary vascular canals were measured. Secondary osteons in the
221 sample area were excluded. We used a simple proportion (number of circumferential canals to
222 the total number of canals) to quantify laminarity. To test the growth hypothesis, we used the
223 laminarity index calculated from all sampled octants (Table 2, Table S1). Because consistent
224 high quality shear strain data are only available from the caudal octant, we used the laminarity
225 index calculated from only the caudal octant to test the mechanical hypothesis (Table 3, Table
226 S2).

227 **Robust Principal Components Analysis (RPCA) and Beta Regression**

228 The explanatory variables thought to affect laminarity in the emu show multicollinearity.
229 For example, mass and age covary with each other (Goonewardene et al., 2003) as well as with
230 growth rate (Montes et al., 2005), and shear strain (Main & Biewener, 2007). If left unaddressed,

231 multicollinearity can decrease precision and reliability when estimating the effect of one variable
232 while holding the others constant (Fekedulegn et al., 2002). Principal components analysis
233 (PCA) accounts for this multicollinearity by forming new uncorrelated variables (i.e., principal
234 components) that are linear combinations of the original explanatory variables while preserving
235 as much of the original variation as possible (Hammer, Harper & Ryan, 2001). However, PCA is
236 highly sensitive to variables with large variances and skewed distributions (Hubert, Rousseeuw
237 & Verdonck, 2009), so we standardized (i.e., centered by the median and scaled by the median
238 absolute deviation) mass, age, growth rate, and shear strain with the function “RobScale”
239 (Signorell, 2019) in R (R Core Team, 2019). This process stabilizes variance and minimizes the
240 effect of absolute scale in the calculation of principal components. Skewed data are often
241 transformed prior to PCA (e.g., logarithmic or Box-Cox), but such transformations may worsen
242 skewness or complicate PCA interpretation (Hubert, Rousseeuw & Verdonck, 2009). Instead, we
243 performed robust PCA (Hubert, Rousseeuw & Verdonck, 2009) as implemented by the R
244 package “rospca” (Reynkens, 2018), which is suitable for skewed data. Three datasets were
245 analyzed separately: (1) cardinal octants from hindlimb elements; (2) caudal octants from
246 hindlimb elements; and (3) cardinal octants from forelimb elements. The results of each robust
247 PCA are presented in Table 4.

248 For each dataset, the minimum number of principal components (PCs) was selected to
249 cover approximately 95% of the observed variance of the original explanatory variables. We
250 assessed the relationship between PC(s) and mean laminarity index (LI) using beta regression as
251 implemented by the R package “gamlss” (Rigby & Stasinopoulos, 2005). This method is
252 appropriate when the response variable (LI) is a proportion (Warton & Hui, 2011). To
253 accommodate values of 0 in the caudal hindlimb and cardinal forelimb datasets, LI values were

254 rescaled to the effective interval of [0.005, 0.995] (Smithson & Verkuilen, 2006). The logit link
255 function was used to connect mean LI to a linear combination of the PCs. Pseudoreplication is a
256 concern because different bone elements were sampled from the same individual (Hurlbert,
257 1984; Gillies et al., 2006; Lee & O'Connor, 2013; Jordan, 2018), so we combined the logit link
258 function with a random-intercept model as follows:

$$259 \quad \mu_{\logit(LI)} = \beta_0 + \beta_1 PC_1 + \beta_2 PC_2 + \beta_3 Element + \gamma \quad (1)$$

260 where PC is the principal component, β is regression coefficient, $Element$ is a dummy variable
261 coding for element type, γ is the random-intercept effect of “specimen ID”, and $\mu_{\logit(LI)}$ is the
262 logit link function for the mean of LI (Ferrari & Cribari-Neto, 2004).

263 For each cardinal dataset, we evaluated two models. The first model includes PC 1 as the
264 sole predictor given that it accounted for approximately 95% of the variance in the original
265 explanatory variables. The second model adds element type as a dummy variable. For the caudal
266 dataset, PC 1 and PC 2 covered at least 95% of the variance in the original explanatory variables.
267 Therefore, we evaluated six models. The first three models involve PC 1 and PC 2 individually
268 as sole predictors as well as together in additive combination. The remaining three models add
269 element type as a dummy variable (Table 5). The small-sample correction of Akaike’s
270 Information Criterion (AIC_c) (Hurvich & Tsai, 1989) was used to compare models within each
271 dataset. In general, the best supported model has the lowest AIC_c value (Burnham & Anderson,
272 2002). Relative support between the best and alternative models was assessed with difference
273 (ΔAIC_c) values. Alternative models with ΔAIC_c values greater than 3, which is equivalent to a p -
274 value of 0.051 (Taper, 2004), were rejected as having weak support. Raw data and R script for
275 analyses can be found in the Supplementary Files (Table S1, Table S2, Code S1).

276

277 RESULTS

278 Measured growth rates ranged from 1.3 $\mu\text{m}/\text{day}$ (radius of 48-week-old individual) to
279 162.6 $\mu\text{m}/\text{day}$ (femur of 4.6-week-old individual) (Table 2). Laminarity indices from cardinal
280 octants ranged from 0 to 0.58 (Table 2, Table S1, Fig 3). Laminarity indices from the caudal
281 octant ranged from 0 to 0.81 (Table 3, Table S2).

282 Regression Analysis of Cardinal Octants from the Femur and Tibiotarsus

283 Principal component (PC) 1 (eigenvalue = 8.181), consisting of mass, age, and growth
284 rate, accounts for 95% of the cumulative variance (Table 4). Mass and age loadings have the
285 same sign, whereas growth rate loading has an opposite sign. The loadings suggest that PC 1
286 represents an “ontogenetic axis” with juvenile features (small size, young age, and rapid growth
287 rate) at one end and adult features (large size, old age, and modest growth rate) at the other (Fig.
288 4). PC 2 (eigenvalue = 0.403) consists of the residual variation in (i.e., “ontogeny-independent”)
289 growth rate and accounts for 4.7% of the cumulative variance (Table 4).

290 The random-intercept beta regression model without element type as a predictor has
291 overwhelming support (Table 5). It predicts that ~89% of the variation in laminarity is explained
292 by the “ontogenetic axis” (Table 5). Juvenile features (e.g., small size, young age, and rapid
293 growth rate) are correlated with lower laminarity values, whereas adult features are correlated
294 with higher laminarity values ($p < 5.51e^{-5}$; Fig. 5).

295 Regression Analysis of Caudal Octants from the Femur and Tibiotarsus

296 Table 4 shows that the first two PCs account for at least 95% of the cumulative
297 variance—88% by PC 1 (eigenvalue = 9.435) and 9% by PC 2 (eigenvalue = 0.989). Similar to
298 cardinal octant data, mass, age, and growth rate contribute strongly to PC 1. Their loadings are
299 also consistent with variation along an “ontogenetic axis” with juvenile features at one end

300 (small size, young age, and rapid growth rate) and adult features at the other (large size, old age,
301 and modest growth rate). Although strain has a minor contribution to PC 1, it dominates PC 2,
302 which we interpret as a “loading effect axis” (Fig. 6).

303 The model with PC 1 as the sole predictor of caudal octant laminarity has strongest
304 support based on ΔAIC_c and explains 78% of the variation in caudal octant laminarity (Table 5).
305 Caudal and cardinal datasets show slightly different estimates for the coefficient of PC 1, which
306 is consistent with slight inter-octant variation in laminarity. Variation aside, the overall
307 ontogenetic trend is similar: higher laminarity values are correlated with adult features, whereas
308 lower laminarity values are correlated with juvenile features (Fig. 7; $p = 0.013$). Although shear
309 strain contributes to PC 1 and generally increases along the “ontogenetic axis”, the effect is
310 relatively weak. To highlight this, we multiplied the regression coefficient and eigenvectors of
311 PC 1. The resulting standardized coefficients of the original predictors (growth rate = -0.041;
312 mass = 0.097; age = 0.150; strain = 0.035) suggest that the relative effects of growth rate, mass,
313 and age on caudal octant laminarity in the hindlimb are 1.2 to 4.3 times greater than that of
314 strain.

315 The caudal hindlimb dataset does not support the “loading effect axis” (PC 2) as a strong
316 predictor for laminarity. Compared to model 1 (PC 1 as the sole predictor), the remaining
317 alternative models with PC 2 only explain an additional 5 – 6% of the variation in caudal
318 hindlimb laminarity. Each of these alternative models has ΔAIC_c larger than 3 indicating weak
319 to no support ($p > 0.05$). Furthermore, the model coefficient for PC 2 in model 2 (sole predictor)
320 and model 3 (additive combination with PC 1) is not significant (p -value equals 0.169 and 0.056,
321 respectively; Table 5).

322 **Regression Analysis of Cardinal Octants from the Humerus, Ulna, and Radius**

323 In the absence of strain data for the forelimb elements, mass, age, and growth rate
324 dominate PC 1 (eigenvalue = 7.977), and this “ontogenetic axis” accounts for 97% of the
325 cumulative variance (Table 4, Fig. 8). PC 2 (eigenvalue = 0.187) absorbs residual variation in
326 growth rate and accounts for an additional 2.3% of the cumulative variance.

