Vitamin D receptor (VDR) modulates host immune responses, including interferon signaling. This study aimed to investigate the associations of VDR polymorphisms with advanced liver fibrosis and response to pegylated interferon (PEG-IFN)-based therapy in patients with chronic hepatitis C virus (HCV) infection. In total, 554 Thai patients with chronic HCV infection treated with a PEG-IFN-based regimen were enrolled. Six single-nucleotide polymorphisms (SNPs) were genotyped: the *IL28B* C>T (rs12979860) SNP and five VDR SNPs, comprising *FokI* T>C (rs2228570), *BsmI* C>T (rs1544410), *Tru9I* G>A (rs757343), *Apal* C>A (rs7975232), and *TaqI* A>G (rs731236). In total, 334 patients (60.3%) achieved sustained virological response (SVR), and 255 patients (46%) were infected with HCV genotype 1. The bAt (CCA) haplotype, consisting of the *BsmI* rs1544410 C, *Apal* rs7975232 C, and *TaqI* rs731236 A alleles, was associated with poor response to PEG-IFN-based therapy. The *IL28B* rs12979860 CT/TT genotypes (OR=3.66, 95%CI: 2.26-5.91, p<0.001), bAt haplotype (OR=2.12, 95%CI: 1.11-4.05, p=0.02), pre-treatment serum HCV RNA (logIU/ml; OR=1.75, 95%CI: 1.33-2.31, p<0.001), and advanced liver fibrosis (OR=1.60, 95%CI: 1.05-2.44, p=0.03) independently predicted poor response. Patients with the bAt haplotype were more likely to have poor response compared to patients with other haplotypes (41.4% vs 21.9%, p=0.03). The *FokI* rs2228570 TC/CC genotypes (OR = 1.77, 95%CI 1.2-2.7, p=0.007) and age ≥55 years (OR=2.28; 95%CI: 1.55-3.37, p<0.001) were independently associated with advanced liver fibrosis. VDR polymorphisms were not associated with pre-treatment serum HCV RNA. In Thai patients with chronic HCV infection, the bAt haplotype is associated with poor response to PEG-IFN-

based therapy, and the *FokI* rs2228570 TC/CC genotypes are risk factors for advanced liver fibrosis.

Genetic Associations of Vitamin D Receptor Polymorphisms with Advanced Liver Fibrosis and Response to Pegylated Interferon-based Therapy in Chronic Hepatitis C

Abstract

Vitamin D receptor (VDR) modulates host immune responses, including interferon signaling. This study aimed to investigate the associations of *VDR* polymorphisms with advanced liver fibrosis and response to pegylated interferon (PEG-IFN)-based therapy in patients with chronic hepatitis C virus (HCV) infection. In total, 554 Thai patients with chronic HCV infection treated with a PEG-IFN-based regimen were enrolled. Six single-nucleotide polymorphisms (SNPs) were genotyped: the *IL28B* C>T (rs12979860) SNP and five *VDR* SNPs, comprising *FokI* T>C (rs2228570), *BsmI* C>T (rs1544410), *Tru9I* G>A (rs757343), *ApaI* C>A (rs7975232), and *TaqI* A>G (rs731236). In total, 334 patients (60.3%) achieved sustained virological response (SVR), and 255 patients (46%) were infected with HCV genotype 1. The bAt (CCA) haplotype, consisting of the *BsmI* rs1544410 C, *ApaI* rs7975232 C, and *TaqI* rs731236 A alleles, was associated with poor response to PEG-IFN-based therapy. The *IL28B* rs12979860 CT/TT genotypes (OR=3.66, 95%CI: 2.26-5.91, p<0.001), bAt haplotype (OR=2.12, 95%CI: 1.11-4.05, p=0.02), pre-treatment serum HCV RNA (logIU/ml; OR=1.75, 95%CI: 1.33-2.31, p<0.001), and advanced liver fibrosis (OR=1.60, 95%CI: 1.05-2.44, p=0.03) independently predicted poor response. Patients with the bAt haplotype were more likely to have poor response compared to patients with other haplotypes (41.4% vs 21.9%, p=0.03). The *FokI* rs2228570 TC/CC genotypes (OR = 1.77, 95%CI 1.2-2.7, p=0.007) and age ≥ 55 years (OR=2.28; 95%CI: 1.55-3.37, p<0.001) were independently associated with advanced liver fibrosis. *VDR* polymorphisms were not associated with pre-treatment serum HCV RNA. In Thai patients with chronic HCV infection, the bAt haplotype is associated with poor response to PEG-IFN-based therapy, and the *FokI* rs2228570 TC/CC genotypes are risk factors for advanced liver fibrosis.

