Background. The effects of global climate change on species inhabiting marine ecosystems are of growing concern, especially for endemic species that are sensitive due to restricted distribution. One method employed for determining the effects of climate change on the distribution of these organisms is species distribution modeling.

Methods. We generated a model to evaluate the potential geographic distribution and breeding distribution of the Peruvian pelican (*Pelecanus thagus*). Based on maximum entropy modeling (MaxEnt), we identified the environmental factors that currently affect its geographic distribution and breeding. Then we predicted its future distribution range under two climate change scenarios: moderate (rcp 2.6) and severe (rcp 8.5).

Results. The mean daytime temperature range and marine primary productivity explain the current potential distribution and breeding of the pelican. Under the future climate change scenarios, the spatial distribution of the pelican is predicted to slightly change. While, the breeding distribution of the pelican can be benefited in the moderate scenario, but is predicted to decrease (near -20 %) in the severe scenario.

Discussion. The current potential geographic distribution of the pelican is influenced to a large extent by thermal conditions and primary productivity. Under the moderate scenario, a slight increase in pelican breeding distribution is predicted. This increase in habitable area is explained by the climatic conditions in southern Chile, and those climatic conditions will likely be similar to the current conditions of the central coast of Chile. We predict that the coasts of southern Chile will constitute an important refuge for the conservation of the Peruvian pelican under future climate change scenarios.

23 **ABSTRACT**

24 **Background.** The effects of global climate change on species inhabiting marine ecosystems are
25 of growing concern, especially for endemic species that are sensitive due to restricted
26 distribution. One method employed for determining the effects of climate change on the
27 distribution of these organisms is species distribution modeling.

28 **Methods.** We generated a model to evaluate the potential geographic distribution and breeding
29 distribution of the Peruvian pelican (*Pelecanus thagus*). Based on maximum entropy modeling
30 (MaxEnt), we identified the environmental factors that currently affect its geographic distribution
31 and breeding. Then we predicted its future distribution range under two climate change
32 scenarios: moderate (rcp 2.6) and severe (rcp 8.5).

33 **Results.** The mean daytime temperature range and marine primary productivity explain the
34 current potential distribution and breeding of the pelican. Under the future climate change
35 scenarios, the spatial distribution of the pelican is predicted to slightly change. While, the
36 breeding distribution of the pelican can be benefited in the moderate scenario, but is predicted to
37 decrease (near -20%) in the severe scenario.

38 **Discussion.** The current potential geographic distribution of the pelican is influenced to a large
39 extent by thermal conditions and primary productivity. Under the moderate scenario, a slight
40 increase in pelican breeding distribution is predicted. This increase in habitable area is explained
41 by the climatic conditions in southern Chile, and those climatic conditions will likely be similar
42 to the current conditions of the central coast of Chile. We predict that the coasts of southern
43 Chile will constitute an important refuge for the conservation of the Peruvian pelican under
44 future climate change scenarios.

47

48 **Introduction**

49 Climate change is of increasing concern for seabirds because it negatively affects their
50 conservation status and has become the third most important threat after exotic invasive species
51 and incidental capture (Croxall et al., 2012). In turn, a great proportion of seabirds (e.g., of the
52 Humboldt Current System) feed in a relatively narrow range of trophic levels, mainly on larger
53 zooplankton, small pelagic fish, or squid (Quillfeldt & Masello, 2013). Most of the prey species
54 consumed by seabirds are strongly affected by climate-induced changes on the productivity of
55 phytoplankton, generating changes in both the abundance and fecundity of herbivorous
56 zooplankton (small copepods and euphausiids). Consequently, carnivorous zooplankton and
57 pelagic fish or squid are also affected (Crawford et al., 2008a, Crawford et al., 2008b; Wynn et
58 al., 2007; Luczak et al., 2011). The dynamics of small pelagic fish have been studied intensively
59 in the marine upwelling ecosystems such the Humboldt and Benguela currents, where the
60 collapse of small populations of pelagic fish is often followed by severe decreases in the
61 populations of seabirds (Crawford & Jahncke, 1999; Crawford et al., 2008a). Seabirds face
62 multiple imminent threats (overfishing and incidental death, pollution, introduced species,
63 habitat destruction, and human disturbance) that may seem more urgent than gradual climate
64 change and its associated climate phenomena (Croxall et al., 2012; Quillfeldt & Masello, 2013).
65 However, some of these threats are locally restricted, whereas the climate phenomena have the
66 potential to alter an entire region and increase the cumulative pressures that affect many seabirds,
67 especially endemic species (Quillfeldt & Masello, 2013; Jenouvrier et al., 2014).