327 Although the model with “ontogenetic axis” (PC 1) as the sole predictor has the best
328 support, it only accounts for 27.7% of the variation in forelimb laminarity. Moreover, the model
329 coefficient for PC 1 is not significant ($p = 0.089$; Table 5).

330

331 **DISCUSSION**

332 **Does bone laminarity reflect fast growth?**

333 The highest periosteal growth rate in all elements was found in the femur of the 4.6-week
334 old individual (Table 2). As expected, hindlimb elements had higher growth rates than forelimb
335 elements, reaching a maximum of 163 $\mu\text{m}/\text{day}$ in the femur and 99 $\mu\text{m}/\text{day}$ in the tibiotarsus. The
336 humerus grew the fastest of the wing elements, reaching a maximum rate of 25 $\mu\text{m}/\text{day}$ measured
337 in the 2.3 and 4.6 week old individuals. Birds older than 8 weeks experienced a drastic decrease
338 in bone growth rate in both hindlimb and forelimb elements. Previous analysis of emu somatic
339 growth rate (increase in body mass) showed the maximum rate of growth (inflection point) to be
340 about 15-17 weeks of age (Goonewardene et al., 2003). Our results reveal that age at maximum
341 bone growth (approximately 5 weeks) precedes the somatic growth inflection, similar to other
342 vertebrates (Lee et al., 2013). Therefore, caution is warranted when inferring somatic life-history
343 milestones, such as growth spurts, solely from skeletal data.

344 Principal components analysis reveals a large proportion of variance lies along an
345 “ontogenetic axis” (Figs. 4, 6, 8). One end of the axis is represented by juvenile traits such as

346 small size, young age, and rapid growth, whereas adult traits such as large size, old age, and
347 modest growth characterize the other end. This “ontogenetic axis” has a significant influence on
348 laminarity in the femur and tibiotarsus (Figs. 5, 7), whether analyzed in cardinal octants ($p <$
349 0.001) a single octant ($p = 0.013$). Elevated laminarity in the hindlimb appears correlated with
350 adult features, including modest growth rate. This relationship is consistent with findings in the
351 king penguin that also reported laminar bone to be associated with modest growth rates in four
352 limb bones: femur, tibiotarsus, humerus, and radius (de Margerie et al., 2004). More recently, a
353 study using microCT to assess three-dimensional vascular canal orientation in the humerus and
354 femur of growth-controlled broiler chickens also found elevated laminarity in a slow-growing
355 (feed-restricted) group (Pratt and Cooper, 2018). Interestingly, the effect of the “ontogenetic
356 axis” on laminarity in the wing elements is weak ($p = 0.089$), only explaining 27.7% of variation
357 (Fig. 9). The weakened “ontogenetic axis” in wing bone laminarity is consistent with relaxed
358 selection on the vestigial wing leading to increased anatomical variability in the species
359 (Maxwell & Larsson, 2007).

360 Notably, our results differ from those previously reported for young emu bones in which
361 laminar and reticular bone was found in the fastest growing hindlimb bones (Castanet et al.,
362 2000). In particular, Castanet et al. (2000) found laminar bone to be most abundant in the femur
363 and tibiotarsus of emu less than 2 months of age, which corresponds to the youngest individuals
364 in our study. Based on reported body masses, the emus included in our study were about 2-3
365 times heavier than the emus in the Castanet et al. (2000) study for a given age (Table 1). The
366 reason for the differences in size and ontogenetic patterns for bone vascularity types between
367 these two emu samples remain unknown, but could be related to genetic, dietary, or rearing
368 conditions between the two groups. If laminarity is associated with lower growth rates, the

369 youngest emu we studied may have been growing too fast for laminar bone to form. The highest
370 growth rate measured was in the femur of the 4.6-week-old bird (162.62 $\mu\text{m}/\text{day}$), which was
371 about twice the highest growth rate found in the femoral reticular bone tissue reported in the
372 prior study (89.4 $\mu\text{m}/\text{day}$). Our study did not specifically address reticular bone, but by taking
373 the proportion of oblique vascular canals (a “reticular index”), we found the amount of reticular
374 bone in the fastest growing individual to be low in the hindlimb elements (femur and tibiotarsus:
375 0.17), and moderate to high in the wing elements (humerus: 0.62, ulna: 0.58, radius: 0.45). This
376 result is, at least, consistent with the previous study because Castanet et al. (2000) found reticular
377 bone to be more abundant in the humerus. The data analysis in the earlier emu study (Castanet et
378 al., 2000) was conducted before a more rigorous method for quantifying canal orientation was
379 developed (de Margerie, 2002), which may contribute to the observed differences between the
380 two separate emu populations. Regardless, the results of the present study do not support the
381 hypothesis that elevated laminarity reflects rapid growth in the emu and instead link elevated
382 laminarity with more modest growth rates.

383 **Does bone laminarity reflect biomechanical load?**

384 Robust PCA is consistent with previous scaling analysis showing that shear strains in the
385 femur and tibiotarsus of the emu increase with growth (Main & Biewener, 2007). Shear strain
386 covaries with mass, age, and growth rate along an “ontogenetic axis” such that juveniles
387 experience smaller shear strains in the caudal octants, whereas adults experience larger strains
388 (Table 4; Fig.6). However, shear strain contributes comparatively less to the “ontogenetic axis”
389 than the other covariates. Consequently, it has a correspondingly minor effect on caudal octant
390 laminarity in the hindlimb. Indeed, transformation of the effect of the “ontogenetic axis” on
391 laminarity back into the scale of the actual covariates reveals that the standardized effects of age

392 (0.150), mass (0.097), and growth rate (-0.041) are relatively larger than that of shear strain
393 (0.035). Elevated laminar bone tissue, in combination with increased bone mineralization and
394 decreased bone curvature during growth, may have collectively helped mitigate shear strains
395 despite the large increase in mass (Main and Biewener, 2007).

396 Residual variation in shear strain that is not accounted for by the “ontogenetic axis”
397 forms a “loading effect axis” (Table 4; Fig. 6). However, this effect does not correlate with
398 laminarity either as the sole predictor ($p = 0.169$) or in additive combination with ontogeny ($p =$
399 0.056). Put together, the results clearly show that ontogenetic factors largely influence the
400 formation of laminar bone in the caudal hindlimb of the emu, although torsion-induced shear
401 strain is a minor additional factor.

402 The weak association between laminarity and shear strain limits the predictive potential
403 of this relationship. Our results for emu hindlimb bones are consistent with previous studies of
404 other limb elements presumably loaded in torsion. For example, when comparing wings of
405 similar shape, laminarity in wing bones can be similar despite differences in presumed
406 biomechanical load associated with unique primary flight modes (Simons and O’Connor, 2012;
407 Marelli and Simons, 2014). In addition, preferred flight mode may only have subtle effects on
408 overall loading of the bones, with the dominant loads being the high strains present during take-
409 off (Biewener and Dial, 1995). Furthermore, despite sharing with birds convergent features
410 related to powered-flight such as torsionally loaded bone with relatively thin cortical walls
411 (Swartz, Bennett & Carrier, 1992), bone mineral density (Dumont, 2010), and metabolic rate
412 (e.g., Maina, 2000), bats lack laminar bone entirely (Lee & Simons, 2015; Pratt et al., 2018).
413 Instead, they have bones that are poorly-vascularized with a parallel-fibered matrix. Because that
414 histology tends to grow very slowly in other species [e.g., $< 5 \mu\text{m d}^{-1}$ (de Margerie, Cubo &

415 Castanet, 2002; Castanet et al., 2004)], Lee and Simons (2015) speculated that bats do not grow
416 fast enough to form laminar bone. Indeed, somatic growth is approximately four times slower in
417 bats than in birds of comparable size (Lee & Simons, 2015). Caution is warranted, however, as
418 we show in the emu that interchanging somatic and skeletal growth may be misleading.
419 Whatever the actual cause is, the evidence is clear that elevated laminarity is not a prescriptive
420 feature of torsionally loaded bone.

421 In this study, age groups are represented by one individual, with the exceptions of the
422 youngest and oldest age groups that contain two. A larger sample of individuals in each age
423 group would allow for investigation of how individual variation may or may not affect the
424 relationship between LI, shear strain, and growth rate. Laminarity indices can be quite variable
425 among individuals in some species. The pigeon humerus, which has been shown to experience
426 large torsional loads, has been documented to exhibit both high and low laminarity in different
427 individuals (Lee and Simons, 2015; Ourfalian et al., 2016; Skedros and Doutré, 2019).
428 Similarly, a pooled sample of humeri from eight Red-tailed hawks show LI values that range
429 from 0.30-0.70 (Simons and O'Connor, 2012; Marelli and Simons, 2014). Whether these
430 variability patterns are biological or methodological is unclear. Laminarity measured on a
431 histological section is a 2-dimensional representation of a 3-dimensional meshwork of vascular
432 canals in cortical bone. This research is limited by the assumption that one or two closely placed
433 mid-shaft histological sections are an accurate representation of vascular canal structure.
434 MicroCT-based assessment of the three-dimensional network of vascular canals suggests that
435 traditional 2D histological methods may overestimate LI, but also recognizes that these
436 differences may be methodological (Pratt and Cooper, 2017; Pratt et al., 2018). Certainly, future
437 studies should continue to use microCT to assess how well laminarity measured on histological

438 sections represents actual biological structure. In addition, the torsional resistance in bones may
439 more likely be linked to the specific orientation of another histological feature: collagen fibers.
440 Collagen fiber orientation (CFO) has been shown to reflect principle strain distributions (Riggs
441 et al., 1993; Skedros and Hunt, 2004; Skedros et al, 2004; Skedros and Doutré, 2019). Analysis
442 of CFO is beyond the scope of the current study. However, given the known positive correlation
443 between transversely oriented collagen fibers and bone laminarity (de Margerie et al., 2005), we
444 would expect a similar pattern for the femora and tibiotarsi examined here.