Key words Vitamin D receptor polymorphisms, hepatitis C virus, pegylated interferon, advanced liver fibrosis

INTRODUCTION

Hepatitis C virus (HCV) infection is a major health problem affecting >71.1 million people worldwide, leading to chronic hepatitis, liver cirrhosis, and hepatocellular carcinoma (HCC) (Organization 2017). The advancement of HCV treatment in terms of the development of direct-acting antiviral agents (DAAs) has evoked international interest in the global elimination of HCV. In 2017, the World Health Organization set targets to eliminate globally viral hepatitis as a public threat by 2030 by achieving a 90% diagnosis rate, an 80% treatment rate, and a 65% reduction in the mortality rate. However, in low- and middle-income countries (including those in Southeast Asia, the Middle East, and North Africa), which have 80% of the global HCV burden, access to DAAs is constrained by financial factors (Jayasekera et al. 2014; Mohd Hanafiah et al. 2013; Zoulim et al. 2015). Pegylated interferon (PEG-IFN)-based therapy is still being used in these countries. The current Asian Pacific Association for the Study of the Liver (APASL) guidelines on the treatment of HCV infection continue to recommend PEG-IFN and ribavirin as first-line therapy in resource-limited countries where DAAs are unavailable (Omata et al. 2016).

Current evidence shows that in addition those in supporting calcium and bone metabolism, vitamin D (VD) plays several important roles in immunomodulation, regulation of cellular proliferation, differentiation, and apoptosis (Holick 2007; Penna et al. 2005; von Essen et al. 2010). Several studies have reported association between VD deficiency and risk of cancer, congestive heart failure, insulin resistance, and autoimmune diseases (Feskanich et al. 2004; Giovannucci et al. 2006; Munger et al. 2006). The liver is a crucial organ in VD synthesis as it is the site of the enzymatic conversion of the inactive form of VD to 25-dihydroxyVD. VD deficiency was found in 70% of patients with chronic liver disease regardless of the etiology, and 22% had severe VD deficiency (Arteh et al. 2010). Patients with chronic HCV infection had lower serum VD levels than sex- and age-matched healthy controls (Petta et al. 2010). In terms of clinical outcomes, low VD level is probably independently related to advanced liver fibrosis and high necroinflammatory activity in chronic HCV patients (Dadabhai et al. 2017; Petta et al. 2010). Two large meta-analyses reported a negative association between sustained virological response (SVR) and VD level in chronic HCV patients treated with PEG-IFN therapy (Garcia-Alvarez et al. 2014; Villar et al. 2013).

Vitamin D receptor (VDR) is a nuclear hormone receptor that can act as a ligand-inducible transcription factor. VDR binds to the active form of VD and thereby mediates its effect (Keane et al. 2018). VDR is expressed in many cells of the human body, including monocytes and activated T lymphocytes in the peripheral blood, non-parenchymal cells (hepatic stellate cells, Kupffer cells, and endothelial cells), and hepatocytes, especially during inflammatory liver injury (Gascon-Barre et al. 2003; Keane et al. 2018). The receptor is encoded by the *VDR* gene, which is located on chromosome 12q. The gene has a promoter, regulatory regions, and exons 2–9, which span over 100 kb (Deeb et al. 2007; Uitterlinden et al. 2004). Using different restriction endonucleases for *BsmI*, *Tru9I*, *ApaI*, and *TaqI* (to cleave the DNA at the 3' end) and *FokI* (to cleave the DNA in exon 2), multiple *VDR* polymorphisms have been explored (Uitterlinden et al. 2004). The bAt (CCA) haplotype is a common genetic variant of the *VDR* gene, comprising the following three polymorphisms at the 3' end of the gene: *BsmI* rs1544410 C, *ApaI* rs7975232 C,

