Among amniotes, numerous lineages are subject to a convergent evolutionary trend towards body mass and size increases. Terrestrial large species may face important constraints linked to weight bearing, and the limb segments are particularly affected by such constraints, because of their role in body support and locomotion. Such groups showing important limb modifications related to body mass have been called "graviportal". Often considered graviportal, rhinos are among the heaviest terrestrial mammals and are thus of particular interest to understand the limb modifications related to body mass and size increase. Here, we propose a morphofunctional study of the shape variation of the limb long bones among the five living rhinos to understand how the shape may vary between these species in relation with body size, body mass and phylogeny. We used 3D geometric morphometrics and comparative analyses to quantify the shape variation. Our results indicate that the five species display important morphological differences pending on the considered bones. The humerus and the femur exhibit noticeable interspecific differences between African and Asiatic rhinos, associated to an important impact of the body mass. The radius and ulna are more strongly correlated with body mass. While the tibia exhibits shape variation both linked with phylogeny and body mass, the fibula displays the maximal intraspecific variation, questioning its functional role and the origin of these morphological changes. We highlight three distinct morphotypes on bone shape, which appear in accordance with the phylogeny. The influence of body mass also appears unequally expressed on the different bones. Body mass increase among the five extant species is marked by an increase of the general robustness, a reinforcement of the main lever arms for muscles, and a development of medial parts of the bones. Our study indicates that the bone morphology is affected differently by body mass and size increases pending on the considered bones and species. It also underlines that the morphological features linked to body mass increase are not similar between rhinos and other heavy

mammals such as elephants and hippos, suggesting that the weight bearing constraint can lead to different morphological responses.

Abstract

Among amniotes, numerous lineages are subject to a convergent evolutionary trend towards body mass and size increases. Terrestrial large species may face important constraints linked to weight bearing, and the limb segments are particularly affected by such constraints, because of their role in body support and locomotion. Such groups showing important limb modifications related to body mass have been called "graviportal". Often considered graviportal, rhinos are among the heaviest terrestrial mammals and are thus of particular interest to understand the limb modifications related to body mass and size increase. Here, we propose a morphofunctional study of the shape variation of the limb long bones among the five living rhinos to understand how the shape may vary between these species in relation with body size, body mass and phylogeny. We used 3D geometric morphometrics and comparative analyses to quantify the shape variation. Our results indicate that the five species display important morphological differences pending on the considered bones. The humerus and the femur exhibit noticeable interspecific differences between African and Asiatic rhinos, associated to an important impact of the body mass. The radius and ulna are more strongly correlated with body mass. While the tibia exhibits shape variation both linked with phylogeny and body mass, the fibula displays the maximal intraspecific variation, questioning its functional role and the origin of these morphological changes. We highlight three distinct morphotypes on bone shape, which appear in accordance with the phylogeny. The influence of body mass also appears unequally expressed on the different bones. Body mass increase among the five extant species is marked by an increase of the general robustness, a reinforcement of the main lever arms for muscles, and a development of medial parts of the bones. Our study indicates that the bone morphology is affected differently by body mass and size increases pending on the considered bones and species. It also underlines that the morphological features linked to body mass increase are not similar between rhinos and other heavy mammals such as elephants and hippos, suggesting that the weight bearing constraint can lead to different morphological responses.

44

Introduction

45

46 Many vertebrate lineages present a convergent evolutionary trend towards a body mass increase

47 through time (Depéret, 1907; Raia et al., 2012; Baker et al., 2015; Bokma et al., 2016). Size and

48 mass augmentation implies metabolic and musculoskeletal modifications for the whole body to

49 bear its own weight (McMahon, 1973). One of the most noticeable body changes related to

50 weight bearing concern modifications of the appendicular skeleton; animals displaying such

51 adaptive traits are said to be "graviportal" (Hildebrand, 1974). This concept introduced by

52 Gregory (1912) and Osborn (1929) has been defined based on both anatomical and locomotion

53 aspects: the commonly accepted criteria are, in addition to a body mass of several hundreds of

54 kilograms, columnar limbs with a stylopodium lengthening and an autopodium shortening,

55 robust bones, large feet with enlarged adipose cushions, reduced phalanges, long strides

56 associated with the inability to gallop (Gregory, 1912; Osborn, 1929; Coombs, 1978). This

57 condition was opposed to the "cursorial" one characterizing light and running animals (e.g.

58 horses and many ungulates). Between these two extremes, intermediate categories tended to

59 sharpen this tentative locomotor classification, with "subcursorial" for moderate cursorial

60 adaptations with good running performances (e.g. felids and canids), and "mediportal" for

61 animals with conformations meeting both the weight bearing aspect and running capacities (e.g.

62 suids, tapirs) (Gregory, 1912; Coombs, 1978; Eisenmann & Guérin, 1984). These categories

63 remain massively used in functional morphology and locomotion studies (e.g. Maynard Smith &

64 Savage, 1956; Coombs, 1978; Eisenmann & Guérin, 1984; Prothero et al., 1986; Biewener,

65 1989a; Stein & Casinos, 1997; Polly, 2007; Scherler et al., 2013; MacLaren & Nauwelaerts,

66 2016). Hildebrand (1974) proposed an arbitrary body mass of 900 kg beyond which the species

67 is considered as graviportal, but without justification for this threshold. Carrano (1999) tackled

68 this problem by replacing these discrete categories by a multivariate continuum of locomotor

69 habits ranging from graviportal to cursorial based on bone and muscular insertion measurements,

70 chosen to be "biomechanically relevant" but performed only on the femur, tibia and third

71 metatarsal.

72 As a consequence, the categorization of some taxa as graviportal may vary depending on authors.

73 Among living mammals, elephants, rhinos and hippos are commonly considered as the three

74 main graviportal taxa (Alexander & Pond, 1992). Elephants obviously fulfil all the

75 morphological and biomechanical criteria defining graviportality (Coombs, 1978; Langman et

76 al., 1995). However, hippo's peculiar morphology (barrel-like body and shortened limbs) linked

77 to semi-aquatic habits has been considered alternately as mediportal (Coombs, 1978; Ross, 1984)

78 or graviportal (Alexander & Pond, 1992; Carrano, 1999; MacFadden, 2005; Stilson, Hopkins &

79 Davis, 2016). Rhino's graviportal condition is surely the less consensual: Gregory (1912) and

80 Osborn (1929) considered rhinos as mediportal whereas later works assigned them a graviportal

81 condition (Prothero and Sereno, 1982; Eisenmann and Guérin, 1984). Becker (2003) and Becker

82 et al. (2009) dug onto this question and developed a "gracility index" based on the work of

83 Guérin (1980) to categorize modern and fossil rhinos, but only based on third metacarpal and

84 metatarsal proportions. The use of this index sharpened the classification of modern rhinos

85 distinguishing mediportal and graviportal forms (Table 1).

86 Regardless of the locomotor type to which they belong, the family Rhinocerotidae includes ones

87 of the heaviest land mammal species after elephants, displaying adaptations to sustain their high

88 body mass (Alexander & Pond, 1992). The five remaining modern rhino species exhibit an

89 important variation in body mass and size (Table 1), ranging from less than a ton for

90 *Dicerorhinus sumatrensis* to more than 3 tons for the biggest known specimens of *Ceratotherium*

91 *simum*. They are all good walkers and runners, able to gallop and reach a max speed of 55 km/h

92 (Dinerstein, 2011). However, important ecological differences also exist (Groves, 1967a,b, 1972;

93 Groves & Kurt, 1972; Laurie, Lang & Groves, 1983; Hillman-Smith & Groves, 1994; Dinerstein,

94 2011; Groves & Leslie, 2011): the three Asiatic rhinos are excellent swimmers and very familiar

95 with a water environment whereas the two African ones are easily stopped by a relatively deep

96 river. While *Ceratotherium simum* is a pure grazer, *Rhinoceros unicornis* can both graze and

97 browse small shrubs, leafy material and fruits, the three other species being mainly leaf

98 browsers. Before the drastic decrease of their natural habitats under human pressure, rhinos

99 occupied a wide geographic range across Africa and Asia (Dinerstein, 2011; Rookmaaker &

100 Antoine, 2013). Moreover, the fossil record of the superfamily Rhinocerotoidea contains many

101 lineages displaying evolutionary convergence towards an increase of body mass (Prothero &

102 Schoch, 1989; Prothero, 1998; Antoine, 2002; Becker, 2003; Scherler et al., 2013). However,

103 despite the importance of rhino species to understand evolution towards high body mass and the

104 fact that they are ones of the heaviest surviving land mammals, only a few studies really

105 explored the variation of their limb bone morphology in relation to their body proportions. After

106   the pioneering works of Cuvier (1812) and de Blainville & Nicard (1839) describing the

107   postcranial anatomy of modern rhinos, almost no work tried to broadly analyse and compare the

108   morphology of their limb bones. Guérin (1980) proposed a substantial comparative anatomy

109   work on the whole skeleton of the five extant species. This study aimed to emphasize

110   determination criteria with a direct application to fossil forms. Despite considerations on inter-

111   and intraspecific osteological variations on modern rhinos, this work did not fully explore the

112   patterns of shape variation in this group. Furthermore, most of the previous studies used a classic

113   morphometric approach with linear measurements on bones, an approach which cannot precisely

114   take into consideration the whole shape of the bone in 3D. To our knowledge, no

115   morphofunctional analyses have been carried out on limb long bones of modern rhinos taking

116   into consideration their whole shape.

117   Here we propose to explore the variation in the shape of the limb long bones among the five

118   modern rhino species using a 3D geometric morphometrics approach. We describe interspecific

119   patterns of morphological variation for the six bones composing the stylopodium and the

120   zeugopodium, taking into account the intraspecific variation. We also explore the potential links

121   of shape patterns with body size and phylogenetic relations between species.

Material and Methods

Sample

124   We selected 62 dry skeletons in different European museums belonging to the five extant rhino

125   species: *Ceratotherium simum* Burchell, 1817; *Dicerorhinus sumatrensis* Fischer, 1814; *Diceros*

126   *bicornis* Linnaeus, 1758; *Rhinoceros sondaicus* Desmarest, 1822 and *Rhinoceros unicornis*

127   Linnaeus, 1758 (Table 2). We followed the taxonomic attribution given by each institution for

128   most of the specimens, except for three individuals determined or reattributed by ourselves on

129   osteological criteria and later confirmed by our morphometric analysis (see Table 2). As some

130   skeletons were incomplete, we studied altogether 53 humeri, 49 radii, 46 ulnae, 56 femora, 52

131   tibiae and 50 fibulae. We kept only mature specimens with fully fused epiphyses (adults) or

132   displaying a majority of fused epiphyses (subadults). Bones showing breakages or unnatural

133   deformations were not considered in our analysis. In accordance with the observations of Guérin

134   (1980), we did not notice any major difference between captive and wild animals, neither

135 through visual and osteological observations nor in our morphometric analyses: we therefore did

136 not take into account this parameter. Sexual dimorphism occurs among rhinos but has been

137 mostly investigated regarding the external morphology of the animals (Dinerstein, 1991, 2011;

138 Berger, 1994; Zschokke & Baur, 2002). The few studies that have explored the osteological

139 variations between sexes indicated only slight absolute metric divergences depending on species

140 (Guérin, 1980; Groves, 1982). This suggests that intraspecific variation due to sex may be

141 marginal when compared to interspecific variation, and probably more related to the size of the

142 bone than to the shape. Furthermore, since almost half of our sample lacked sex information and

143 that we had twice more males than females, we could not carefully address gender in our study

144 (see Results).

145 **3D models**

146 Bones were mostly digitized with a structured-light three-dimensional scanner (Artec Eva) and

147 reconstructed with the Artec Studio Professional software (v12.1.1.12 – Artec 3D, 2018).