445 Although there is no direct biomechanical data for the forelimb elements of these birds,
446 the wing elements presumably experience minimal loading. The emu wing is extremely reduced
447 in size, even when compared to other ratites, and has almost no observed function (del Hoyo et
448 al., 1992). Wing muscles of emu contain primarily slow acting tonic muscle fibers that may not
449 allow much wing movement (Maxwell and Larsson, 2007), which suggests the underlying wing
450 elements would experience minimal biomechanical loading. Despite the assumption that the emu
451 wing is under minimal load, a moderate to high degree of laminarity was found in at least the
452 humerus and ulna (Table 2). This laminarity can be attributed to the modest bone growth rate
453 observed in the wing elements and/or to the third factor affecting bone microstructure:
454 phylogenetic relationships. Within the paleognaths, it has been hypothesized that at least three
455 independent flight losses have occurred, with only one order (the tinamous) still retaining the
456 ability to fly (Harshman et al., 2008; Mitchell et al., 2014). The moderate/high wing bone
457 laminarity may be a feature of the flighted common ancestor of paleognaths that is retained in the
458 flightless descendants. Indeed, significant phylogenetic signal has been found in some
459 osteohistological features in a sample of paleognaths (Legendre et al., 2014). Future studies
460 should investigate the histological and *in vivo* loading of the flighted relatives of emus to better

461 understand the potential influence of phylogeny on bone laminarity.

462

463 **CONCLUSIONS**

464 In the emu limb skeleton, ontogenetic factors such as size, age, and growth rate have
465 major effects on vascular canal orientation. The effect of shear strain is relatively weak and
466 suggests that laminar bone is not a good predictor of torsional loading. Even though the forelimb
467 elements likely experience minimal loading, the humerus and ulna show wide variation in
468 laminarity, perhaps due to relaxed selection. Future studies should investigate laminarity in other
469 palaeognathous birds to better understand the effects phylogeny, ontogeny, and torsional loading
470 have on bone laminarity. Other future work should focus on the experimental manipulation of
471 biomechanical loads to observe the effects on vascular canal orientation in limb bones and to
472 better understand to what extent torsional load influences the development of limb bone
473 laminarity. It is also important that variation found between different populations be addressed
474 and studied further. Emu body mass growth rates vary among populations (e.g. Goonewardene et
475 al., 2003), but it is unknown to what extent laminar bone also varies with environmental, dietary,
476 or genetic factors. This study has shown that in emu limb bones, laminarity reflects a complex
477 interplay of ontogeny and biomechanical loads.

478

479 **ACKNOWLEDGEMENTS**

480 The authors would like to thank K Ezell for assistance with histological preparation and imaging.
481 We are grateful for free access to the microscopes in the Microscopy Core Facility at
482 Midwestern University. We thank Andrew Biewener and the graduate students and postdocs at
483 the Concord Field Station (2002-2006) for assistance with bone strain data collection. We thank

484 reviewers Edina Prondvai and Jorge Cubo for useful comments that improved the manuscript.

Figure 1

Representative histological sections of emu femora, tibiotarsi, and humeri from a range of ages.

2.3 weeks (A, B, C), 8.1 weeks (D, E), 12 weeks (F), 16 weeks (G, H, I), 60 weeks (L, J, K). Femora (A, D, G, J), tibiotarsus (B, E, H, K) and humeri (C, F, I, L). Scale bars equal 1000 μm for femora and tibiotarsi, and 250 μm for humeri. Bright field images of non-straightened caudal or medial octants.