and *TaqI* rs731236 A, which are in strong linkage disequilibrium. Recent research shows that *VDR* genetic variations lead to susceptibility and chronicity regarding HCV infection (Wu et al. 2016). In addition, *VDR* polymorphisms may be related to the response to PEG-IFN and ribavirin therapy in chronic HCV patients. However there have been conflicting results regarding these relationships among previous studies (Baur et al. 2012b; Garcia-Martin et al. 2013; Hung et al. 2016; Shaker et al. 2016). This study aims to investigate whether the common *VDR* polymorphisms are associated with the response to PEG-IFN-based therapy and advanced liver fibrosis in patients with chronic HCV infection.

MATERIALS & METHODS

Patients

This study included Thai patients with chronic HCV infection at Chulalongkorn University hospital (Bangkok, Thailand) and Srinagarind hospital (Khon Kaen, Thailand) from June 2012 to December 2013. All patients were seropositive for anti-HCV antibody and HCV RNA and they were treated with PEG-IFN and ribavirin in accordance with standard guideline recommendations (European Association for the Study of the 2011; Ghany et al. 2009). Patients who had co-infection with hepatitis B virus or human immunodeficiency virus, decompensated cirrhosis, or liver transplants were excluded. Baseline characteristics were recorded, and biochemical and virological tests were conducted at baseline during treatment and at 24 weeks after treatment. Liver biopsy or the Fibrosis-4 (Fib-4) index were used for assessing liver fibrosis. Advanced liver fibrosis was defined as fibrosis stage 3–4 by histology or Fib-4 index > 3.25 (Vallet-Pichard et al. 2007).

The study followed the principles of the Declaration of Helsinki and was approved by the local Institutional Review Board (IRB) committee on medical ethics. Written informed consent was obtained from each participant.

Virological testing

The quantitative serum HCV RNA level was evaluated using the real-time polymerase chain reaction (RT-PCR) COBAS® Taqman® HCV test (Roche Diagnostics, Basel, Switzerland). HCV genotyping was performed using the INNO-LiPA HCV II assay (Innogenetics, Ghent, Belgium).

Genotyping

Genotyping of the following six single-nucleotide polymorphisms (SNPs) was performed: the interleukin 28B (*IL28B*; also known as interferon lambda 3 [IFNλ3]) C>T (rs12979860) SNP and five *VDR* SNPs, comprising *FokI* T>C (rs2228570), *BsmI* C>T (rs1544410), *Tru9I* G>A (rs757343), *Apal* C>A (rs7975232), and *TaqI* A>G (rs731236). DNA was extracted from 100 μL of peripheral blood leukocytes using a standard phenol-chloroform protocol and then kept at –80°C. Next, 2 μL DNA was subjected to PCR (total volume, 25 μL) using Perfect *Taq* Plus MasterMix (5 PRIME GmbH, Hamburg, Germany). The PCR-specific probes and conditions are summarized in Supplementary Table 1. This was followed by restriction fragment length polymorphism (RFLP) assays except genotyping *IL28B* was done by sequencing method (First

BASE Laboratories, Selangor, Malaysia). Subsequently, 2% agarose gel electrophoresis was used to assess the resulting DNA fragments. The separated DNA was viewed under ultraviolet light after staining with ethidium bromide.

Three of the SNPs located at the 3' end of the *VDR* gene (*BsmI*, *ApaI*, and *TaqI*) are in strong linkage disequilibrium, and the bAt (CCA) haplotype involves *BsmI* rs1544410 C, *ApaI* rs7975232 C, and *TaqI* rs731236 A.