148 Complementarily, 19 bones were digitized with a photogrammetric approach, following Mallison

149 & Wings (2014) and Fau, Cornette & Houssaye (2016). Sets of photos were taken all around the

150 bones and aligned to reconstruct a 3D model with the Agisoft Photoscan software (v1.4.2 –

151 Agisoft, 2018). Previous studies indicated no significant difference between 3D models obtained

152 with these two methods (Petti et al., 2008; Remondino et al., 2010; Fau, Cornette & Houssaye,

153 2016). Five bones were digitized using medical computed tomography scanners at the Royal

154 Veterinary College, London (Equine Hospital) and at the University of California, San Francisco

155 (Department of Radiology & Biomedical Imaging). Bone surfaces were extracted as meshes

156 using the Avizo software (v9.5.0 – Thermo Fisher Scientific, 2018). Each mesh was decimated to

157 reach 250,000 vertices and 500,000 faces using MeshLab (v2016.12 - Cignoni et al., 2008). We

158 mainly selected left bones during acquisition: when this was impossible, right bones were

159 selected and then mirrored before analysis.

160 **Anatomical terminology**

161 All anatomical terms used to describe bones were borrowed to classic references: the *Nomina*

162 *Anatomica Veterinaria* (World Association of Veterinary Anatomists & International Committee

163 on Veterinary Gross Anatomical Nomenclature, 2005) and anglicized terms of Barone (2010a)

164 for general osteology and bone orientation, Guérin (1980) for precise rhino anatomy, completed

165 by the contributions of Colyn (1980), Antoine (2002) and Heissig (2012). Despite these previous

166 works, one anatomical feature remained unnamed, leading us to use our own designation: we

167 called "palmar process" the process facing the coronoid process on the palmar border of the

168 radius proximal epiphysis. Muscle insertions were described after the general anatomy of horses

169 (Barone, 2010b), completed by the work of Beddard & Treves (1889) and some complementary

170 information from Guérin (1980) on rhino myology and Fisher, Scott & Naples (2007) and Fisher,

171 Scott & Adrian (2010) on hippo's.

172 **Geometric Morphometrics**

173 To analyse shape variation in our sample, we performed 3D geometric morphometrics, a widely

174 used approach allowing to quantify morphological differences between objects using landmark

175 coordinates (Adams, Rohlf & Slice, 2004; Zelditch et al., 2012).

176   **Landmark digitization**

177 Following the procedure described by Gunz, Mitteroecker & Bookstein (2005), Gunz &

178 Mitteroecker (2013) and Botton-Divet et al. (2016), we defined the bones' shape using

179 anatomical landmarks and curve and surface sliding semi-landmarks. Each curve is bordered by

180 anatomical landmarks as recommended by Gunz & Mitteroecker (2013). We placed all

181 landmarks and curves using the IDAV Landmark software (v3.0 – Wiley et al., 2005). We used

182 35 anatomical landmarks on the humerus, 23 on the radius, 21 on the ulna, 27 on the femur, 24

183 on the tibia and 12 on the fibula. Details of landmark numbers and locations used for each bone

184 are given in Supplemental Data S1.

185 Following the procedure detailed by Botton-Divet et al. (2016), we created a template to place

186 surface semi-landmarks for each bone: a specimen was randomly chosen on which all anatomical

187 landmarks, curve and surface sliding semi-landmarks were placed. We then used this template

188 for the projection of surface sliding semi-landmarks on the surface of the other specimens.

189 Projection was followed by a relaxation step to ensure that projected points matched the actual

190 surface of the meshes. Curve and surface sliding semi-landmarks were then slid to minimize the

191 bending energy of a Thin Plate Sline between each specimen and the template at first, and then

192 two times between the result of the preceding step and the Procrustes consensus of the complete

193   dataset. Therefore, all landmarks can be treated at the end as anatomical landmarks and analysed

194   with classic procedure as Procustes Analysis (see below). Projection, relaxation and sliding

195   processes were conducted using the Morpho package in the R environment (R Core Team,

196   2014). Details of the process are provided in the documentation of the package (Schlager, 2018).

197   **Repeatability tests**

198   For each bone, we tested the repeatability of the anatomical landmark digitization taking

199   measurements ten times on three specimens of the same species, *Ceratotherium simum*, chosen

200   to display the closest morphology and size. We superimposed these measurements using a

201   Generalized Procrustes Analysis and visualized the results using a Principal Component Analysis

202   (PCA). Results showed a variation within specimens clearly smaller than the variation between

203   specimens (see Supplemental Fig. S2) and allowed us to consider our anatomical landmarks as

204   relevant to describe shape variation.

205   **Generalized Procrustes Analyses**

206   After the sliding step, we performed Generalized Procrustes Analyses (GPA) (Gower, 1975;

207   Rohlf & Slice, 1990) to remove the effects of size and of the relative position of the points and to

208   isolate only the shape information. As our dataset contained more variables than observations,

209   we used a Principal Component Analysis (PCA) to reduce dimensionality as preconized by Gunz

210   & Mitteroecker (2013) and visualize the specimen repartition in the morphospace. We computed

211   theoretical consensus shape of our sample and used it to calculate a TPS deformation of the

212   template mesh. We then used this newly created consensus mesh to compute theoretical shapes

213   associated with the maximum and minimum of both sides of each PCA, as well as mean shapes

214   of each bone for each species. GPA, PCA and shape computations were done using the

215   "Morpho" and "geomorph" packages (Adams & Otárola-Castillo, 2013; Adams, Collyer &

216   Kaliontzopoulou, 2018; Schlager, 2018) in the R environment (R Core Team, 2014). Neighbour

217   Joining method was used to construct trees displaying relative Euclidian distances between

218   individuals based on all principal component scores obtained with the PCA, allowing a global

219   visualisation of the relationships between all the specimens. Trees were computed with the "ape"

220   package (Paradis et al., 2018).

221 **Allometry effect**

222 We tested the effect of allometry, defined as "the size-related changes of morphological traits"

223 (Klingenberg, 2016). Pearson's correlation tests were performed to look for correlation between

224 the principal components and the centroid size ($\log_{10}$) for each bone. We also used the function

225 *procD.allometry* of the "geomorph" package to perform a Procrustes ANOVA (a linear

226 regression model using Procrustes distances between species instead of covariance matrices – see

227 Goodall, 1991) to quantify the shape variation related to the centroid size, and to visualize

228 theoretical shapes associated to minimal and maximal sizes of our sample (Adams &

229 Otárola-Castillo, 2013; Adams, Collyer & Kaliontzopoulou, 2018). This test was performed

230 taking into account group affiliation (e.g. species) to highlight respective roles of centroid size

231 and species determination on the shape variation. In the absence of individual body mass for the

232 majority of our sample, we also performed a Procrustes ANOVA with the cube root of the mean

233 mass attributed to each species (Table 1), each species being associated to the mean mass of its

234 species. As for the centroid size, theoretical shapes associated to minimal and maximal mean

235 mass were computed. Plots of the linear regressions of shape scores against log-transformed

236 centroid size were also computed.

Results

237

Shape analysis

238

239 We describe here the results of our PCA for each bone and focus on the theoretical shape

240 variations along the two main axes. For each bone, we chose to represent relevant views and

241 anatomical features. Complete visualizations of the different theoretical shapes for the two first

242 axes are available in Supplemental Data S3. Analysis of shape relations among our sample is

243 completed by the Neighbour Joining trees provided in Supplemental Figure S4.

244 **Humerus**

245 The first two axes of the PCA computed on the humerus represent 60.6% of the total variance

246 (Fig. 1A). The first axis represents more than half of the global variance (53%) and the five

247 species appear clearly sorted along it, opposing *D. sumatrensis* on the positive side to *C. simum*

248   on the negative one, i.e. the lightest and heaviest species, respectively. *D. bicornis* is grouped

249   with *C. simum* on the negative part of the axis, whereas *R. sondaicus* is on the positive part. *R.*

250   *unicornis* occupies the centre of the axis, between *D. bicornis* and *R. sondaicus*. Points

251   repartition in the morphospace and Neighbour Joining trees indicate a clear separation between

252   African and Asiatic rhinos (Fig. S4A). The theoretical shape at the PC1 minimum (Fig. 1B, D, F,

253   H) displays a massive morphology, with broad both medio-laterally and cranio-caudally

254   epiphyses and shaft; a wide humeral head, very little overhanging the diaphysis in the caudal

255   direction; a lesser tubercle paradoxically more strongly developed than the greater tubercle, with

256   an intermediate tubercle separating a widely open bicipital groove into unequal parts, the lateral

257   one being the largest; a lesser tubercle convexity medially extended whereas the greater tubercle

258   one is quite reduced in this direction; a broad and diamond-shaped *m. infraspinatus* imprint on

259   the lateral side; a broad deltoid tuberosity not extending beyond the lateral border of the bone; a

260   shaft with its maximal width situated between the head neck and the deltoid tuberosity; a distinct

261   but very smooth and flat *m. teres major* tuberosity; a distal epiphysis very large because of the

262   development of the lateral epicondyle; a smooth epicondylar crest; a medial epicondyle medio-

263   laterally wide and cranio-caudally compressed; shallow and proximo-distally compressed

264   olecranon fossa and trochlea, a wide trochlea displaying a main axis tilted in the dorso-ventral

265   direction; a capitulum with a small surface area. At the opposite, the theoretical shape at the PC1

266   maximum (Fig. 1C, E, G, I) shows a slender and thin aspect; a more rounded humeral head

267   overhanging caudally the diaphysis; a greater tubercle more strongly developed than the lesser

268   one and extending medially, conferring a more closed aspect to the bicipital groove, where the

269   intermediate tubercle is almost absent; a slightly marked lesser tubercle convexity whereas the

270   greater tubercle one is massive; a rounded and reduced *m. infraspinatus* insertion; a deltoid

271   tuberosity strongly protruding laterally; a straight and thin shaft; no visible *m. teres major*

272   tuberosity; a narrow distal epiphysis, with a small development of the lateral epicondyle; a sharp

273   epicondylar crest; ; a medial epicondyle cranio-caudally developed and overhanging the

274   olecranon fossa; a deep and wide olecranon fossa; a far less compressed trochlea, with an axis

275   less dorso-ventrally tilted; and an almost completely absent capitulum.

276   Along the second axis (7.6%), we observe this time that *C. simum* and *D. sumatrensis* are

277   grouped together on the negative part of the axis, with the three other species on the positive

278   part, whereas they are opposed along the first axis. This second axis expresses the separation

279   between the lightest and the heaviest rhino species on the one hand and the three other species on

280   the other hand. The theoretical shape at the PC2 minimum displays a humeral head stretched in

281   the caudal direction; a lesser tubercle more developed than the greater one, delimiting a W-

282   shaped bicipital groove; a distal epiphysis proximo-distally extended, with an epicondylar crest

283   starting almost on the middle of the shaft; a rounded and wide olecranon fossa. At the opposite,

284   the theoretical shape at the PC2 maximum shows a rounded humeral head; a strong development

285   of both tubercles and a more closed bicipital groove; a distal epiphysis medio-laterally stretched,

286   with the epicondylar crest starting at the distal third of the shaft; an olecranon fossa proximo-

287   distally compressed and more rectangular; and a well-developed lateral epicondyle.