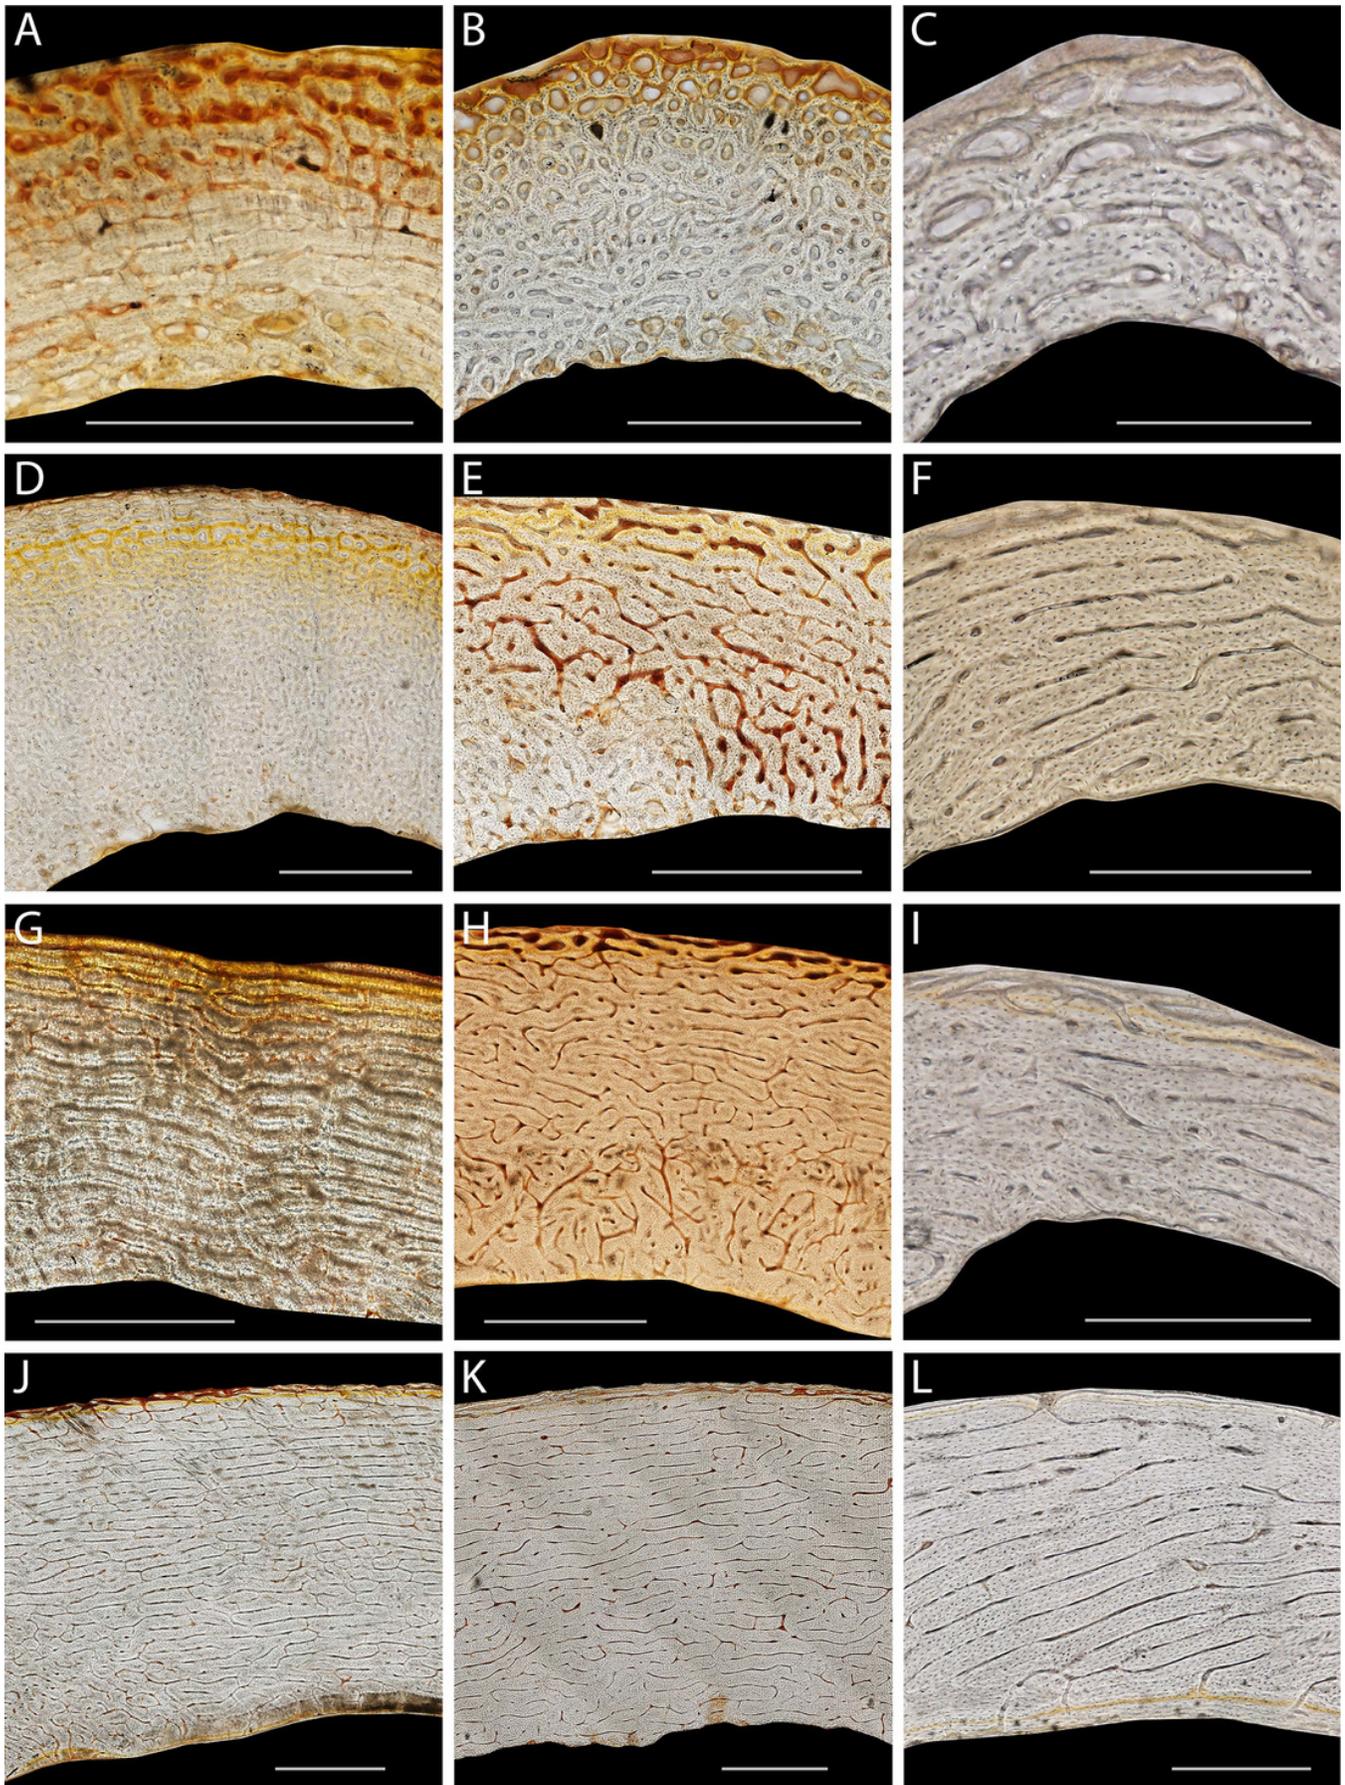

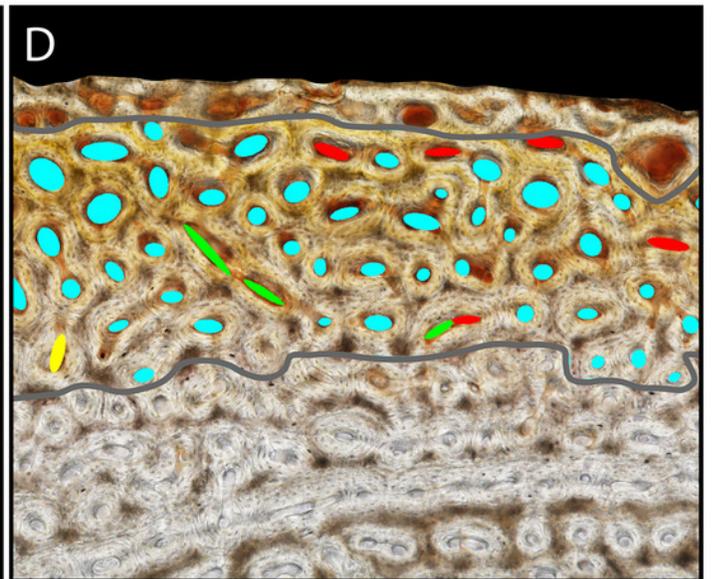

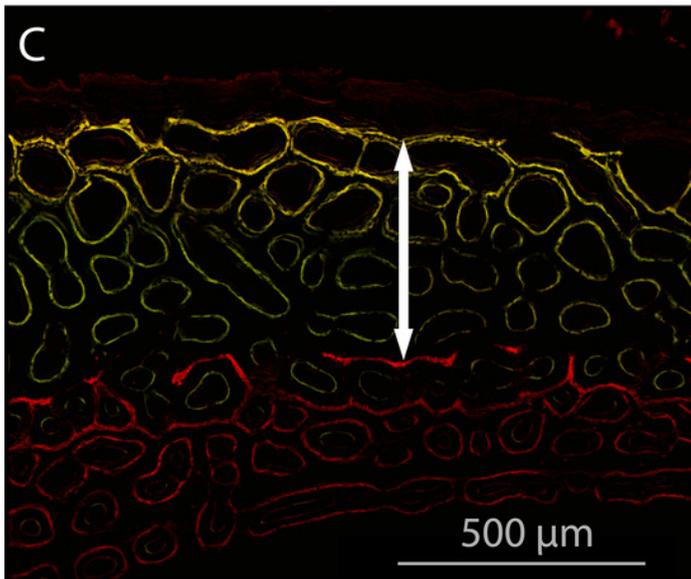

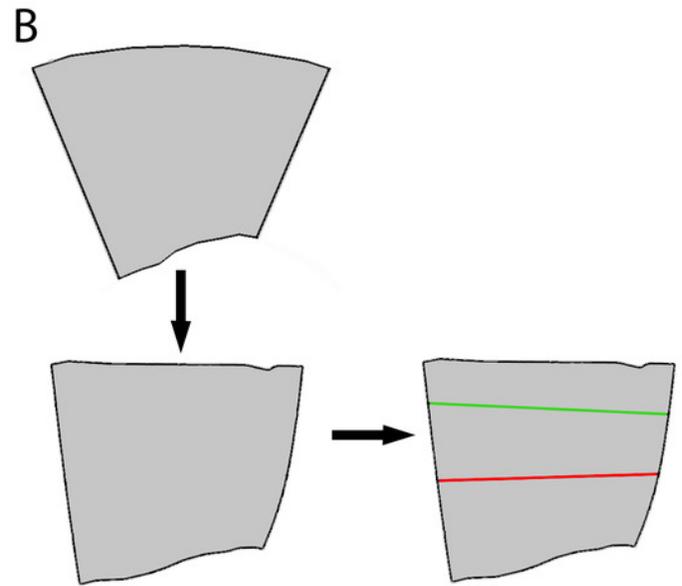

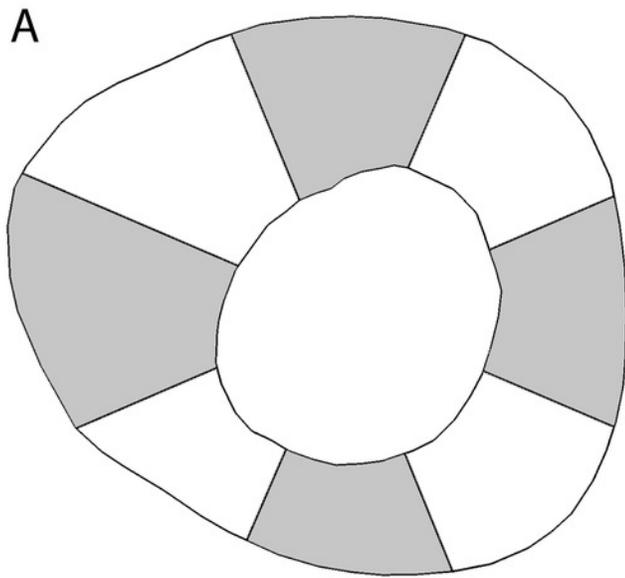

Figure 2

Sampling methods for growth rate and laminarity measures.

(A) Gray shading indicates the four octants (wing elements: cranial, caudal, dorsal, ventral; hindlimb elements: cranial, caudal, lateral, medial) sampled on each cross-section. (B) Each octant was isolated, straightened, and a sample area indicated: between fluorochrome reference lines. (C) On fluorescent images, growth rate was measured by taking the mean distance (white arrow) between the periosteal extent of the xylenol (red) and calcein (green/yellow) tags divided by number of days between injections. (D) Laminarity was measured by approximating each in-focus primary vascular canal with the best-fitting ellipse, using the best-fitting ellipse to categorize canal orientations, and calculating the proportion of circumferential canals. (Tibiotarsus 17, 4.6 wks).

● Circumferential ● Longitudinal ● Oblique ● Radial

Figure 3

Laminarity Indices for the forelimb and hindlimb bones included in this study.

Laminarity indices (LI) measured from the cardinal octants for each bone (Fem=femur, Tbt=tibiotarsus, Hum=humerus, Ulna, Rad=radius) from specimens (A) 15 - 2 week, (B) 1c - 2 week, (C) 17 - 5 week, (D) 14b - 8 week, (E) 16 - 12 week, (F) 2a - 16 week, (G) 21 - 48 week, and (H) 23 - 60 week. LI was measured between fluorochrome reference lines on all sampled octants.