68 The Peruvian pelican *Pelecanus thagus* (hereafter pelican) is a seabird endemic to the Humboldt
69 Current Large Marine Ecosystem (HCLME) of South America. The pelican's home range lies on

70 the Pacific coast from southern Ecuador, through Peru down to southern Chile (BirdLife
71 International, 2018). However, its breeding distribution is not continuous along the coast, but is
72 very localized in certain coastal islands from Santa Clara Island (3°S) in southern Ecuador, to
73 Mocha Island (38°S) in central Chile (Housse, 1945; Vinuela, Sornoza & Yañez, 2015). At the
74 global level, the pelican is classified as near threatened (BirdLife International, 2018). In Peru,
75 this species is considered endangered (MINAGRI, 2018). In Chile and Ecuador there is no
76 classification concerning its conservation status, even though the Chilean coastline comprises
77 more than 50% of pelican's habitat range (Cursach et al., 2018). Between 2010 and 2015 the
78 abundance of pelicans in Chile decreased significantly on the central coast, area encompasses the
79 main breeding population (Cursach et al., 2018).

80 Predicting the response of biodiversity to climate change has developed into an active field of
81 research (Bellard et al., 2012; Molinos et al., 2015; Pecl et al., 2017). Therefore, projections of
82 species distribution models play an important role in alerting scientists and decision makers to
83 assess the potential future risks of climate change (Pereira et al., 2010; Parmesan et al., 2011).
84 Climate change may alter the suitability of habitat and contraction of the distribution range of
85 several groups of marine and terrestrial organisms, including Southern Ocean seabirds (Marzloff
86 et al., 2016; Krüger et al., 2017). The current study aims to generate models of the potential
87 geographic distribution and breeding of the pelican, to identify the environmental factors that
88 affect its current distribution, and to predict its future distribution range under two climate
89 change scenarios (moderate and severe). Our hypothesis was that the spatial distribution and
90 breeding distribution of the pelican will decrease and that the main cause of this will be climate
91 change.

92

93 **Materials & Methods**

94 **Species records**

95 Pelican nesting and occurrence data were compiled from four main sources: the Neotropical
96 Waterbird Census (<https://lac.wetlands.org/>), eBird (<https://ebird.org/>), the Global Biodiversity
97 Information Facility (<https://www.gbif.org/>), and the literature. The geo-coordinates for each
98 data point were referenced from the information in the literature or through the use of
99 coordinates in Google Earth. We excluded duplicate or unclear locations and verified the
100 accuracy of the data. We found a total of 4,818 georeferenced data points referring to pelican
101 sightings (in resting place, nesting sites, coves, beaches, etc.), encompassing its entire geographic
102 distribution from 2000 to 2015. Of these records, a subsampling was performed at a distance of
103 15 km (cell size), obtaining a total of 264 records, with which the modeling was performed. This
104 subsampling was conducted in R, version 3.0.2 (R Development Core Team 2013). The
105 breeding distribution of the pelican was modeled with information for 34 nesting sites (Vinuela
106 et al., 2015; Zavalaga et al., 2015; Cursach et al., 2018).