288   **Radius**

289   The first two axes of the PCA performed on the radius express 52.3% of the total variance (Fig.

290   2A). The first axis (36.4%) opposes *D. sumatrensis* and *D. bicornis* to *R. unicornis* and *C.*

291   *simum*. *R. sondaicus* overlaps both *R. unicornis* and *D. bicornis* clusters. Point dispersion along

292   this axis indicates an important intraspecific variation for *D. sumatrensis*, and to a lesser extent

293   for *D. bicornis* and *R. sondaicus*. Unlike for the humerus, phylogenetically related species are

294   not grouped together on PCA and Neighbour Joining trees (Fig. S4B). The theoretical shape at

295   the PC1 minimum (Fig. 2B, D, F, H) displays a massive morphology with large shaft and

296   epiphyses; an asymmetrical proximal articular surface (constituting the ulnar notch), with a

297   medial portion twice as large as the lateral one; a protruding lateral insertion relief whereas the

298   radial tuberosity is little prominent; a lateral synovial articulation surface for the ulna medio-

299   laterally reduced; a rectangular and thin medial synovial articulation surface for the ulna; a

300   triangular proximal articular surface for the ulna as wide medio-laterally as proximo-distally; a

301   thick shaft with an interosseous space opening close to the proximal epiphysis: consequently, the

302   interosseous crest runs along the diaphysis to the distal articular surface for the ulna; a broad

303   distal epiphysis in the medio-lateral direction, with a strong medial tubercle developed on the

304   dorsal face; a distal articular surface compressed in the dorso-ventral direction; an articular

305   surface for the scaphoid little extended proximally; a trapezoid and wide articular surface for the

306   semilunar; a well-developed radial styloid process. The theoretical shape at the PC1 maximum

307   (Fig. 2C, E, G, I) displays a more slender morphology; a proximal articular surface less

308   asymmetrical despite the development of the medial part; an almost absent lateral insertion

309   relief; a completely flat radial tuberosity; a lateral synovial articulation for the ulna medio-
310   laterally stretched; a rectangular and thin medial synovial articulation for the ulna; a triangular
311   proximal articular surface for the ulna, medio-laterally short and proximo-distally stretched; a
312   thin and slender shaft, with an interosseous space opening at the proximal third of the total
313   length; a poorly visible interosseous crest; a distal epiphysis far less dorso-ventrally compressed
314   and a lateral tubercle on the dorsal side poorly developed; a distal articular surface dorso-
315   ventrally wide with the surface responding to the scaphoid extending proximally; a trapezoid and
316   reduced articular surface for the semilunar; a less developed radial styloid process with a
317   rounded border.

318   The second axis (15.9%) discriminates mainly *R. sondaicus* from the four other species. *R.*
319   *unicornis* displays little extension along this axis; neither does *D. bicornis*, only driven on the
320   negative side by a single individual. *R. unicornis*'s extension along the second axis is very
321   limited, contrary to *C. simum*'s and *D. sumatrensis*'s. The theoretical shape at the PC2 minimum
322   displays a slender morphology, with a strongly asymmetrical proximal articular surface; a palmar
323   process opposed to the coronoid process proximally reduced; a distal epiphysis dorso-ventrally
324   broad, with a developed lateral prominence; a little developed radial styloid process; an articular
325   surface for the scaphoid proximally extended. The theoretical shape at PC2 maximum displays a
326   more massive shape; a deeper and more symmetrical proximal articular surface with a well-
327   developed palmar process; a dorso-ventrally compressed distal epiphysis with a more developed
328   styloid process.

329   **Ulna**

330   The first two axes of the PCA performed on the ulna express 41.5% of the total variance (Fig.
331   3A). The first axis (22.1%) separates *D. sumatrensis* and *D. bicornis* on the positive part and *R.*
332   *sondaicus*, *R. unicornis* and *C. simum* on the negative part. However, *C. simum*'s and *R.*
333   *unicornis*'s clusters overlap along this axis. The general pattern on both PCA and Neighbour
334   Joining trees is close to the one observed for the radius (Fig. S4C). The theoretical shape at the
335   PC1 minimum (Fig. 3B, D, F, H) displays a thick morphology with large epiphyses; a massive
336   olecranon tuberosity with a medial tubercle – where inserts the medial head of the *m. triceps*
337   *brachii* – oriented dorsally; an anconeus process poorly developed dorsally and medio-laterally
338   wide, as is the articular surface constituting the trochlear notch (receiving the humeral trochlea);

339   a medially stretched medial part of the articular surface for the humerus; a short interosseous

340   crest ending at the shaft half, with the interosseous space; a broad shaft with a triangular section;

341   a straight palmar border whereas the shaft is medially curved; a massive distal epiphysis with a

342   wide insertion surface for the radius; an articular surface for the triquetrum medio-laterally wide

343   and little concave, while the one responding to the pisiform is crescent-shaped and little extended

344   proximally. The theoretical shape for the PC1 maximum (Fig. 3C, E, G, I) displays a more

345   gracile morphology; a slender olecranon tuberosity with a medial tubercle where inserts the

346   medial head of the *m. triceps brachii* oriented in the palmar direction; an anconeus process

347   dorsally developed and medio-laterally narrow, as is the articular surface of the trochlear notch; a

348   slightly medially stretched medial part of the articular surface; a sharp interosseous crest; a thin

349   and straight shaft; a distal epiphysis medio-laterally compressed and little concave; an articular

350   surface for the triquetrum medio-laterally narrow; a triangular and proximally well-developed

351   articular surface for the pisiform.

352   The second axis (19.4%) separates quite clearly the three Asian species from the African ones.

353   The theoretical shape at the PC2 minimum displays a slender and straight morphology with a

354   high square-shaped olecranon process, medio-laterally flattened, more stretched in the palmar

355   direction; a wide and squared anconeus process; a straight and regular shaft; a distal epiphysis

356   medio-laterally compressed with a concave articular surface for the triquetrum and a distally

357   developed styloid process; a proximally extended articular facet for the pisiform. The theoretical

358   shape at the PC2 maximum displays a more massive and medially concave shape with an

359   olecranon process medio-laterally inflated and rounded in the palmar direction; an anconeus

360   process little developed dorsally and laterally tilted; an articular surface constituting the trochlear

361   notch proximo-distally compressed and extending medially; a medio-laterally wide articular

362   surface for the triquetrum; a little developed styloid process; an articular surface for the pisiform

363   poorly extended proximally and square-shaped.

364   **Femur**

365   The first two axes of the PCA performed on the femur express 45.0% of the global variance (Fig.

366   4A). The first principal component (36.1%) clearly separates the heaviest and lightest rhino

367   species, with *D. sumatrensis* on the positive part and *C. simum* on the negative part. *D.*

368   *bicornis*'s, *R. sondaicus*'s and *R. unicornis*'s clusters overlap on the negative part of the axis. *D.*

369 *bicornis* and *R. unicornis* specimens partly overlap *C. simum* cluster too. The isolation of *D.*
370 *sumatrensis* drives the clusters organization along the first axis. The general pattern observed on
371 the Neighbour Joining tree is closer to the humerus one, with African and Asiatic species
372 grouped together, respectively (Fig. S4D). The theoretical shape at the PC1 minimum (Fig. 4B,
373 D, F, H) displays a massive morphology with large epiphyses and a curved medial border,
374 conferring a concave aspect to the diaphysis axis; a large femoral head, off-centred relatively to
375 the shaft main axis, supported by a very large neck; a small and shallow *fovea capitis* oriented
376 medio-caudally; a greater trochanter convexity expending strongly latero-distally; the absence of
377 trochanteric notch between the convexity and the top of the trochanter (Fig. 4F); a proximo-
378 distally reduced trochanteric fossa; a sharp lesser trochanter running along the medial edge,
379 which is cranio-caudally flattened below the humeral head; a third trochanter extending strongly
380 laterally, cranially and proximally towards the greater trochanter convexity, and much curved
381 towards the medial direction; a quite irregular shaft section along the bone – flattened below the
382 proximal epiphysis and more trapezoid towards the distal epiphysis; a broad distal epiphysis with
383 developed medial and lateral epicondyles; a shallow supracondylar fossa; a wide trochlea, with a
384 main rotation axis aligned with the shaft axis; a large and cranially expended medial lip of the
385 trochlea separated from the lateral one by a deep trochlear groove; a medial condyle surface area
386 larger than the lateral condyle one, both being separated by a narrow intercondylar space. At the
387 opposite, the theoretical shape at the PC1 maximum (Fig. 4C, E, G, I) is more slender with a
388 straight and regular shaft; a rounded femoral head aligned with the shaft main axis and supported
389 by at thinner neck; a more pronounced and rounded *fovea capitis* oriented almost completely
390 caudally; a greater trochanter convexity little developed latero-distally; a more pronounced
391 trochanter top despite the absence of trochanteric notch; a thin lesser trochanter situated on the
392 caudal border of the medial side; a rounded third trochanter more developed laterally than
393 cranially; a quite regular and trapezoid shaft section; a distal epiphysis medio-laterally broader
394 and oriented medially; an almost absent supracondylar fossa; a less developed trochlear medial
395 lip separated from the lateral one by a shallow trochlear groove; a lateral condyle more oblique
396 and divergent relatively to the medial one, increasing the intercondylar space; symmetrical
397 medial and lateral condylar surfaces.

398 The second axis (8.9%) clearly opposes *D. sumatrensis*, *C. simum* and *D. bicornis* on the positive
399 part to the two *Rhinoceros* species on the negative part, *D. sumatrensis*'s cluster being driven

400 towards negative values by a single individual. The theoretical shape at the PC2 minimum is

401 mainly characterized by a flattened femoral head with a strong neck; a rounded and large *fovea*

402 *capitis* oriented medio-caudally; a greater trochanter convexity latero-distally expended; a long

403 and thin lesser trochanter; an extremely developed third trochanter in lateral, cranial and

404 proximal directions; a straight and regular shaft; a broad distal epiphysis with important

405 development of both epicondyles; a trochlea rotation axis aligned with the main axis of the shaft.

406 The theoretical shape at the PC2 maximum displays a more rounded head, with a more stretched

407 neck; no *fovea capitis* at all but a little groove on the head border; a greater trochanter convexity

408 little expanded latero-distally; a short and more medially developed lesser trochanter; a rounded

409 third trochanter little developed in cranial and proximal directions; a straight shaft; a distal

410 epiphysis less medio-laterally broad; a narrower intercondylar space; a more inflated medial

411 condyle.

412 **Tibia**

413 The first two axes of the PCA performed on the tibia express 50.0% of the global variance (Fig.

414 5A). The first axis (29.1%) separates roughly *D. bicornis* and *D. sumatrensis* on the positive part

415 and *C. simum, R. sondaicus* and *R. unicornis* on the negative part. *D. bicornis* and shows an

416 important intraspecific variation along both axes. Neighbour Joining tree structure is less clear

417 than for previous bones: both *Rhinoceros* species isolate from most of the other specimens, *C.*

418 *simum* appears also separated from *D. bicornis* and *D. sumatrensis*. However, one *C. simum* and

419 three *D. sumatrensis* specimens are closer from the *Rhinoceros* group than from their own

420 respective species (Fig. S4E). The theoretical shape at the PC1 minimum (Fig. 5B, D, F, H)

421 displays a massive morphology with broad shaft and epiphyses, both in cranio-caudal and medio-

422 lateral directions; medial and lateral intercondylar tubercles having the same height and a

423 reduced central intercondylar area; a broad cranial intercondylar area; a medial articular surface

424 larger than the lateral one, with the sliding surface for the *m. popliteus* tendon extending

425 caudally; a U-shaped popliteal notch; a rounded tibial tuberosity, laterally deflected and medially

426 bordered by a shallow groove; a shallow extensor groove; a regularly triangular proximal

427 articular surface for the fibula extending distally; a thick tibial crest disappearing at the middle of

428 the shaft, where the bone section is the smallest; a distal epiphysis medio-laterally broad and

429 rectangular in section; a distal articular surface for the fibula reduced in height and triangular-

430   shaped, surmounted by a smooth interosseous crest running towards the middle of the shaft; a

431   distal articular surface for the talus roughly rectangular, with a lateral groove larger and

432   shallower than the medial one, separated by a prominent intermediate process without synovial

433   fossa; an articular surface with a rotation axis aligned with the bone main axis; a prominent

434   medial malleolus. The theoretical shape at the PC1 maximum (Fig. 5C, E, G, I) displays a

435   slender morphology with a thin shaft; a lateral intercondylar tubercle more proximally extended

436   than the medial one and a relatively large central intercondylar area; a lateral condylar surface

437   extending cranially, reducing the cranial intercondylar area; medial and lateral articular roughly

438   equal surface areas; a V-shaped popliteal notch; a tibial tuberosity slightly more laterally

439   deflected; a deeper tuberosity groove; a nail-shaped proximal articular surface for the fibula; a

440   sharper tibial crest disappearing just before the first half of the shaft; a distal epiphysis more

441   compressed cranio-caudally; a distal articular surface for the fibula displaying a large triangle

442   synostosis area occupying a third of the shaft and prolonged by a sharp interosseous crest. There

443   is no major difference in the distal articular shape between PC1 maximum and minimum, except

444   that the caudal apophysis is less prominent in the distal direction.