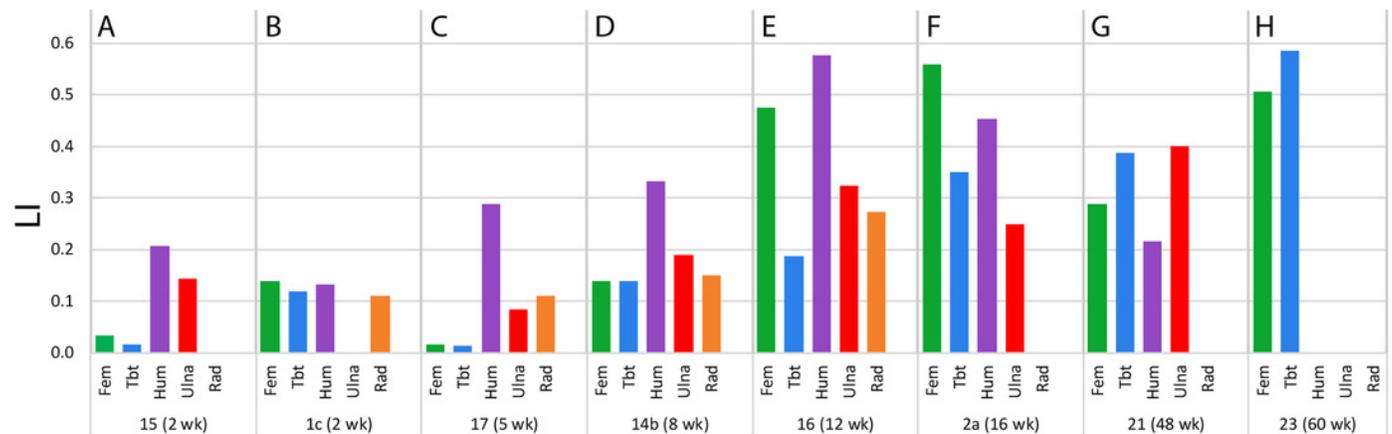

Figure 4

Robust principal components analysis of the cardinal octants from the femur and tibiotarsus.

An “ontogenetic axis” (PC 1) accounts for 95% of the variance with juvenile features to the left (small size, young age, and rapid growth) and adult features to the right (large size, old age, and modest growth). Residual variation in growth rate is absorbed into PC 2, which accounts for another 4.7% of the cumulative variance.

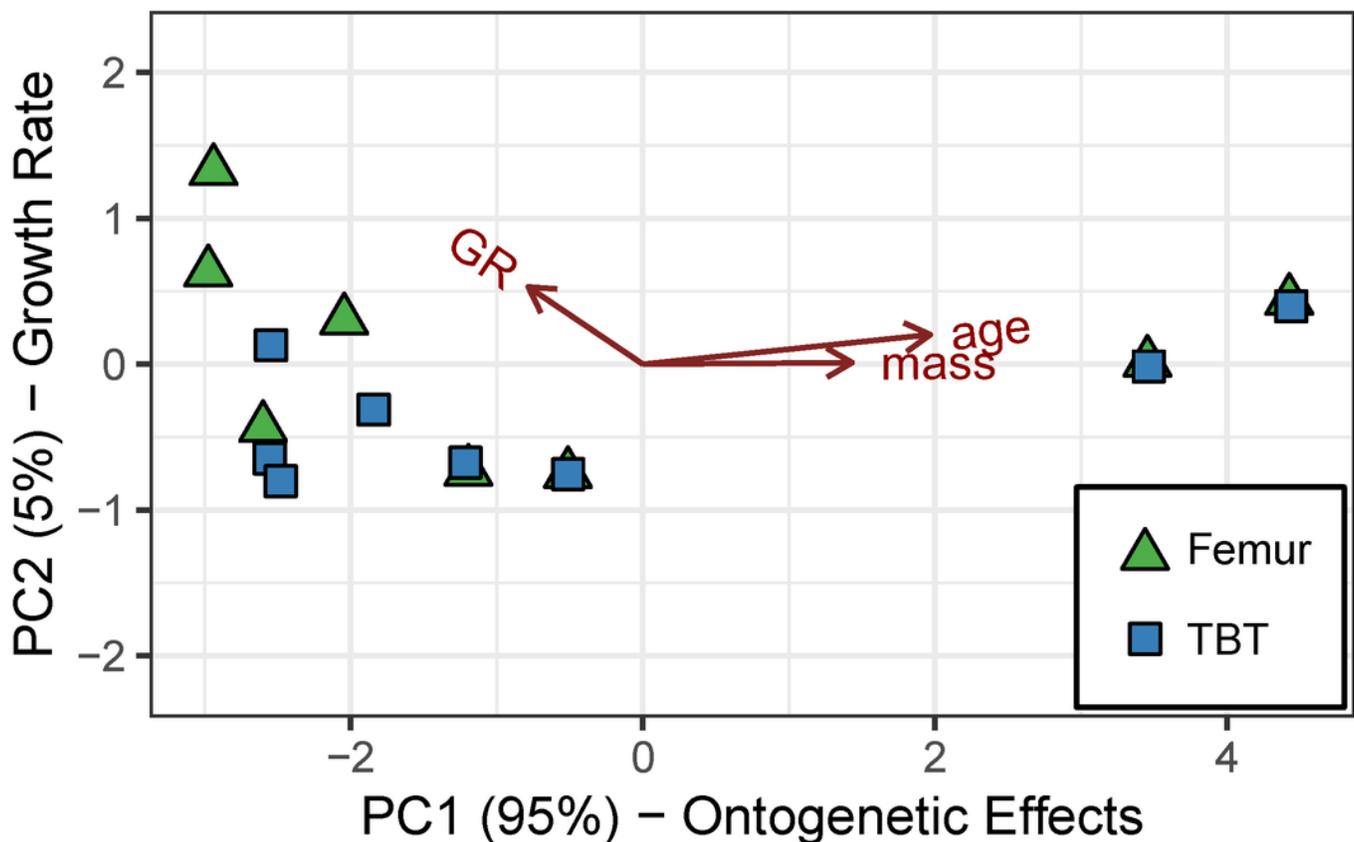

Figure 5

Effect of the “ontogenetic axis” (PC 1) on laminarity (LI) in the cardinal octants of the hindlimb.

Random-intercept beta regression reveals that the “ontogenetic axis” (PC 1) accounts for 89% of the variation in laminarity from the cardinal octants of femur (green triangles) and tibiotarsus (blue squares). Elevated laminarity values are strongly correlated with adult features such as large size, old age, and modest growth rate ($p < 5.51e^{-5}$).