107

108 Environmental variables

109 The environmental variables used to characterize the current distribution (and breeding) of the
110 pelican were selected based on climate and oceanography. The climate variables used in this
111 study were downloaded from the EcoClimate database (<http://www.ecoclimate.org>) (Lima-
112 Ribeiro et al., 2015). These variables were represented by maximum, minimum, and mean values
113 of monthly, quarterly, and annual temperatures, and the precipitation values recorded between
114 1950 and 2000. These parameters provided a combination of means, extremes, and seasonal
115 differences in variables known to influence the distribution of species (Root et al., 2003). With
116 the species distribution modeling toolbox extension implemented in ArcGIS, all bioclimate
117 variables that showed a correlation higher than 0.7 were eliminated (Brown, 2014). Finally, six
118 climate variables were selected: annual mean temperature, mean daytime temperature range,
119 isothermality, seasonality in temperature, annual precipitation, seasonality in precipitation. The
120 oceanographic variables used were sea surface temperature (SST) and marine net primary
121 productivity ($\text{mg C m}^{-2} \text{ day}^{-1}$), as they are considered the main descriptors of the spatial
122 distribution of seabirds (Quillfeldt et al., 2015; Ingenloff, 2017). These variables were obtained
123 from the National Oceanic and Atmospheric Administration (NOAA,
124 <http://www.ngdc.noaa.gov/>). For the analyses, we used mean values per climate season for a
125 period of nine years (2004 to 2013), totaling eight oceanographic variables. All environmental
126 variables used in this study were interpolated by the kriging method, with a uniform resolution of
127 $0.5^\circ \times 0.5^\circ$ using the QGIS 3.2.0 software (Lima-Ribeiro et al., 2015; Varela, Lima & Terribile,
128 2015).

129 To evaluate the effects of the different climate change scenarios on the spatial distribution of
130 pelicans, we did not include the oceanographic variables. The future climate scenarios
131 corresponded to those proposed by the Intergovernmental Panel on Climate Change (IPCC,
132 2014). These scenarios were obtained from the ecoClimate website (<http://ecoclimate.org/>),
133 which contains climate models available for different temporal intervals. To do this, we used the
134 model developed by the Community Climate System Model version 4 of the National Center for
135 Atmospheric Research (Gent et al., 2011). This is due to the good results for the South-East
136 Pacific (Larson, Pegion & Kirtman, 2018; Zheng et al., 2018).

137 The projections for the six preselected variables and the projected minimum and maximum
138 trajectories of the concentrations of greenhouse gases were obtained. That is 2.6 and 8.5 rcp
139 (representative concentration pathways), respectively. These values indicate increases in the heat
140 absorbed by the planet Earth due to the concentration of greenhouse gases up to 2100, in each
141 trajectory and expressed in watts per square meter. Thus, 2.6 rcp is the moderate projection for
142 the scenario with the least climate change; whereas, 8.5 rcp is a more pessimistic projection and
143 represents a severe scenario with the greatest climate change (Taylor, Stouffer & Meehl, 2012).

144

145 **Modeling of the potential geographic distribution**

146 The MaxEnt software (MaxEnt version 3.3.3k, <http://www.cs.princeton.edu/~schapire/maxent/>)
147 has been frequently used for species distribution models under current and future climate
148 scenarios (Phillips & Dudík, 2008). We used MaxEnt to model the geographic distribution of the
149 pelican, including under two previously described climate change scenarios (Elith et al., 2006;
150 Taylor, Stouffer & Meehl, 2012). The model was elaborated by MaxEnt auto-features (5,000
151 iterations). Logistic output was used for all analyses. The quality of the model was evaluated
152 using the area under the curve (AUC) and the continuous Boyce index (Hirzel et al., 2006). AUC
153 values can vary from 0 to 1, where a value greater than 0.9 is considered an indicator of “good”
154 discrimination skills (Peterson et al., 2011). Values of the Boyce index vary between -1 and 1 ,
155 where positive values indicate a model with predictions that are consistent with the distribution
156 of observed presences in the evaluation dataset (Boyce, 2002). Both analyses were conducted in
157 R using the “biomod2” package (R Development Core Team 2013).

158 For each distribution model, a 30-fold cross-validation was used, with a data proportion of 25%
159 for training and 75% for evaluation. The most important environmental variables were identified
160 by estimating the relative contribution (%) to the model (Phillips, Anderson & Schapire, 2006).
161 Jackknife test was used to evaluate the importance of the environmental variables for predictive
162 modeling (Almalki et al. 2015).