445   The second axis (20.9%) clearly separates the two African species (*C. simum* and *D. bicornis*) on

446   the positive part from the three Asian species (*D. sumatrensis, R. sondaicus* and *R. unicornis*) on

447   the negative part. The theoretical shape at the PC2 minimum displays a slightly more slender

448   morphology; a proximal plateau higher cranially than caudally and forming a closer angle with

449   the diaphysis axis; a high intercondylar eminence; a lateral articular surface more caudally

450   extended than the medial one; a tibial tuberosity well separated from the condyles by deep

451   tuberosity and extensor grooves; a straight shaft ending with divergent borders forming a large

452   and rectangular distal epiphysis; a distal articular surface for the fibula forming a regular triangle

453   surmounted by a sharp interosseous crest; a medially extended medial malleolus, resulting in a

454   rectangular articular surface with the talus, where the medial groove is narrow and deep,

455   occupying a third of the area, whereas the lateral groove is shallow and broad. The theoretical

456   shape at the PC2 maximum displays a more massive morphology, with a cranio-caudal inflation

457   of the epiphyses; a proximal plateau almost perpendicular to the diaphysis axis; a lower

458   intercondylar eminence; a lateral condyle surface almost twice less large than the medial one,

459   which is more developed caudally; a massive tibial tuberosity strongly deviated laterally,

460   delimited by very shallow tuberosity and extensor grooves and resulting in a very large cranial

461   intercondylar area; a straight shaft ending with almost parallel medial and lateral borders and a

462   square-shaped distal epiphysis; a medial malleolus less medially deflated; a squared distal

463   articular surface for the talus with medial and lateral grooves showing similar surface area and

464   depth.

465   **Fibula**

466   The first two axes of the PCA performed on the fibula express 55.9% of the global variance (Fig.

467   6). Contrary to the five previous analyses, the first axis (40.7%) here seems particularly driven

468   by a strong intraspecific variation. *C. simum*'s and *D. sumatrensis*'s clusters are stretched along

469   the PC1 and overlap with almost every other specimens. *D. bicornis*'s cluster is quite stretched

470   along the axis too and only the two *Rhinoceros* species display less intraspecific variation. This

471   pattern does not seem linked to sex, age class or condition (wild or captive): despite the presence

472   of slightly more females and subadults on the negative part of the component, we did not

473   consider this observation as robust enough to state on this question. Consequently, we chose to

474   display and analyse the specimen repartition along the second and third components instead.

475   Theoretical shapes associated to the PC1 are available in Supplemental Data S3.

476   PC2 and PC3 express 22.9% of the global variance (Fig. 7A). The second component (15.2%)

477   opposes *C. simum* on the negative side to *D. sumatrensis* on the positive side, whereas *D.*

478   *bicornis*'s, *R. sondaicus*'s and *R. unicornis*'s clusters have a more central disposition. As for the

479   tibia, the Neighbour Joining tree structure appears less clearly sorted by species than for other

480   bones. If *Rhinoceros* species group together and African ones as well, *D. sumatrensis*'s sample is

481   split in two subgroups mixed with *R. unicornis* and African rhinos respectively (Fig. S4F). The

482   theoretical shape at the PC2 minimum (Fig. 7B, D, F, H, J) displays a broad morphology with

483   large epiphyses and a straight shaft; a rounded head with a proximal articular surface for the tibia

484   cranio-medially oriented; a head width similar to the shaft one; a robust shaft with two strong

485   cranio-lateral and caudo-lateral lines running down the distal epiphysis and enlarging cranio-

486   caudally towards the distal epiphysis; a sharp and irregular interosseous crest; a distal epiphysis

487   medio-laterally compressed with little development of the two distal tubercles at the end of the

488   lateral crests; a shallow lateral groove; a triangular distal articular surface for the tibia, occupying

489   only the last distal quarter of the bone length; a short and ovoid articular surface for the talus

490   with a sharp distal ridge. The theoretical shape at the PC2 maximum (Fig. 7C, E, G, I, K)

491 displays a slender morphology with a strongly curved shaft; a medio-laterally flat head extending

492 cranio-caudally and overhanging strongly the diaphysis; a thin shaft with two sharp lateral crests

493 running along it: these crests end with two developed tubercles surrounding a deep lateral

494 groove; a distal articular surface for the tibia extending from the distal third of the shape and

495 forming a stretched triangle; a wider and kidney-shaped articular surface for the talus, forming

496 two distal tips responding to the two lateral tubercles: between them on the distal face, a large

497 groove is visible, ending at the centre of the face.

498 The third component (7.7%) mainly opposes *D. bicornis* on the positive part to *R. sondaicus* on

499 the negative part. However, this opposition is mainly driven by a small number of individuals

500 (two for *D. bicornis* and four for *R. sondaicus*) and the majority of the other individuals overlap.

501 The theoretical shape at the PC3 minimum shows a massive morphology, with broad shaft and

502 epiphyses; a cranio-caudally broad head, overhanging the shaft laterally; a proximal articular

503 surface for the tibia oriented almost completely medially; a straight shaft displaying a constant

504 width along the bone; cranio-lateral and caudo-lateral crests running almost parallel towards the

505 distal end of the bone, forming two developed tubercles surrounding a deep groove; an

506 interosseous space covered by irregular reliefs and bordered by a sharp interosseous crest; a

507 distal articular surface for the tibia forming a triangle cranially deported; a kidney-shaped distal

508 articular surface for the talus, with a distal border separated from the lateral tubercles by a

509 groove stopping at the middle of the distal face. The theoretical shape at the PC3 maximum

510 shows an extremely thin morphology with a flattened and poorly developed head; a proximal

511 articular surface oriented almost completely in the cranial direction; a torsion of almost 90

512 degrees between the orientation of the proximal and distal articular surfaces for the tibia; a very

513 thin and flat shaft; cranio-lateral and caudo-lateral crests running along the diaphysis ending on

514 the distal epiphysis with few developed tubercles; a distal articular surface for the tibia forming a

515 slender triangle; a relatively small distal articular surface for the talus, with a less pronounced

516 kidney-shape; a groove on the distal face medio-laterally compressed.

517 **Interspecific morphological variation**

518 In addition to global interspecific patterns of shape, we shortly describe the main morphological

519 features characterizing each species. Mean shapes of each bone for the five species are available

520 in Supplemental Data S5.

521   Limb long bones of *C. simum* present a general massive and robust aspect. The humerus is thick

522   and shows a strong development of the lesser tubercle and the lateral epicondyle, as well as a

523   proximal broadening in the cranio-caudal direction. The radius and ulna are robust and display

524   an important medial development of the articular parts constituting the trochlear notch. The ulna

525   bears a strong olecranon tubercle. The distal articular surface for the carpals constituted by the

526   two bones is medio-laterally wide and compressed in the cranio-caudal direction. The hind limb

527   bones are robust as well, this robustness being mainly expressed in the medio-lateral direction

528   for the femur. This bone displays a rounded and thick head, strong greater and third trochanters,

529   and a distal trochlea laterally oriented. The tibia and fibula are robust as well, with a wide tibial

530   plateau supporting the knee articulation and a squared distal articulation for the talus.

531   For *D. bicornis*, the general aspect of the humerus is close to the one observed on *C. simum*,

532   particularly for the epiphyses (e.g. the shape of the bicipital groove, the development of the

533   lesser tubercle and of the lateral epicondyle), though its degree of robustness is less intense. The

534   radius is relatively slender but the proximal articular surface displays a cranial border with a

535   marked groove under the coronoid process, also observed on *C. simum*. The ulna is slender as

536   well with a thin olecranon process and limited medial development. Both distal epiphyses form a

537   medio-laterally wide articular surface for the carpals, poorly cranio-caudally compressed. As for

538   hind limb bones, the femur is only slightly robust, with poorly developed trochanters and a

539   slender diaphysis. Tibia and fibula are less thick too, with a squared articular surface for the talus

540   as well. *D. bicornis* displays noticeable morphological similarities with *C. simum*.

541   The bone general morphology is very similar between both *R. sondaicus* and *R. unicornis*, being

542   often more robust in *R. sondaicus*. For these two species, the humerus displays an important

543   development of both lesser and greater tubercles, resulting in an asymmetrical bicipital groove.

544   *R. sondaicus*'s greater tubercle is even sometimes higher than the lesser one, which is not the

545   case for *R. unicornis*. The distal epiphysis is wide but with a medial epicondyle less developed

546   than in *C. simum* and *D. bicornis*, and a rectangular olecranon fossa. The radius exhibits medio-

547   laterally large epiphyses and a quite robust diaphysis, with a proximal articular surface similar in

548   both *Rhinoceros* species, with a straight cranial border unlike in African rhinos. The distal

549   epiphysis is rectangular and cranio-caudally compressed. *R. unicornis* distinguishes from *R.*

550   *sondaicus* in having a more robust radius, with a more asymmetrical proximal epiphysis, a

551   deeper radial tuberosity and a larger distal articular surface. The ulna is also very similar, the one

552   of *R. unicornis* being slightly more robust. The general aspect remains extremely close, with a

553   developed olecranon, a medial development of the articular surface constituting the trochlear

554   notch and a quite wide distal articular surface. On the hind limb, the femur appears different, the

555   *R. unicornis*'s ones showing important development of the greater and third trochanters,

556   sometimes fused by a bony bridge as previously stated by Guérin (1980). The femur of *R.*

557   *sondaicus* appears slightly less robust, and the greater and third trochanters are less developed

558   and never fused. On the tibia, the proximal plateau is as wide as for the African taxa but the tibial

559   tuberosity is more detached from the condyles by deep tuberosity and extensor grooves. The

560   diaphysis is relatively thick and the distal articular surface is clearly rectangular. The fibula is

561   very similar as well in the two species, with a distal epiphysis curved in the caudal direction and

562   a kidney-shaped articular surface for the talus.

563   *D. sumatrensis* clearly differs from the other species. Despite clear rhinocerotid features, limb

564   long bones display unique morphological traits, with a more pronounced slenderness. On the

565   humerus, the development of the greater tubercle results in a more closed and asymmetrical

566   bicipital groove. The distal epiphysis is medio-laterally narrow with a straight trochlea axis. The

567   thin radius possesses a proximal articular surface almost symmetrical despite a medial glenoid

568   cavity slightly more developed. The ulna is thin as well, and forms with the radius a rectangular

569   articular surface for the carpals. The femur shows a high and rounded head and a poorly

570   developed third trochanter. The distal trochlea axis is more medially oriented. On the tibia, the

571   plateau is far less wide than in other species and the distal articular surface for the talus is

572   rectangular. The thin fibula displays a large head caudally bordered by a thin crest and the

573   diaphysis is strongly curved medially towards the tibia. The kidney-shape of the distal articular

574   surface for the talus resembles the *Rhinoceros* ones.