Statistical analysis

Statistical analysis was performed using SPSS version 22.0 (IBM Corp., Armonk, NY, USA). Categorical data are expressed as number (percentage), and the differences between groups were compared using the chi-square test. Continuous data are expressed as mean \pm standard deviation, and the differences between groups were compared using Student's t-test and the Mann-Whitney *U* test. The effects of pre-treatment factors and the SNPs on the response to PEG-IFN-based therapy (in term of SVR) and the presence of advanced liver fibrosis were investigated using univariate and stepwise multivariate logistic regression analyses. A *p*-value <0.05 was considered statistically significant. The chi-square test was used to verify whether the genotype frequencies related to the SNPs in patients with and without SVR were in accordance with the Hardy-Weinberg assumption.

RESULTS

Patient characteristics

A total of 554 Thai patients with chronic HCV infection were enrolled. There were 365 men (65.9%) and the mean age was 50.9 ± 9.2 years. Three hundred and thirty-four patients (60.3%) achieved SVR, 255 patients (46%) were infected with HCV genotype 1, and 179 patients (32.3%) had advanced liver fibrosis. Table 1 shows the participants' baseline demographic and laboratory data according to treatment response at 24 weeks after PEG-IFN discontinuation. Compared to patients with poor response, patients who achieved SVR were older, had lower pre-treatment serum HCV RNA levels, and were less likely to have HCV genotype 1, advanced liver fibrosis, and the unfavorable *IL28B* rs12979860 CT/TT genotypes.

Prevalence of VDR polymorphisms and bAt (CCA) haplotype and their associations with response to PEG-IFN-based therapy

The frequencies of the *VDR* genotypes and the bAt (CCA) haplotype and their associations with response to PEG-IFN-based therapy are shown in Table 2. The genotypic frequencies of the SNPs were in Hardy-Weinberg equilibrium ($p>0.05$) except for *Tru9I* (rs757343). The genotypic frequencies of the SNPs were not different between patients with and without SVR.

The *FokI*, *BsmI*, *Tru9I*, *ApaI*, and *TaqI* polymorphisms were not associated with response to PEG-IFN-based therapy. However, the bAt (CCA) haplotype was significantly associated with poor response to PEG-IFN-based therapy. Overall, 41.4% of patients with the bAt (CCA) haplotype were poor responders, resulting in an OR of 1.82 (95% CI: 1.04-3.18, $p=0.03$) when compared to patients who had other haplotypes (27.9%).

Factors associated with response to PEG-IFN-based therapy

Based on univariate analysis, advanced age, HCV genotype 1, high pre-treatment HCV RNA level, advanced liver fibrosis, *IL28B* rs12979860 CT/TT, and the bAt (CCA) haplotype were significantly associated with poor response to PEG-IFN-based therapy. Stepwise multivariate regression analysis showed that the *IL28B* rs12979860 CT/TT genotypes (OR=3.66, 95%CI: 2.26-5.91, $p<0.001$), the bAt (CCA) haplotype (OR=2.12, 95%CI: 1.11-4.05, $p=0.02$), pre-treatment HCV RNA level (logIU/ml; OR=1.75, 95%CI: 1.33-2.31, $p<0.001$), and advanced liver fibrosis (OR=1.60, 95%CI: 1.05-2.44, $p=0.03$) were independent baseline predictors of poor response to PEG-IFN-based therapy.

Comparison between bAt (CCA) and other haplotypes

Among the participants, 486 (87.7%) had the bAt (CCA) haplotype. To explore the mechanisms underlying the association between this haplotype and poor response to PEG-IFN-based therapy, the baseline patient characteristics, virological factors, and liver fibrosis stage were compared between the chronic HCV patients with the bAt (CCA) haplotype and any other haplotypes (Table 3). There were no differences in sex, age, body mass index, diabetes mellitus, HCV genotype, pre-treatment HCV RNA level, advanced liver fibrosis, or rapid or early virological response. However, patients with the bAt (CCA) haplotype were more likely to drink alcohol and have unfavorable *IL28* rs12979860 CT/TT genotypes, and had lower pre-treatment alanine Aminotransferase (ALT) levels than patients with other haplotypes.