163

164 **Results**

165 **Model yield for potential distribution**

166 The model of presence with the best fit showed a gain of 3.04 and a Boyce Index of 0.99. Also,
167 an AUC_{training} of 0.98 and an $AUC_{\text{evaluation}}$ of 0.98 and a standard deviation of 0.004. While, the
168 modeling of breeding distribution showed a gain of 2.24 and a Boyce Index of 0.98, with an
169 AUC_{training} of 0.98 and an $AUC_{\text{evaluation}}$ of 0.98 and a standard deviation of 0.003. The AUC
170 values were relatively similar, so the models used are appropriate for predicting the presence and
171 breeding distribution of the species. $AUC_{\text{evaluation}}$ 0.98 indicates that the pelican has a wide
172 geographic distribution and breeding in relation to the area corresponding to the environmental
173 data. The model predicts that the potential geographic distribution of the pelican reaches an
174 approximate surface area of 466,836 km², latitudinally distributed from southern Ecuador
175 ($2^{\circ}13'09''\text{S}$) to southern Chile ($46^{\circ}59'07''\text{S}$). Over this extensive marine–coastal surface, the
176 probability of occurrence for this species varied between a 0.16 (minimum) and 0.84 (maximum)
177 (Table 1). Areas with the highest probabilities of occurrence for the pelican are represented with
178 intense red colors in Figure 1A and Figure 2A. These areas are mainly distributed from northern
179 Peru to central Chile.

180

181 **Importance of environmental variables**

182 Among the six climatic variables and eight oceanographic variables, the mean daytime
183 temperature range (Bio2) and the summer marine primary productivity, contributed the most to
184 the current and potential distribution of the pelican (Table 2). These two factors explained
185 78.47% of the modeled distribution. The mean daytime temperature responded to the probability
186 of the presence of the pelican, with a high probability of finding the species in areas where the
187 mean daytime temperature ranges between 6 and 8°C. In turn, the summer marine primary
188 productivity also influenced the probability of the presence of the pelican, with a greater
189 probability of finding the species during the summer season in areas with high primary
190 productivity. The other factors such as, spring marine primary productivity, isothermality, and
191 seasonality in temperature, contributed 9.24%, 3.23%, and 1.74%, respectively, to the modeled
192 distribution. Therefore, thermal and primary productivity conditions are more important than
193 other variables for mapping pelican distribution (Table 2).

194 The modeling of breeding distribution showed that the mean daytime temperature range
195 contributed with 91.5% to the model, while the summer marine primary productivity contributed
196 with 8.5%.

197

198 **Potential geographic distribution of the pelican as a function of climate change**

199 Based on the six climatic variables selected in the study, the model predicts that the projected
200 pelican distribution currently attains an area of 596,753 km² (Table 3). This area is larger than
201 that initially projected (466,836 km²), where the oceanographic variables were integrated.
202 Regarding the projections of climate change for 2100, under the moderate scenario of 2.6 rcp a
203 slight decrease (−0.68%) in pelican spatial distribution is predicted (Table 3). Under the severe
204 scenario of 8.5 rcp, a slight increase (4.51%) in pelican spatial distribution is predicted (Table 3).

205 The projected habitable surface area under climate change of 2.6 rcp does not presents a major
206 change with respect to the current geographic distribution of the pelican (Table 3). Under the
207 severe scenario, the model predicts that the pelican habitable surface will vary depending on
208 geographic area (Fig. 1). For example, in northern Chile its habitable surface would decrease,
209 whereas in central and southern Chile it would increase over time (Fig. 2). The projected
210 habitable surface area and the probabilities of occurrence for the pelican are spatially
211 schematized in Figure 2.

212 For the case of the modeling of breeding distribution, an area of 435,640 km² is projected (Table
213 4). Regarding the projections of climate change for 2100, under the moderate scenario of 2.6 rcp
214 an increase (8.77%) in pelican breeding distribution is predicted (Table 4). Under the severe
215 scenario of 8.5 rcp, a decrease (−19.30%) in pelican breeding distribution is predicted (Table 4).
216 Under the severe scenario, the model predicts a decrease of occurrence probability of nesting
217 sites of the pelican in northern Ecuador and north-central Chile (Fig. 2).