575   **Correlation with the centroid size**

576   Table 3 provides the results of the Pearson's correlation tests between the centroid size and the

577   two first principal components for each bone (and the third component for the fibula). There is a

578   significant correlation in each case between the first component and the centroid size, with

579   higher correlation coefficient values for the radius and ulna, and smaller values for the humerus

580   and fibula. The second principal component is also significantly correlated with the centroid size

581   for the humerus, femur and fibula, with smaller correlation coefficient values than for PC1,

582   except for the humerus.

583   **Allometry**

584   Table 4 and Table 5 provide the main anatomical differences observed between theoretical

585   shapes associated with minimal and maximal centroid size for the forelimb and hind limb bones

586   respectively. Theoretical shapes associated with minimal and maximal centroid size are provided

587   in Supplementary Figures S6. In the case of the fibula, we found a pattern very close to the one

588   observed along the second axis of the PCA. Replacing the log centroid size by the cube root of

589   the mean mass of each species results in almost identical theoretical shapes for each bone (Fig. 8

590   and Figure S7), only distinguishable by smooth details: towards body mass maximum, the radius

591   and ulna appear slightly more robust than for centroid size maximum (Fig. 8D, F); the greater

592   and third trochanters of the femur are slightly less developed towards each other (Fig. 8H).

593   Theoretical shapes associated to minimum and maximum of centroid size are slightly more

594   massive than the ones obtained with the body mass for the humerus, the tibia and the fibula. All

595   theoretical shapes associated with minimal and maximal mean mass are provided in

596   Supplementary Figures S7.

597   Table 6 and Table 7 provide the results of the two Procrustes ANOVAs performed on shape data,

598   where the centroid size and the cube root of the mean body mass were respectively the

599   independent variable. Centroid size is significantly correlated with shape for the six bones, with a

600   determination coefficient varying between 0.10 for the fibula and 0.18 for the ulna. In every

601   case, the correlation coefficient is higher for species than for centroid size, indicating a more

602   important influence of the group affiliation than of the allometry. This is especially the case for

603   the humerus, with a determination coefficient of 0.53 for the species affiliation and of only 0.13

604   for the centroid size. Mean body mass is also significantly correlated with shape for the six

605   bones, with slightly higher determination coefficient values than those obtained with the centroid

606   size. The humerus, the radius and the femur display the highest coefficients, between 0.33 and

607   0.26. These higher values may be due to the use of a same mean body mass for each rhino

608   species instead of individual mass. Group affiliation could not be used in this case because of the

609   mean body mass redundancy.

610 Linear regressions of shape scores against log-transformed centroid size (Fig. 9) show that *D.*
611 *sumatrensis* has the smallest centroid size and is well separated from the other rhino species in
612 most cases, except for the tibia and fibula. *R. unicornis* possesses the highest centroid size in
613 most of the cases, except for the radius and ulna, where it shares similar centroid size values and
614 shape scores as *C. simum*. Different tendencies can be observed: for the humerus, Asiatic rhinos
615 have lower shape scores than African ones for a given size. Radius and ulna data display a point
616 pattern similar to each other, with the isolation of *D. sumatrensis* towards low values, a second
617 cluster formed by *D. bicornis* and *R. sondaicus* at average values, and a third cluster with *C.*
618 *simum* and *R. unicornis* showing the highest values. This separation in three groups can be
619 observed at a lesser extent for the femur, where *D. bicornis* and *R. sondaicus* share almost the
620 same centroid size and shape score variations, whereas *C. simum* and *R. unicornis* are separated
621 by their respective centroid size despite similar shape scores. Finally, tibia and fibula display
622 rather similar patterns with an important intraspecific shape variation for some species like *D.*
623 *sumatrensis* and *D. bicornis*. There is a more important continuity between the different clusters
624 for the tibia and the fibula than for other bones, where clusters are more separated from each
625 other.

626 ## Discussion

627 **Identification of morphotypes and phylogenetic influence**

628 Morphological variation isolates each rhino species from the others, more or less clearly
629 depending on the bone considered. The observed morphological variation reflects the
630 phylogenetic relationships between the five extant rhinos. The shape analysis of the six bones
631 enables to clearly isolate three general bone morphotypes: the African morphotype grouping *C.*
632 *simum* and *D. bicornis*, the *Rhinoceros* morphotype grouping the two *Rhinoceros* species, and
633 the *D. sumatrensis* morphotype.

634 Despite the fact that we could not test the phylogenetic signal in our data because of the small
635 number of studied species (Adams, 2014), our observations tend to indicate an impact of the
636 phylogenetic relations. It is accepted that the two African rhino *C. simum* and *D. bicornis* are
637 closely related (Tougard et al., 2001): they may both belong to the same subfamily – called
638 Dicerotinae (Guérin, 1982; Gaudry, 2017) or Rhinocerotinae (Antoine, 2002; Becker, Antoine &

639 Maridet, 2013), pending on the authors. The two species composing the genus *Rhinoceros* are

640 also closely related (Tougard et al., 2001), the bones of *R. unicornis* and *R. sondaicus* having

641 sometimes been confused with each other (Groves & Leslie, 2011). Conversely, the phylogenetic

642 position of *D. sumatrensis* remains non-consensual (Willerslev et al., 2009; Gaudry, 2017), this

643 species being considered alternately as sister taxon of the two African species (Antoine,

644 Duranthon & Welcomme, 2003; Cappellini et al., 2018), of the two *Rhinoceros* species (Tougard

645 et al., 2001; Welker et al., 2017) or of all four other rhino species (Fernando et al., 2006; Piras et

646 al., 2010). Our analyses reveal different relationship patterns, with *D. sumatrensis* more closely

647 resembling African species for some bones (radius, ulna and tibia) and Asiatic ones for the others

648 (humerus, femur and fibula).

649 Some anatomical features seem strongly influenced by phylogenetic relationships, among which

650 some have previously been used as characters for cladistics analyses (Prothero, Manning &

651 Hanson, 1986; Cerdeño, 1995; Antoine, 2002). On the humerus, the bicipital groove allows the

652 sliding of a large *m. biceps brachii*, a forearm flexor playing an important locomotor role in

653 coordinating the scapula and arm movements (Watson & Wilson, 2007; Barone, 2010b). This

654 groove appears more closed by the greater tubercle for Asiatic rhinos, allocating less space for *m.*

655 *biceps brachii* contractions. Although most analyses (Prothero, Manning & Hanson, 1986;

656 Antoine, 2002) have coded a few characters related to the tubercles of the humerus, the

657 complexity of the shape of this bone proximal epiphysis remains generally underestimated in

658 phylogenetic reconstructions. Moreover, the case of the greater tubercle development observed

659 on the humerus of Asiatic species, and mainly for *D. sumatrensis*, is of particular interest, as its

660 functional implications are not clear (see Supplemental Data S5). *D. sumatrensis* displays the

661 slenderest humerus of all modern rhinos, with morphological traits close to tapirs' and horses'

662 (MacLaren & Nauwelaerts, 2016). The proximal epiphysis of *D. sumatrensis* resembles the

663 tapirs' one, regarded by some authors as a plesiomorphic condition among Perissodactyla

664 (Hermanson & MacFadden, 1992). This particular shape may thus represent an evolutionary

665 heritage and it is unclear whether and how functional constraints may have also affected this

666 shape. The greater tubercle being also an insertion area for the *m. supraspinatus*, extension

667 movements thus seem achieved differently between African and Asiatic rhinos. The lever arm is

668 medially stronger for *C. simum* and *D. bicornis*, and distributed both medially and laterally for

669 *Rhinoceros* species and *D. sumatrensis*. On the distal epiphysis, characters related to the shape of

670 the olecranon fossa have been used in phylogenies (Heissig, 1972; Antoine, 2002). Our results
671 confirm that the shape and depth of this fossa do not seem directly linked to the general bone
672 robustness as observed in these studies. Moreover, this fossa is proximo-distally larger for the
673 genus *Rhinoceros* than for *Ceratotherium* and *Diceros*.

674 The role of shoulder joint remains crucial in weight bearing and locomotion, and its shape may
675 be influenced by several factors. The development of a massive greater tubercle is encountered
676 among hippos (Fisher, Scott & Naples, 2007) and may be interpreted as a direct link with semi-
677 aquatic habits and displacements into muddy swamps or riverbanks. This particular morphology
678 is yet also encountered among domestic bovids for example (Barone, 2010a), which are not
679 semi-aquatic, and, at the opposite, extinct Amynodontidae, presumed to have been semi-aquatic
680 Oligocene rhinos (Averianov et al., 2017), did not display this greater tubercle development
681 (Scott & Jepsen, 1941).

682 On the femur, the *fovea capitis* is extremely reduced in *C. simum* and absent in *D. bicornis*,
683 whereas it is well developed in Asiatic rhinos, especially in *R. sondaicus*, confirming previous
684 observations (Guérin, 1980; Antoine, 2002). This *fovea* provides an attachment for the accessory
685 ligament and the femoral head ligament (Hermanson & Macfadden, 1996), acting as a hip
686 stabilizer. The absence or reduction of *fovea capitis* in African species may be both associated to
687 their phylogenetic proximity. This *fovea* is indeed present in many fossil rhinos (Antoine, 2002),
688 regardless of the ecological preferences of these species. The shapes of the greater and of the
689 third trochanters, also seem driven more by the phylogeny than by functional constraints,
690 endorsing their use in phylogenies (Cerdeño, 1995; Antoine, 2002). On the distal epiphysis, the
691 medial lip is more developed and inflated in all rhinos than in horses: this feature has been
692 previously interpreted as associated to "locking" the knee joint during long standing periods in
693 equids (Hermanson & Macfadden, 1996). But no evidence of such "knee-locking" mechanism
694 exists among rhinos. Other authors saw in the development of this medial lip an adaptation to a
695 more important degree of cursoriality, linked to the openness of the habitat (Janis et al., 2012).
696 But tapirs, yet able to gallop (Sanborn & Watkins, 1950), do not display such an enlargement of
697 the medial lip of the trochlea (Holbrook, 2001; C.M. pers. obs.). This trait may thus be
698 phylogenetically inherited between horses and rhinos only, or results of a convergence towards a
699 knee-locking apparatus (which has yet to be demonstrated for rhinos).

700   On the tibia, the massive development of the tibial tuberosity seem more pronounced among

701   African species than in Asiatic ones. The angle between the tibial plateau and the shaft axis is

702   interpreted as a functional character linked to the limb posture (Lessertisseur & Saban, 1967): a

703   plateau caudally lowered may reflect an angulated limb associated to a cursorial habit, whereas

704   an horizontal plateau tends to indicate more columnar limbs. Here, despite a slight change in the

705   plateau orientation between light and heavy rhino species, this trait seems more likely related to

706   phylogeny, African species having a more horizontal plateau than African ones. Similarly, on the

707   distal epiphysis, the rectangular shape of the articular surface for the talus is encountered mainly

708   in the three Asiatic species and not in African specimens.

709   **Role of the ecology**

710   Phylogenetically related rhinos share biotopes with important similarities, making it difficult to

711   accurately assess the environmental effect on bone shape. Furthermore, as historical ranges and

712   habitats of rhinos have been drastically reduced and modified under human pressure (Hillman-

713   Smith & Groves, 1994; Dinerstein, 2011; Groves & Leslie, 2011; Rookmaaker & Antoine,

714   2013), ecological inferences must be assessed with caution regarding the current rhino biotopes.