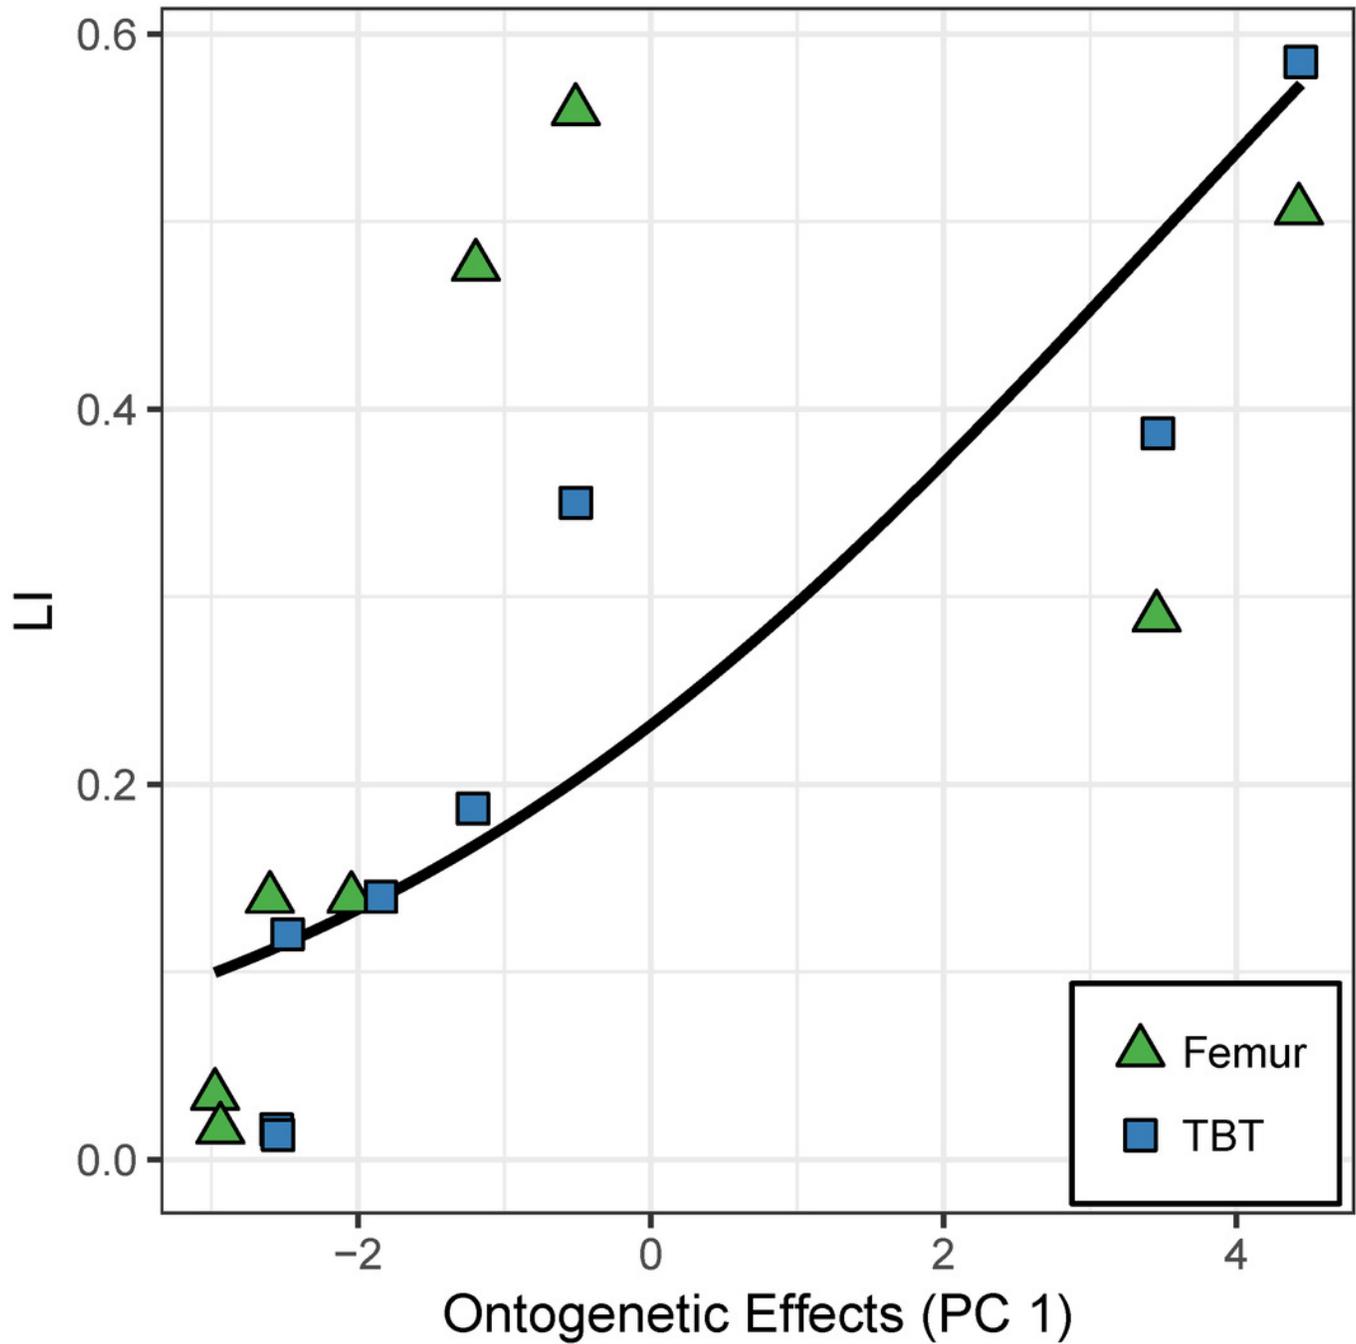

Figure 6

Robust principal components analysis of the caudal octants from the femur and tibiotarsus.

An “ontogenetic axis” (PC 1) accounts for 88% of the variance with juvenile features to the left (small size, young age, and rapid growth) and adult features to the right (large size, old age, and modest growth). PC 2 explains 9% of the cumulative variance and is dominated by shear strain, forming a “loading-effect axis.”

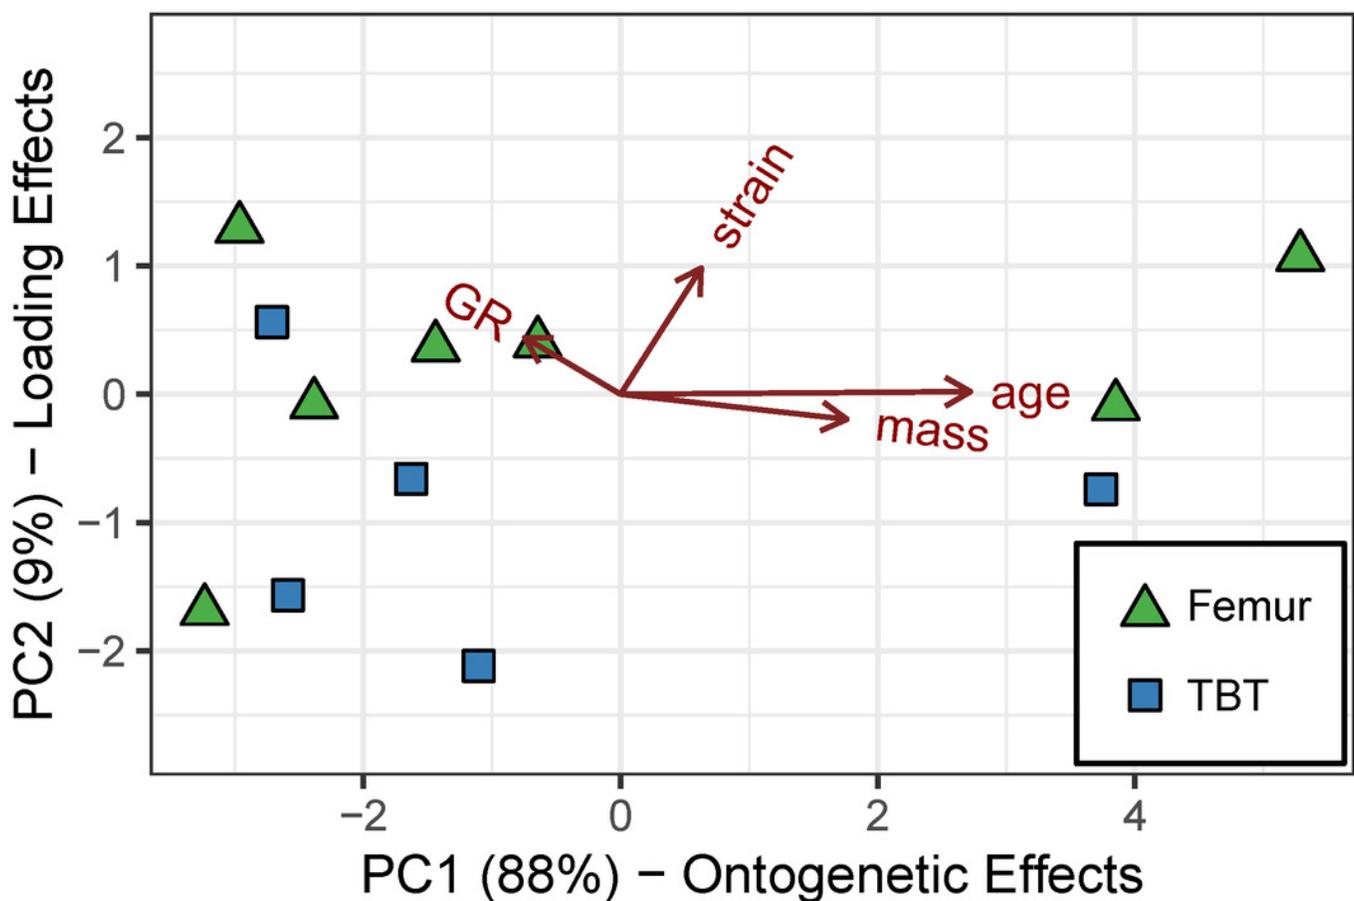

Figure 7

Effect of the “ontogenetic axis” on laminarity (LI) in the caudal octants of the hindlimb.

Random-intercept beta regression reveals that the “ontogenetic axis” (PC 1) accounts for 78% of the variation in laminarity from the caudal octants of femur (green triangles) and tibiotarsus (blue squares). Laminarity generally increases along that axis ($p = 0.013$) to which shear strain has a minor contribution.