Advanced liver fibrosis and HCV RNA level according to VDR polymorphisms

Five hundred and ten patients (92.1%) had data on liver fibrosis stage. Of these, 269 (52.7%) underwent liver biopsy before treatment with PEG-IFN and ribavirin, and 179 patients (52.3%) were diagnosed with advanced liver fibrosis. Figure 1 shows the percentage of advanced liver fibrosis according to each *VDR* genotype. Chronic HCV patients with the *FokI* rs2228570 TC/CC genotypes (38.8%) were more likely to have advanced liver fibrosis compared to patients with the CC genotype (26.3%). The associations between the *VDR* genotypes and pre-treatment HCV RNA level are shown in Figure 2. Pre-treatment HCV RNA level was not significantly different among patients who had different *VDR* genotypes.

Factors associated with advanced liver fibrosis

Univariate and multivariate analysis results for advanced liver fibrosis are shown in Table 4. Based on the univariate analysis, advanced liver fibrosis (assessed by liver histology or FIB-4 index) was associated with age ≥ 55 years ($p<0.001$), being male ($p=0.08$) and *FokI* TC/CC genotypes ($p=0.007$). Factors with $p<0.1$ in the univariate analysis were included in the multivariate model. Based on the multivariate analysis, age ≥ 55 years (OR=2.28; 95%CI: 1.55-3.37, $p<0.001$) and *FokI* TC/CC genotypes (OR=1.58; 95%CI: 1.03-2.43, $p=0.03$) were independent predictors of advanced liver fibrosis. The *BsmI*, *Tru9I*, *ApaI*, and *TaqI* genotypes, and the bAt (CCA) haplotype were not associated with advanced liver fibrosis.

DISCUSSION

The main findings are that the *FokI* rs2228570 TC/CC genotypes are independently associated with an increased risk of advanced liver fibrosis in Thai chronic HCV patients. Additionally, the *VDR* bAt (CCA) haplotype was independently associated with poor response to PEG-IFN and ribavirin in patients with chronic HCV infection. Interestingly, these associations did not depend on the unfavorable *IL28B* rs12979860 CT/TT genotypes, HCV genotype, or pre-treatment HCV viral load. This study provides evidence indicating the important effects of *VDR* polymorphisms on clinical outcomes in patients with chronic HCV infection.

VDR acts as a ligand-induced transcription factor that binds to 1, 25-dihydroxyVD and exerts its effects by regulating the expression of >900 genes in target tissues (Kato 2000). Recent studies have indicated that 1, 25-dihydroxyVD and *VDR* are important regulators of both the innate and adaptive immune response (Khammissa et al. 2018; Rosen et al. 2012). *VDR* expression is exhibited in almost all immune cells including B cells, activated T lymphocytes, neutrophils, natural killer cells, and antigen-presenting cells (Bhalla et al. 1983; Provvedini et al. 1983). The 1, 25-dihydroxyVD/*VDR* signaling pathway can activate monocytes, inhibit lymphocyte proliferation, and prevent the differentiation of dendritic cell precursors into antigen-presenting cells (Berer et al. 2000). In addition, 1, 25-dihydroxyVD is able to suppress *IFN-γ* transcription via the binding of *VDR* to a silencer region in the *IFN-γ* gene promoter (Saggese et al. 1989). Genetic variations of the *VDR* gene can result in a dysfunctional receptor that subsequently affects the function of VD. *VDR* polymorphisms have been implicated in susceptibility to a variety of autoimmune diseases and cancers in a genome-wide association study and meta-analysis (Raimondi et al. 2009; Ramagopalan et al. 2010). Interestingly, *VDR* gene variants regulate the biological effects of VD independently of the serum 1, 25-dihydroxyVD level (Khammissa et al. 2018).