715   The related *C. simum* and *D. bicornis* both live in African savannas and display a common

716   general bone morphotype (see above). *D. bicornis* is a ubiquitous species, often visiting both

717   open savannas and clear forests and browsing various vegetal species, whereas *C. simum* is an

718   open grassland grazer (Dinerstein, 2011). The same assessment can be done for the two

719   *Rhinoceros* species, closely phylogenetically related and sharing an important part of their

720   historical geographic range. Despite their strong affinity with water, their ecological preferences

721   are quite different, *R. unicornis* feeding frequently in semi-open floodplains whereas *R.*

722   *sondaicus* prefers denser forests. *R. sondaicus* and *D. sumatrensis* share a similar lifestyle in

723   dense and closed forest biotopes but only their humerus, femur and fibula tend to display slight

724   shape similarities. If long bone shape is impacted by environmental factors, these constraints are

725   difficult to distinguish from the ones linked to phylogeny. This tends to confirm previous

726   observations indicating that rhino long bones can hardly be used as accurate environmental

727   markers (Guérin, 1980; Eisenmann & Guérin, 1984).

728 **Shape variation, evolutionary allometry and functional implications**

729 Increase in body size and mass between the lightest and heaviest rhinos is associated with a

730 global broadening of the limb long bones, with a clear enlargement of both the diaphysis and

731 epiphyses, confirming previous general observations on different mammalian clades (Bertram &

732 Biewener, 1990, 1992). However, this broadening is not uniform for all the bones. It is directed

733 both medio-laterally and cranio-caudally for the humerus (especially for the proximal part), and

734 mainly medio-laterally for the radius and the femur. Conversely, for the ulna, tibia and fibula, we

735 rather observe a cranio-caudal enlargement, particularly visible on the proximal part of the tibia.

736   **Forelimb bones**

737 The difference between high and low size among extant rhinos is expressed on the humerus by a

738 general enlargement in both cranio-caudal and medio-lateral directions, particularly for the

739 proximal first half. This may be related to the constraints exerted both by weight bearing and

740 braking role of the forelimb during locomotion (Dutto et al., 2006). The important development

741 of the lesser tubercle at the expense of the greater tubercle allows both a greater stability of the

742 shoulder articulation, preventing hyperextension, and a larger insertion area for the medial head

743 of the *m. supraspinatus*, also considered as a shoulder stabilizer (Fisher, Scott & Naples, 2007;

744 Watson & Wilson, 2007). This muscle being one of the main extensors of the forelimb (Barone,

745 2010b), the developed lesser tubercle acts as a strong medial lever arm for extension movements.

746 This configuration has been previously interpreted as a reinforcement to resist the adduction of

747 the arm (Hermanson & MacFadden, 1992). However, the lesser tubercle also displays an

748 important development in *D. bicornis*, more pronounced than in *R. unicornis* and *R. sondaicus*,

749 though these species are heavier and taller. This indicates a possible impact of phylogenetic

750 proximity or similar habitats between the African species (see above). The medio-lateral

751 enlargement of the distal epiphysis observed towards high body size ensures both a greater

752 stability of the elbow articulation and larger insertion areas for the different flexor muscles for

753 the digits (Barone, 2010a). The distal trochlea of the humerus is also subjected to a proximo-

754 distal compression and a medio-lateral extension, increasing the articular surface area to sustain

755 high body mass (Jenkins, 1973).

756   Zeugopodial paired bones seem to express complementary shape variations linked to body size.

757   Whereas the radius broadens mainly medio-laterally for high body size, the ulna expends in the

758   cranio-caudal direction: they respond conjointly to the increase in body mass and size to form a

759   structure reinforced in all directions, as it has been observed on the humerus. All rhinos have an

760   ulnar proximal epiphysis situated caudally to the radius, while its shaft expends laterally,

761   possibly allowing a medio-lateral weight display. Moreover, almost all the weight is borne by the

762   proximal articular surface of the radius (Bertram & Biewener, 1992), which expends medially

763   and becomes asymmetrical for heavier rhinos. The concave radial tuberosity shows a deep *m.*

764   *biceps brachii* insertion delivering a strong forearm flexion (Antoine, 2002) and the developed

765   insertion lateral relief offers a greater surface for extensor muscles of the digits. On the ulna, the

766   developed olecranon process constitutes a strong lever arm for forearm extensors such as the *m.*

767   *triceps brachii* and the *m. anconeus*. The anconeus process, although cranially reduced, prevents

768   a complete extension of the forearm (Hildebrand, 1974). The distal epiphysis shows a reduction

769   of both radial and ulnar styloid processes towards high body proportions, adding a medio-lateral

770   degree of freedom to the wrist articulation. However, the proximally reduced articular surface for

771   the scaphoid limits the cranio-caudal wrist flexion. These morphological traits allow the foot to

772   bear the weight on different substrates while limiting the risk of wrist hyperflexion (Domming,

773   2002).

774   **Hind limb bones**

775   In the hind limb, the femur expends mainly in the medio-lateral direction for high body mass and

776   size, tending to indicate a stronger resistance both linked to body propulsion and weight bearing

777   (Lessertisseur & Saban, 1967), exerted in the medio-lateral direction (Hildebrand, 1974). The

778   medio-lateral reinforcement of the femur is mainly located under the head and the neck,

779   responding to a concomitant enlargement of the medial condyle on the distal epiphysis, both

780   indicating an increase of the body load near the sagittal plane. The more distal location of the

781   lesser trochanter improves the lever arm of the *mm. psoas major* and *iliacus*, developing slower

782   but stronger hip flexions (Hildebrand, 1974; Polly, 2007). The same phenomenon is observed

783   with the third trochanter, situated at half of the shaft – contrary to in cursorial Perissodactyla like

784   equids, where the third trochanter is more proximally situated (Hermanson & Macfadden, 1996;

785   Holbrook, 2001; Barone, 2010a). The extreme development of the third trochanter associated

786 with a disto-lateral development of the greater trochanter also create a large lever arm for the

787 *fascia glutea*, the *mm. gluteus superficialis* and *gluteus medius* allowing strong hip flexion and

788 abduction. This association seems maximal for *R. unicornis*, where the greater and third

789 trochanters can be fused by a bony bridge. At the opposite, the greater trochanter is less

790 proximally developed than in related groups like horses and tapirs (Hermanson & Macfadden,

791 1996; MacLaren & Nauwelaerts, 2016): as this trochanter is the insertion area for the *m. gluteus*

792 *medius*, the main extensor of the hip, the extension in rhinos seems less powerful than in

793 cursorial perissodactyls. On the distal epiphysis, the lateral torsion of the rotation axis of the

794 trochlea in heavy rhinos also indicates a more laterally deviated position of the knee: this

795 conformation may improve weight bearing, deporting the body mass laterally to the body, as

796 previously observed on a study of pressure patterns of the feet in *C. simum* (Panagiotopoulou,

797 Pataky & Hutchinson, 2018). No real difference on the bone curvature related to body proportion

798 was noticed, confirming previous observations on the independence of femur curvature with

799 regard to body mass increase in quadrupedal mammals (Bertram & Biewener, 1992).

800 On the zeugopodial elements, when the proximal epiphysis of the tibia broadens cranio-caudally,

801 the one of the fibula one is reduced in this direction, despite an increased general robustness. The

802 proximal epiphysis of the fibula is also oriented far more cranially than in lighter specimens. The

803 enlargement of the tibial plateau thus seems to involve a relative reduction in size of the fibula

804 head. The distal epiphyses of both bones variate conjointly too, with a broadening mainly

805 expressed in the cranio-caudal direction. The medial condyle of the tibial plateau enlarges

806 strongly, resulting into an asymmetrical proximal epiphysis. Moreover, the broadening of the

807 tibial tuberosity correlates with a stronger and larger patellar ligament, reinforcing the knee

808 articulation and the lever arm created by the patella (Hildebrand, 1974). On the distal epiphysis,

809 the two malleoli are more medio-laterally inflated but less distally expended, allowing the tarsal

810 articulation to move more freely in heavier rhinos (Lessertisseur & Saban, 1967). This trait is

811 associated to a slightly shallower distal articular surface, conferring more important degrees of

812 freedom to the ankle articulation for high body size and mass (Polly, 2007). This observation is

813 coherent with similar analyses conducted on rhino ankle bones (Etienne et al., submitted).

814 In addition to the reduction of the proximal epiphysis, the fibula displays a straighter diaphysis

815 for large rhinos as opposed to the greatly curved one for lighter rhinos. This is consistent with

816 previous observations: although the fibula was not considered in their study, Bertram &

817 Biewener (1992) noted a decrease of the tibia curvature while body mass increases among

818 terrestrial mammals. In our rhino sample, the tibia shows a very slight straightening of the

819 diaphysis. However, this straightening, maybe linked to the load carrying capacity, appears to be

820 more pronounced on the fibula.

821 **Differences between body mass and body size**

822 As the exact body mass was only known for five specimens of our sample, we were not able to

823 precisely express the shape variation regarding the animal's individual weight. However,

824 theoretical bone shape obtained with mean body mass are very similar to the ones obtained with

825 centroid size (see above). Comparing the values of the centroid size and mean body mass

826 highlights some interspecific differences: if *D. sumatrensis*, the smallest rhino, has the lowest

827 values for both centroid size and body mass, the tallest *R. unicornis* displays the highest values

828 of centroid size in most of the cases, confirming its higher general size among modern rhinos

829 (Guérin, 1980; Dinerstein, 2011), despite a mean body mass (2,000 kg) lower than that of *C.*

830 *simum* (2,300 kg). Furthermore, the centroid size of an isolated bone may neither reflect the

831 actual global size of an animal, nor be strictly correlated with its body mass. This is particularly

832 visible for taxa displaying brachypodial adaptation (i.e. shortening of limb length relatively to

833 the body size), as it is the case for modern hippos or some fossil rhinos like *Brachypotherium* or

834 *Teleoceras* (Cerdeño, 1998). However, as bone size and body mass are intimately entangled

835 (Berner, 2011), the centroid size of isolated bones may still constitute a useful body mass

836 approximation when precise body mass remains unknown and if considered cautiously. This is

837 coherent with previous results obtained on cranial shape data indicating a marked correlation

838 between body mass and centroid size (both of the skull and mandible) for many mammalian

839 lineages, especially modern rhinos (Cassini, Vizcaíno & Bargo, 2012).

840 **Limb bone shape and graviportality**

841 One of the criteria defining graviportality are the straight and columnar limbs (Gregory, 1912;

842 Osborn, 1929; Biewener, 1989b). Rhino's limb long bones do not display a true columnar

843 organisation (Osborn, 1900, 1929). Morphological changes between light and heavy rhino

844 species do not imply a clear change in the orientation of the articular facets: the elbow joint

845   remains unable to completely open like the elephant's one and the knee remains markedly

846   angulated. Only the humeral proximal epiphysis displays a tenuous orientation change between

847   light and heavy rhinos, allowing a more slightly vertical orientation of this bone for *C. simum*

848   and *R. unicornis*.