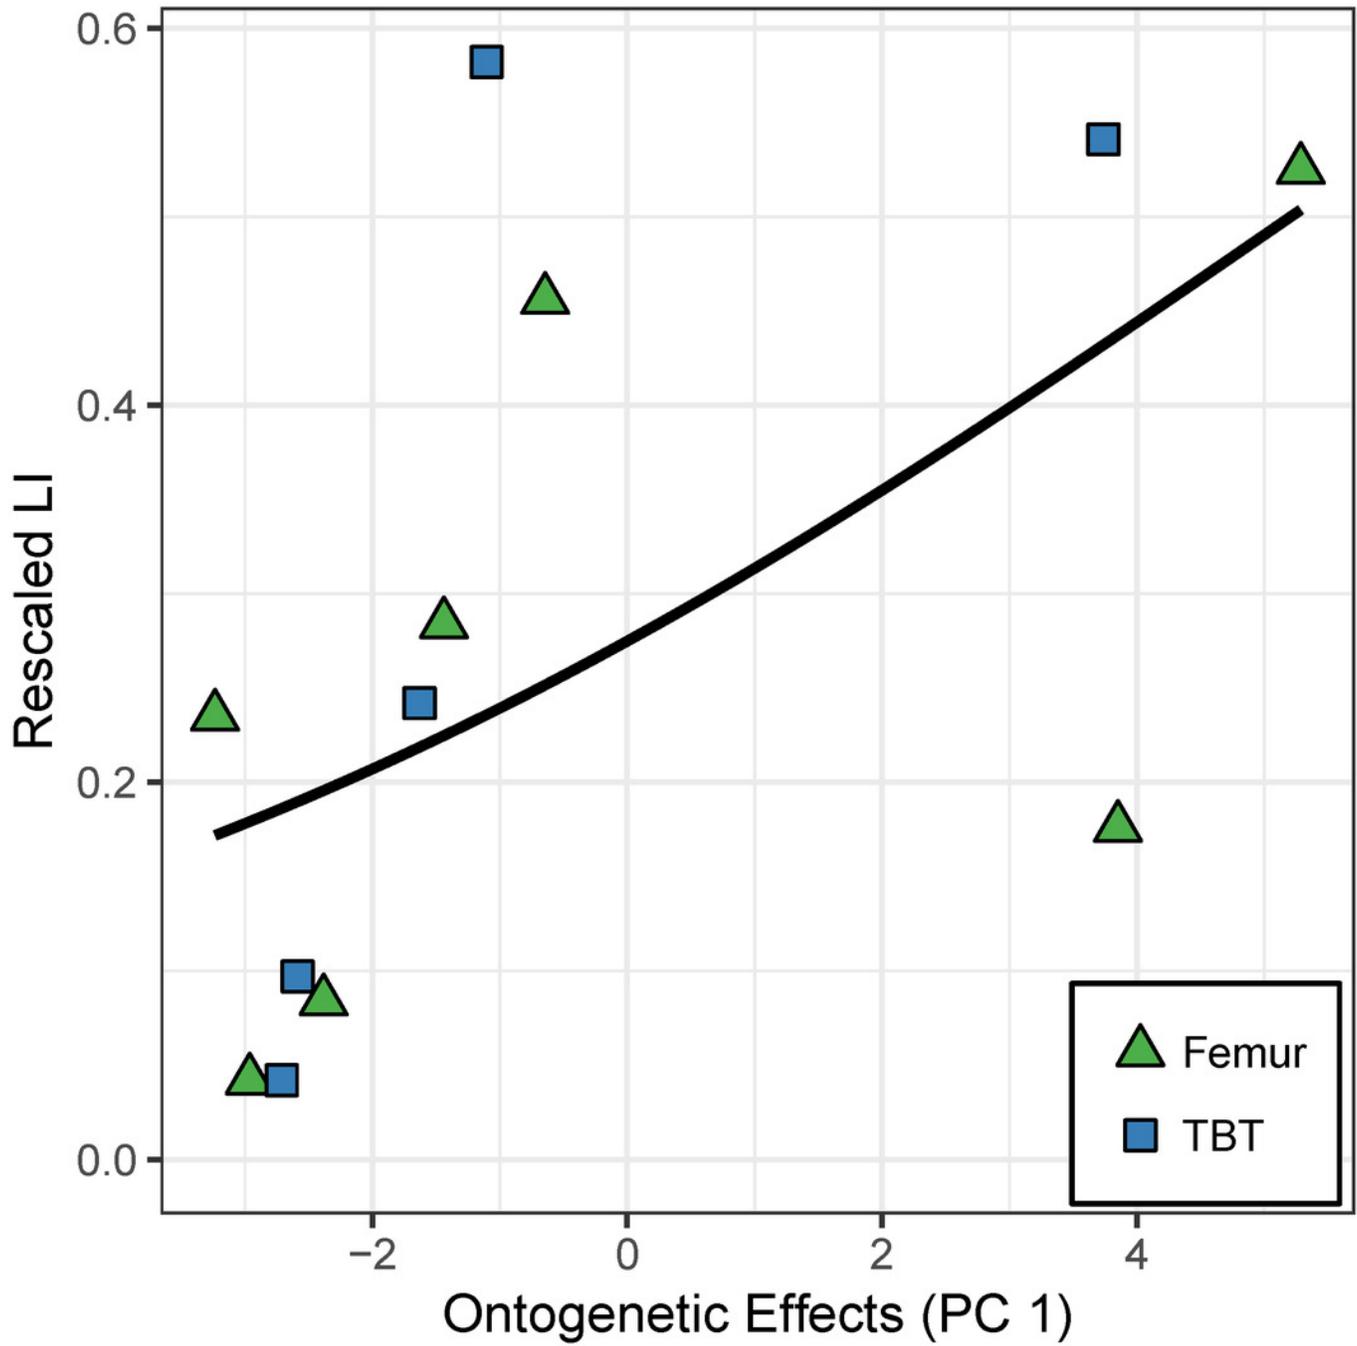

Figure 8

Robust principal components analysis of the cardinal octants from the humerus, ulna, and radius.

An “ontogenetic axis” (PC 1) accounts for 97% of the variance with juvenile features to the left (small size, young age, and rapid growth rate) and adult features to the right (large size, old age, and modest growth rate). Residual variation from growth rate largely contributes to an “ontogeny-independent growth rate axis” along PC 2. This axis only explains 2.3% of the cumulative variance.

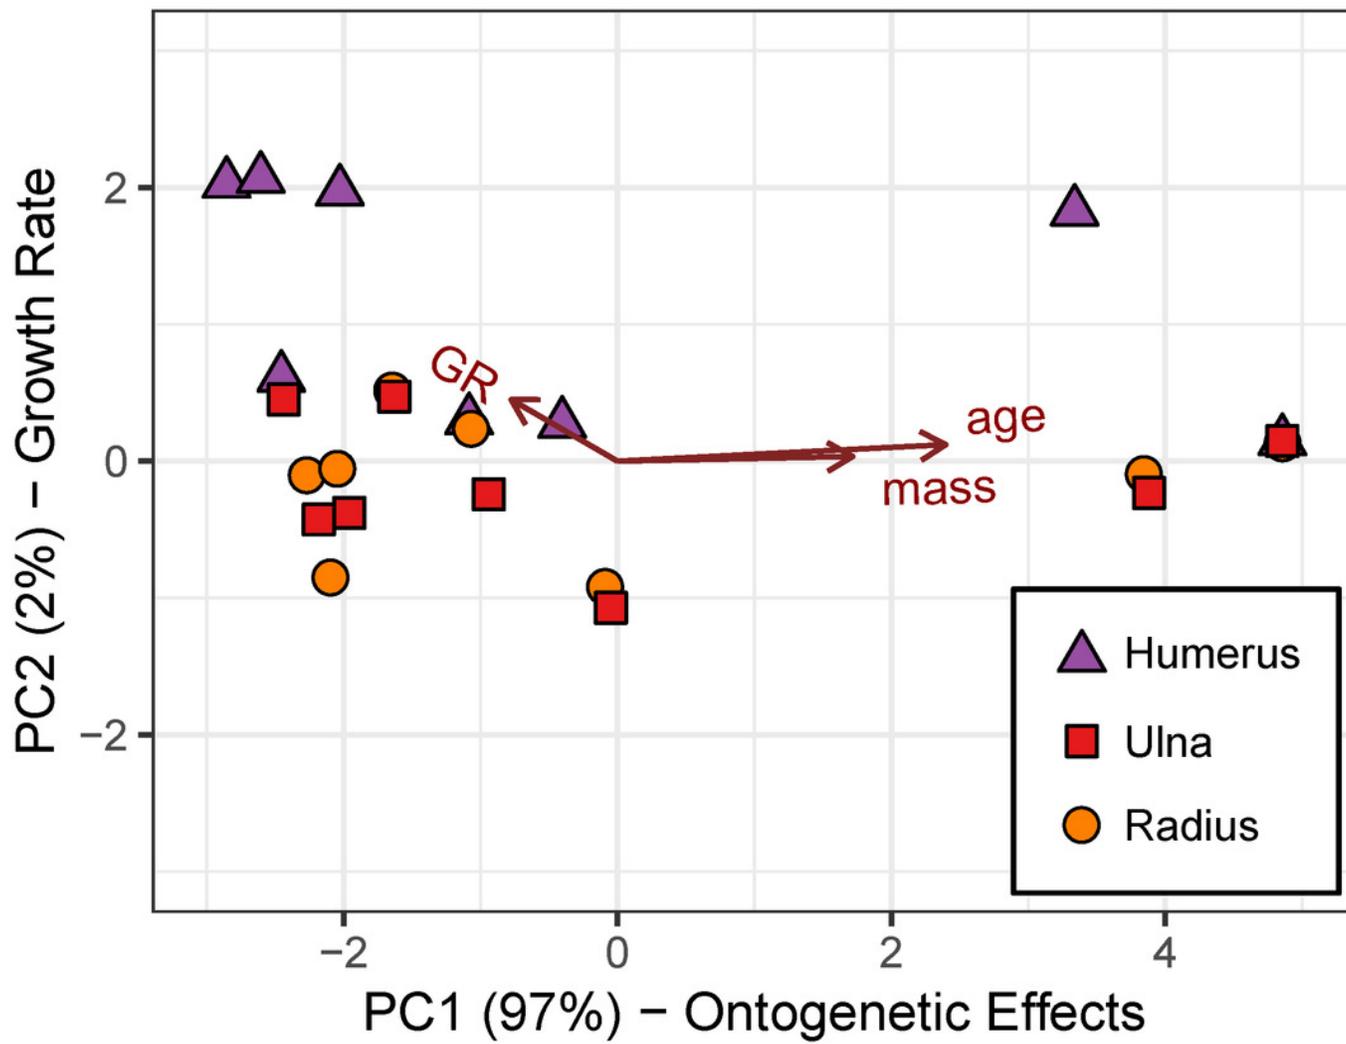

Figure 9

Effect of the “ontogenetic axis” on laminarity (LI) in cardinal octants of the forelimb.