218

219 **Discussion**

220 The potential geographic distribution of the pelican currently attains an approximate area of
221 466,836 km², distributed latitudinally from southern Ecuador (2°13'09"S) to the Taitao Peninsula
222 in southern Chile (46°59'07"S). While, the potential breeding distribution of the pelican currently
223 attains an approximate area of 435,640 km². The mean daytime temperature range and marine
224 primary productivity explain the current potential distribution and breeding of the pelican, which
225 is an endemic species closely associated with the oceanographic barriers of the Humboldt
226 Current Ecosystem (Jeyasingham et al., 2013; Kennedy et al., 2013). In South America, the
227 Humboldt Current encompasses the greater part of the Pacific coast. Despite the wide latitudinal
228 gradient, the marine–coastal area exhibits a mean daytime temperature range between 4°C and
229 8°C. This is consistent with the highest probability of occurrence of the pelican
230 (<https://climatologia.meteochile.gob.cl/application/>). In turn, marine productivity is the main
231 predictor of biodiversity and especially of the presence of top predators such as seabirds
232 (Wakefield, Phillips & Matthiopoulos, 2009). In the case of the pelican, there is an overlap
233 between areas with high summer marine primary productivity and areas with nesting sites.

234 Under the future climate change scenarios, the spatial distribution of the pelican is predicted to
235 slightly change. The pelican's breeding distribution might be facilitated by the moderate
236 scenario, increasing near 9 %. However, under the severe scenario, the prediction decreased to
237 near –20 %. This trend is similar to other studies described for seabirds, whose breeding
238 distribution will be reduced by climate change (Jenouvrier et al., 2014; Krüger et al., 2017). This
239 increase in habitable area is explained by the climatic conditions in southern Chile, and those
240 climatic conditions will likely be similar to the current conditions of the central coast of Chile
241 (Falvey & Garreaud, 2009; Garreaud, 2011). Over the last decade, an increase in pelican
242 abundance has been reported along the coast of southern Chile, with observations of large flocks
243 following schools of pelagic fishes in the inner sea (Imberti, 2005; Häusserman, Forsterra &
244 Plotnek, 2012; Cursach, Rau & Vilugrón, 2016; Cursach et al., 2018). In this area, there has even
245 been one report of an unsuccessful attempt to nest (Cursach, Rau & Vilugrón, 2016). The
246 occurrence of competitive interactions with other seabirds has also been observed with endemic
247 species from Patagonia (Cursach, Rau & Vilugrón, 2016). In southern Chile, a group of pelicans
248 was observed displacing nesting pairs of Imperial shag (*Phalacrocorax atriceps*), causing the
249 abandonment of the nest (Cursach, Rau & Vilugrón, 2016).

250 The present study is one of only a few evaluations of the potential effects of climate change on
251 seabirds on the Pacific coast of South America. To evaluate the different scenarios caused by
252 climate change on the spatial distribution of the pelican, we did not include oceanographic
253 variables. This is because the climatic variable “Mean daytime temperature range” was what
254 largely explained the potential spatial distribution and breeding of the pelican. However, further
255 studies are required to assess the effects of climate change on seabird populations, including

256 oceanographic variables. In addition, it is important to recognize that the species spatial
257 distribution models have methodological constraints, including operating based on climatic
258 variables without integrating ecological interactions (Soberón, Osorio-Olvera & Peterson, 2017).
259 The co-occurrence of fishing exploitation and El Niño events generates synergistic ecological
260 effects that may push the pelican to critical levels of abundance (Passuni et al., 2016; Barbraud et
261 al., 2018). In addition, the human disturbances on nesting sites are a key factor in the pelican
262 population dynamics (Coker, 1919; Figueroa & Stucchi, 2012). Future modeling analyses should
263 include field data about fishing, aquaculture, ENSO events, and human disturbances in nesting
264 sites of the pelican.

265 In conclusion, the current potential geographic distribution of the pelican is influenced to a large
266 extent by thermal conditions and primary productivity. Under the future climate change
267 scenarios, the spatial distribution of the pelican is predicted to slightly change. While the range
268 of breeding distribution of the pelican will be decrease by main cause of climate change. Under a
269 moderate scenario, we predict that the coasts of southern Chile will constitute an important
270 refuge for the conservation of the pelican. It is necessary that future investigations evaluate in
271 detail the ecological interactions of the pelican and its population increase in southern Chile,
272 considering the different dimensions of the local socio-ecological system.