849   Limb straightness can results from the reorientation of the trochlear notch of the ulna in the

850   dorsal direction, allowing an efficient support of the humerus (Gregory, 1912), as in

851   proboscideans (Christiansen, 1999). Our sample tends to indicate instead that the radius is the

852   main support of the body weight in the forelimb among modern rhinos. The shape of the radius

853   becomes gradually more robust from light to heavy rhinos, with a strong medial reinforcement of

854   the proximal epiphysis. The particular role of the radius was previously highlighted among a

855   large sample of mammal clades (Bertram & Biewener, 1992), its vertical position being opposed

856   to ground reaction forces. This supportive role of the radius is widespread among Ungulata and

857   remains of importance even in larger fossil rhinos like Elasmotheriinae (Antoine, 2002) and

858   Paraceratheriidae (Qiu & Wang, 2007; Prothero, 2013). Unlike in elephants, increase in body

859   mass among rhinos is correlated to a more important supportive role of the radius. At the

860   opposite, the ulna role has not been extendedly explored in morphofunctional studies. Our work

861   underlines the complementary role of the ulna relatively to the radius, providing more lateral and

862   caudal weight bearing by an enlargement in the dorso-palmar direction. In this regard, the

863   forearm conformation in rhinos is close to the one encountered in hippos (Fisher, Scott &

864   Naples, 2007).

865   Forelimb elements bear more weight than hind limb ones (Lessertisseur & Saban, 1967;

866   Hildebrand, 1974; Polly, 2007) and play an additional braking role during locomotion,

867   particularly proximal elements (Dutto et al., 2006). Forelimb bones such as the humerus thus

868   need to be reinforced in all directions in order to support these higher weight constraints in

869   heavier animals. Hind limb bone shape is affected differently than in forelimb by increases in

870   body mass and size. Hind limb bears relatively less weight than the forelimb and plays an

871   additional propulsive role during locomotion (Lessertisseur & Saban, 1967; Hildebrand, 1974;

872   Barone, 2010a). The femur displays important reinforcement and development of strong lever

873   arms in large rhino species, possibly to support increasing stress due to locomotion and body

874   mass, but the variations in shape of the tibia and the fibula seem driven as much by the body size

875   as by the phylogenetic influence. The shape of the fibula is particularly variable within several

876   rhino species, questioning its functional role but also the factors driving this strong intraspecific

877   variation. It has been shown that the human fibula plays, in addition to its ankle stabilizer role, a

878   small but important weight bearing role, receiving one sixth of the load applied to the knee

879   (Lambert, 1971; Takebe et al., 1984). In horses, the diaphysis of the fibula is absent and the

880   malleolus is fused with the tibia, ensuring mainly ankle stabilization (Barone, 2010a). Rhino's

881   fibula, contrary to the horse's one, ensures both load bearing and talus stabilization roles (Polly,

882   2007). In addition, this bone often bears crests along the diaphysis with no apparent correlation

883   with weight bearing (see above). These crest developments may be due to individual variations

884   in bone development, without clear functional implications, but this first analysis does not allow

885   us to state on this question.

886   Bertram & Biewener (1990, 1992) and Polly (2007) previously called "allometry increase" the

887   tendency to body size and mass rise among terrestrial mammals. Although reduced, this

888   allometry clearly affects our sample (Tables 6 and 7). In addition, the robustness increase is

889   associated with a slight relative length reduction of the bone for larger rhinos (Guérin, 1980), a

890   general trend observed among heavy mammals (Christiansen, 1999). Another trait associated to

891   body size augmentation among extant rhino species is the expansion of the epiphysis medial

892   parts (e.g., medial epicondyle and trochlear lip on the humerus, medial glenoid cavity on the

893   radius, medial condyle and trochlear lip on the femur, medial condyle on the tibia). These medial

894   reinforcements result in more asymmetrical bones, potentially increasing parasagittal weight

895   bearing (Barone, 2010a). This conformation is coherent with foot posture during walk: rhino

896   forefeet are placed under the body, close to the sagittal plane of the animal (Paul & Christiansen,

897   2000). Hind feet are more spaced and oriented laterally, especially for heavy rhinos

898   (Panagiotopoulou et al., 2018), which seems coherent with our observations regarding the

899   rotation axis of the femoral trochlea, oriented more laterally as well. However, the distal articular

900   surface of the tibia displays a broader lateral groove and appears as a counterexample (Figure 5).

901   This lateral broadening of the ankle joint, also observed on the talus (Etienne et al., submitted),

902   may be correlated with the hind limb posture of rhinos: as the pelvic bone is large and the feet

903   are placed under the body and oriented more laterally than forefeet, the legs are not parallel to

904   the sagittal plane (Paul & Christiansen, 2000; C.M. pers. obs.). The vertical forces exerted by the

905   body mass may therefore cross the axis of the tibia. This appears in accordance with the fact that

906 the forces may be medially higher on the proximal plateau but laterally higher at the ankle joint:

907 this point would need to be tested more precisely *in vivo*. As studies of pressure patterns indicate

908 that foot pressure is more intense laterally (Pfistermüller, Walzer & Licka, 2011;

909 Panagiotopoulou, Pataky & Hutchinson, 2018), it will be crucial to explore relations that exist

910 between stylopodium, zeugopodium and autopodium organisation in the complete limb, as well

911 as the gait and posture of the rhinos.

912 Conclusion

913 This study conducted on the limb long bones among modern rhinos highlights the occurrence of

914 three distinct morphotypes. These latter reflect phylogenetic relationships, and also differently

915 impacted by body size and mass. The shape of the stylopodium bones, though affected by body

916 mass variations, remains highly constrained by phylogeny, whereas it is more strongly impacted

917 by body mass and size in zeugopodial bones, especially the radius and ulna, which underlies

918 their important role in weight bearing. As for the shape of the tibia, it is influenced by both

919 changes in body mass and size, and phylogeny. The unique pattern of the fibula reveals that,

920 beyond the important intraspecific variation, this bone also plays a substantial role in weight

921 bearing. Quick comparisons with hippos and elephants show clear differences and convergences

922 and highlight the interest of investigating shape variation in other heavy mammal taxa. This

923 would enable to describe the different ways to sustain an increase of body mass in mammals and,

924 eventually, to sharpen the concept of "graviportality".

925 Acknowledgments

Author contributions

945 All authors designed the frame of the study. C.M. did most of the data acquisition with additions

946 from A.H. C.M. performed the analyses under the guidance of R.C. C.M. drafted the manuscript.

947 All authors reviewed and contributed to the final manuscript, read it and approved it.

Table 1(on next page)

Main characteristics of the five studied species

Length, height and body mass data compiled and calculated after (Dinerstein, 2011) .
Ecological data compiled after (Becker, 2003) . **Abbreviations: G**: graviportal; **M**:
mediportal. *: African species; **: Asiatic species

Species name	Length (cm)	Shoulder height (cm)	Mean body mass (kg)	Ecology	Locomotor type		
					(Gregory, 1912; Osborn, 1929; Coombs, 1978)	(Eisenmann & Guérin, 1984)	(Becker, 2003)
Ceratotherium simum*	340 – 420	150 – 180	2,300	Open savanna	M	G	G
Dicerorhinus sumatrensis**	236 – 318	100 – 150	775	Dense forests and swampy lakes	M	G	M
Diceros bicornis*	300 – 380	140 – 170	1,050	Open savanna and clear forest	M	G	M
Rhinoceros sondaicus**	305 – 344	150 – 170	1,350	Dense forests and swampy areas	M	G	G
Rhinoceros unicornis**	335 – 346	175 – 200	2,000	Floodplains and swamps	M	G	M

Table 2 (on next page)

List of the studied specimens with skeletal composition, sex, age class, condition and 3D acquisition details

Abbreviations: Bones – H: humerus; **R**: radius; **U**: ulna; **Fe**: femur; **T**: tibia; **Fi**: fibula. **Sex: F**: female; **M**: male; **U**: unknown. **Age – A**: adult; **Sa**: sub-adult. **Condition – W**: wild; **C**: captive; **U**: unknown. **3D acquisition – SS**: surface scanner; **P**: photogrammetry; **CT**: CT-scan. **Institutional codes: BICPC**: Powell Cotton Museum, Birchington-on-Sea. **CCEC**: Centre de Conservation et d'Étude des Collections, Musée des Confluences, Lyon. **MHNT:** Muséum d'Histoire Naturelle de Toulouse, Toulouse. **MNHN:** Muséum National d'Histoire Naturelle, Paris. **NHMUK:** Natural History Museum, London. **NHMW:** Naturhistorisches Museum Wien, Vienna. **NMS:** National Museums Scotland, Edinburgh. **RBINS:** Royal Belgian Institute of Natural Sciences, Brussels. **RMCA:** Royal Museum for Central Africa, Tervuren. **UCMP:** University of California Museum of Paleontology, Berkeley. **UMZC:** University Museum of Zoology Cambridge, Cambridge. **ZSM:** Zoologische Staatssammlung München, Munich. * Specimens NHMUK ZD 2018.143 and NHMUK ZD 1972.822 were determined by ourselves during the visit of the collections on the basis of morphological observations and measurements on the post-cranial elements. These determinations were later confirmed by our shape analysis. ** The specimen MNHN-ZM-AC-1885-734 was previously determined as *Rhinoceros sondaicus* based on a supposed Javan origin. The observations made on both long bones and tarsal elements led us to consider this individual as an Indian rhino (*Rhinoceros unicornis*). This attribution was later confirmed by our shape analysis

Table 4(on next page)

Main anatomical differences observed between theoretical shapes associated with minimal and maximal centroid size for each bone of the forelimb

B: Bone; H: Humerus; R: Radius; U: Ulna.

B	Anatomical feature	Centroid size minimum	Centroid size maximum
	General aspect	Slender	Robust
	Head	Rounded, overhanging the shaft	Rounded, overhanging poorly the shaft
	Lesser tubercle	Developed	Poorly developed
	Intermediate tubercle	Almost absent	Poorly developed
	Greater tubercle	Developed	Strongly developed
	Bicipital groove	Asymmetrical and closed	Almost symmetrical and widely open
	M. infraspinatus insertion	Diamond-shaped and strongly developed	Ovoid and less developed
H	Deltoid tuberosity	Poorly laterally deviated and caudally sharp	Laterally deviated and caudally smooth
	Distal epiphysis	Medio-laterally compressed	Medio-laterally extended
	Supracondylar crest	Smooth	Very smooth
	Lateral epicondyle	Poorly extended laterally	Strongly extended laterally
	Medial epicondyle	Overhanging the olecranon fossa	Not overhanging the olecranon fossa
	Olecranon fossa	Triangular and deep	Rectangular and deep
	Trochlea	Sharp lips and deep groove	Smooth lips and shallow groove
	Capitulum	Extremely reduced	Extremely reduced
	General aspect	Slender	Robust
	Proximal articular surface	Open and little concave; medial glenoid cavity slightly larger than the lateral one	Concave; medial glenoid cavity twice as large as the lateral one
	Radial tuberosity	Poorly developed	Poorly developed
	Lateral insertion relief	Poorly developed	Knob-shaped
	Lateral synovial articulation surface	Trapezoid and laterally extended	Trapezoid and laterally reduced
R	Medial synovial articulation surface	Thin and rectangular	Thin and rectangular
	Proximal articular surface for the ulna	Triangular, wide and proximo-distally short	Triangular, slender and proximo-distally long
	Interosseous crest	Smooth	Sharp
	Interosseous space position	Mid-shaft	First proximal third of the shaft
	Distal articular surface for the ulna	Long and slender triangle	Short and wide triangle
	Articular surface for the carpal bones	Broad in dorso-palmar direction	Compressed in dorso-palmar direction

	Articular surface for the scaphoid	Proximally extended	Poorly extended proximally
	Articular surface for the semilunar	Trapezoid and narrow	Trapezoid and wide
	Radial styloid process	Short	Long
	General aspect	Slender	Robust
	Olecranon	Medio-laterally compressed	Medio-laterally large
	Olecranon tuberosity	Oriented medially with a medial tubercle pointing in the medio-palmar direction	Oriented laterally with a medial tubercle pointing in the medio-dorsal direction
	Anconeus process	Developed in dorsal direction	Little developed dorsally
U	Articular surface for the humerus	Medio-laterally reduced, lateral lip developed in proximal direction	Medio-laterally broad with an important development of the medial part
	Interosseous crest	Irregular and sharp	Smooth
	Distal epiphysis	Thin with a small lateral extension	Large and extending largely in lateral and dorsal directions
	Articular surface for the triquetrum	Narrow and concave	Wide and slightly concave
	Articular surface for the pisiform	Extended in proximal direction	Little developed in proximal direction

1

Table 5(on next page)

Main anatomical differences observed between theoretical shapes associated with minimal and maximal centroid size for each bone of the hind limb

B: Bone; Fe: Femur; Fi: Fibula; T: Tibia.