Random-intercept beta regression reveals poor correlation ($p = 0.089$) between laminarity and the “ontogenetic axis” in the humerus (purple triangles), ulna (red squares), and radius (orange circles).

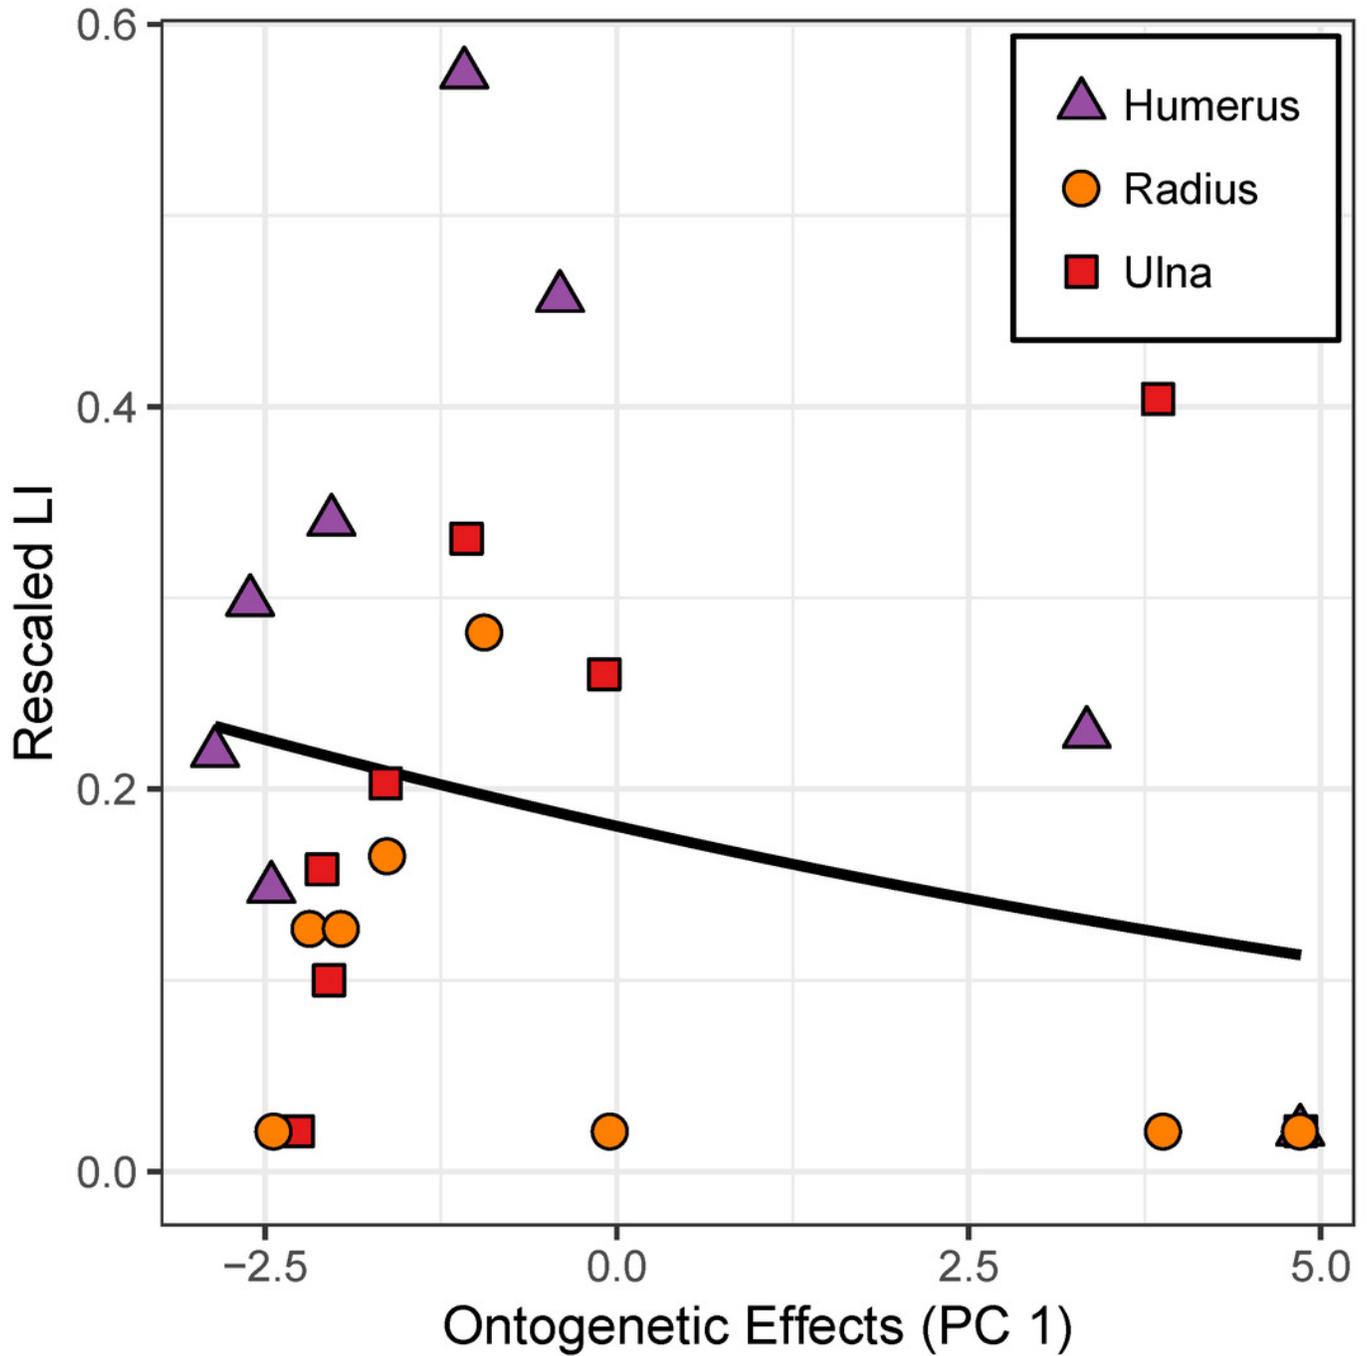

Table 1 (on next page)

Emu identification number, age at sacrifice, and mass.

1

Specimen	Age (weeks)	Mass (kg)
15	2.3	0.74
1c	2.4	0.94
17	4.6	1.53

Table 3(on next page)

Caudal shear strain and caudal octant laminarity for emu specimens.

Caudal shear strain data were previously collected by Main and Biewener (2007). Caudal laminarity index (LI) was measured in a sample area outlined by the periosteal extent of two bone fluorochromes in the caudal octant only. LI values were rescaled following (Smithson & Verkuilen, 2006) to prepare data with 0 values for beta regression. Only specimens for which caudal shear strain data were available are included.

1

Specimen	Age (weeks)	Element	Caudal Shear Strain (microstrain)	Caudal Octant LI	Rescaled Caudal LI
1c	2.4	Femur	-308	0.21	0.24
17	4.6	Femur	-1503	0	0.04
		Tibiotarsus	-1397	0	0.04
14b	8.1	Femur	-997	0.05	0.08

Growth rate	-0.221	0.403	0.880	0.121
C. Cardinal Octants from Humerus, Ulna, and Radius				
	PC 1	PC 2	PC 3	
Eigenvalues	7.977	0.187	0.039	
Standard deviation	2.824	0.433	0.197	
Proportion of variation	0.972	0.023	0.005	
Cumulative Proportion	0.972	0.995	1.000	
Mass	0.563	0.074	0.823	
Age	0.786	0.259	-0.561	
Growth rate	-0.255	0.963	0.087	

Table 5 (on next page)

Comparison of random-intercept beta regression models.

Model selection was based on Akaike's Information Criterion (AIC_c) value and ΔAIC_c . (A) Cardinal octants from hindlimb, (B) caudal octants from hindlimb, and (C) cardinal octants from forelimb. For each dataset, the best supported model showed the "ontogenetic axis" (PC 1) as the sole predictor of laminarity.

1 **A. Cardinal Octants from Hindlimb**

Variable	Model 1		Model 2	
	β	p-value	β	p-value
Intercept	-1.120	1.25e-5	-1.053	3.19e-4