B	Anatomical feature	Centroid size minimum	Centroid size maximum
Fe	General aspect	Slender	Robust
	Head	Rounded, well separated from the shaft by a narrow neck	Massive and flattened, surmounting a large neck
	Fovea capitis	Formed by a simple shallow notch on the border head in medio-caudal direction	Small and shallow, oriented more medially
	Greater trochanter	Small and developed in the cranial direction	Large and developed in the latero-distal direction
	Lesser trochanter	Thin and bordering the caudal border of the shaft medial side	Thick, occupying the whole width of the medial side
	Lines on the cranial side	Medial line running straight along the side	Medial line strongly concave along the side
	Third trochanter	Rounded and poorly developed	Strong and developed towards the greater trochanter
	Trochlea	Oriented medially with a shallow groove and developed medial lip	Oriented cranially with a deep groove and an extremely developed medial lip
	Condyles	Almost of the same size	Medial condyle more developed than the lateral one
	Intercondylar space	Wide	Narrow
T	General aspect	Slender	Robust
	Proximal condyles	Nearly equal surface areas; lateral condyle more developed caudally with a sliding surface for the *m. popliteus*	Medial condyle surface twice as wide as the lateral one and more developed caudally
	Intercondylar tubercles	Nearly of equal height	Medial tubercle higher than the lateral one
	Central intercondylar area	Wide	Narrow
	Tibial tuberosity	Laterally deviated	Massive and oriented in lateral direction
	Tuberosity groove	Deep	Shallow
	Extensor sulcus	Shallow	Shallow
	Proximal articular surface for the fibula	Nail-shaped	Triangular
	Interosseous crest	Sharp	Smooth
	Distal articular surface for the fibula	Narrow and triangular	Wide and triangular
	Articular surface for the talus	Rectangular, slightly tilted laterally	Squared, slightly oriented medially
	Medial groove for	Deep and narrow	Deep and narrow

	the talus		
	Lateral groove for the talus	Shallow and wide	Shallow and wide
	General aspect	Slender	Robust
	Head	Flat and large, oriented cranio-medially	Small and oriented cranially
	Proximal articular surface for the tibia	Nail-shaped	Triangular
Fi	Shaft	Thin and slightly concave, with two sharp crests running along the lateral side	Broad and straight, with two smooth crests running along the lateral side
	Distal articular surface for the tibia	Triangular, narrow and long	Triangular, wide and short
	Lateral malleolus	Two well-developed tubercles caudally oriented and separated by a deep groove	Two flat tubercles laterally oriented, with the cranial one being more developed, and separated by a shallow groove
	Articular surface for the talus	Kidney-shaped, broad in proximo-distal direction	Triangular, proximo-distally compressed

Figure 1

esults of the PCA performed on morphometric data of the humerus

A: distribution of the specimens along the two first axes of the PCA; B to I: theoretical shapes associated with the minimum and maximum values of PC1: caudal (B, C), lateral (D, E), proximal (F, G) and distal (H, I) views for PC1 minimum (B, D, F, H) and PC1 maximum (C, E, G, I). Abbreviations – **B.g.**: Bicipital groove; **C.**: Capitulum; **D.t.**: Deltoid tuberosity; **E.c.**: Epicondylar crest; **G.t.**: Greater tubercle; **G.t.c.**: Greater tubercle convexity; **H.**: Head; **I.t.**: Intermediate tubercle; **L.e.**: Lateral epicondyle; **L.l.b.**: Lateral lip border; **L.t.**: Lesser tubercle; **L.t.c.**: Lesser tubercle convexity; **M.e.**: Medial epicondyle; ***M.i.i.***: *M. infraspinatus* insertion; **M.l.b.**: Medial lip border; ***M.t.m.t.***: *M. teres major* tuberosity; **N.**: Neck; **O.f.**: Olecranon fossa; **T.**: Trochlea; **T.g.**: Trochlear groove.
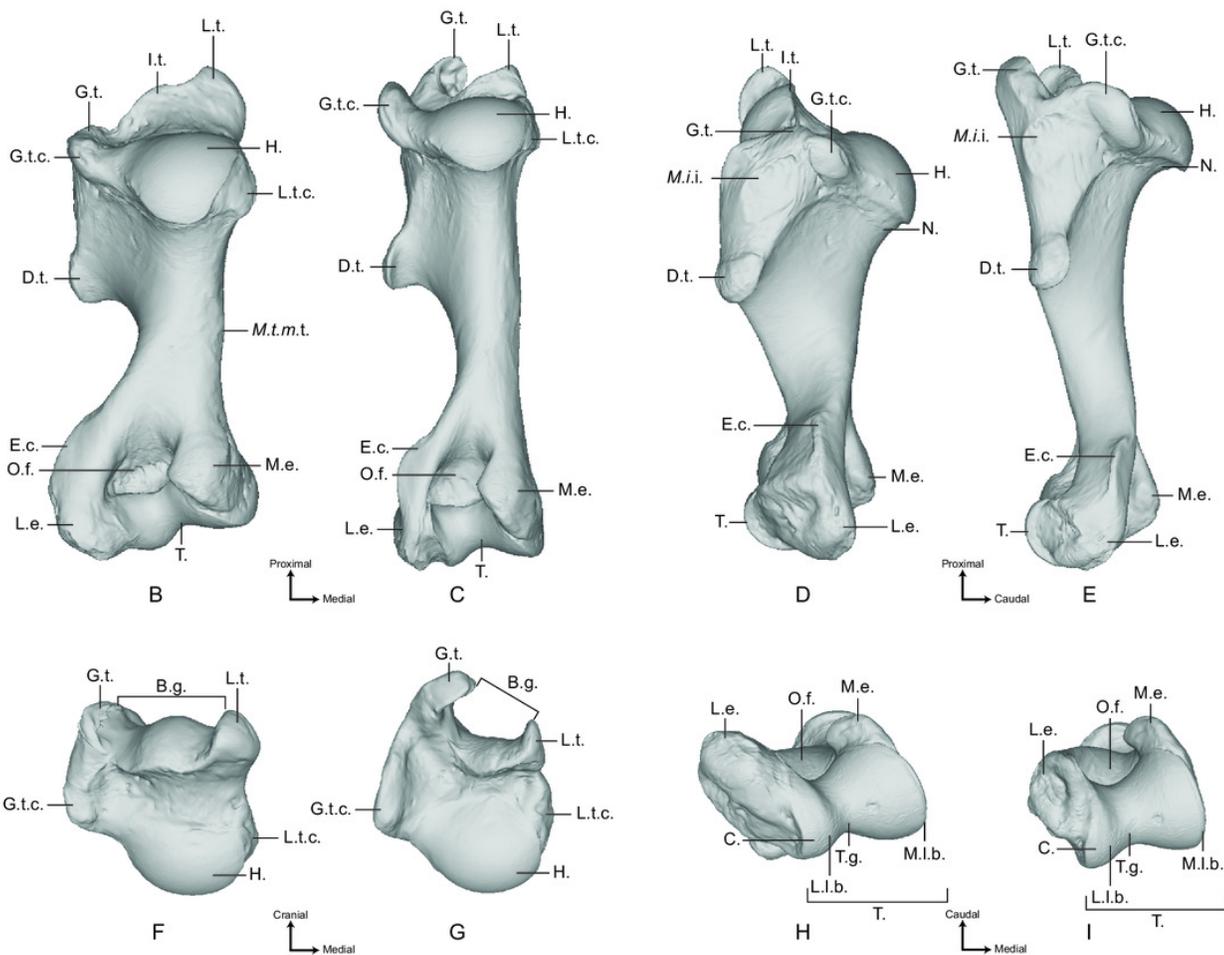

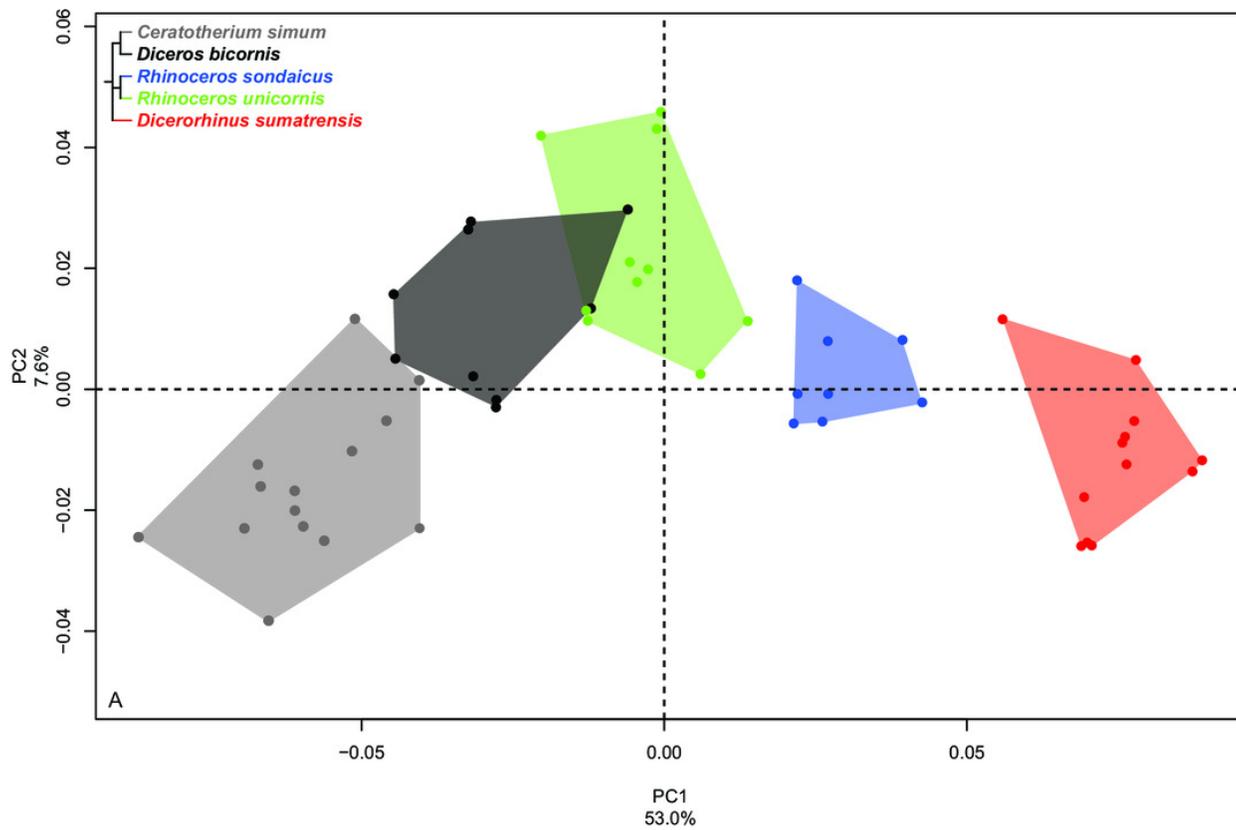

Figure 2

Results of the PCA performed on morphometric data of the radius

A: distribution of the specimens along the two first axes of the PCA; B to I: theoretical shapes associated with the minimum and maximum values of PC1: dorsal (B, C), palmar (D, E), proximal (F, G) and distal (H, I) views for PC1 minimum (B, D, F, H) and PC1 maximum (C, E, G, I). Abbreviations – **A.s.s.**: Articular surface for the scaphoid; **A.s.sl.**: Articular surface for the semilunar; **C.p.**: Coronoid process; **D.a.s.u.**: Distal articular surface for the ulna; **I.c.**: Interosseous crest; **I.s.**: Interosseous space; **L.g.c.**: Lateral glenoid cavity; **L.i.r.**: Lateral insertion relief; **L.s.a.s.**: Lateral synovial articular surface; **M.g.c.**: Medial glenoid cavity; **M.s.a.s.**: Medial synovial articular surface; **P.a.s.u.**: Proximal articular surface for the ulna; **P.p.**: Palmar process; **R.s.p.**: Radial styloid process; **R.t.**: Radial tuberosity.