Regarding the association between *VDR* and response to PEG-IFN-based therapy in chronic HCV infection, a recent *in vitro* study reported that 1, 25-dihydroxyVD promotes the inhibitory effect of IFN-α on HCV replication by enhancing the expression of IFN-stimulated genes (ISGs) [39]. The crosstalk between *VDR* and IFN-α signaling may help to better understand the underlying mechanisms in clinical studies of HCV infection. The results from the current study showed that the *VDR* bAt (CCA) haplotype was associated with poor response to PEG-IFN-based therapy in Thai patients with chronic HCV infection. Although this association has been reported in several previous studies, the findings have been conflicting. Baur *et al.* and García-Martín *et al.* reported that Caucasian patients with chronic HCV infection with the bAt (CCA) haplotype had an impaired response to PEG-IFN and ribavirin [23, 25]. In contrast, Hung *et al.* did not find an association between the bAt (CCA) haplotype and antiviral response to PEG-IFN therapy in 139 Taiwanese patients with chronic HCV genotype-1 infection [22]. The possible reason for the discordant results between the two studies in Asian chronic HCV patients (i.e., our study and the Hung *et al.* study) may be the lower prevalence of the bAt haplotype in the previous study (54.7%) compared to our study (87.7%). The mechanism underlying the association between the bAt (CCA) haplotype and poor response to PEG-IFN is still unclear. It may be due to the effect of this haplotype on the immune response-related IFN signaling cascade [36], as we found no relationship between the bAt (CCA) haplotype and pre-treatment HCV RNA level or liver fibrosis stage. Additionally, our study did not find any relationships between the *VDR* SNPs and the response to

PEG-IFN-based therapy. In contrast, previous studies reported negative associations between the response to PEG-IFN-based therapy and both the *FokI* T allele [23, 40, 41] and the *TaqI* G allele [41] in patients with chronic HCV infection.

With regard to the relationship between *VDR* polymorphisms and clinical outcomes, an *in vitro* analysis showed that *VDR* ligands inhibited transforming growth factor (TGF)- β 1-induced hepatic stellate cell activation and reduced liver fibrosis, while, in a mouse model, genetic knockout of *VDR* expression led to spontaneous liver fibrosis (Ding et al. 2013). The response of human hepatic stellate cells to TGF- β 1 and VD partially depends on the *VDR* polymorphisms (Beilfuss et al. 2015). In patients with chronic HCV genotype 1 infection, low serum VD level is related to severe liver fibrosis (Petta et al. 2010). *VDR* expression is exhibited in hepatic parenchymal and inflammatory cells of patients with chronic HCV infection, and low *VDR* expression is associated with high portal inflammation (Barchetta et al. 2012). The current study showed the *VDR FokI* rs2228570 TC/CC genotypes and age ≥ 55 years were independent risk factors for advanced liver fibrosis in Thai patients with chronic HCV infection. The *BsmI*, *Tru9I*, *ApaI*, and *TaqI* polymorphisms, and the bAt (CCA) haplotype were not associated with advanced liver fibrosis or pre-treatment HCV RNA level in our cohort. Previous research reported that *VDR* variants might be related to decrease HCV infection susceptibility in a Chinese population (Wu et al. 2016). A cohort study of Swiss chronic HCV patients by Baur *et al.* showed the bAt (CCA) haplotype was associated with rapid fibrosis progression and cirrhosis (Baur et al. 2012a). *BsmI* and *TaqI* polymorphisms were associated with liver fibrosis in a Brazilian cohort in a study by Scalioni *et al.* (Scalioni et al. 2018). In Taiwanese patients with chronic HCV infection, the bAt (CCA) haplotype, *ApaI* CC genotype, and *TaqI* AA genotype were associated with increased HCV RNA levels compared to other genotypes/haplotypes (Hung et al. 2016). Furthermore, the *ApaI* CC genotype was an independent factor for the development of HCC in a Taiwanese HCV cohort (Hung et al. 2014).

The *FokI* polymorphism restriction site is located in exon 2 in the 5' coding region of *VDR*. This polymorphism leads to a T>C (threonine to cysteine) substitution and the generation of a protein shortened by three amino acids, which makes the protein less functionally active than the wild type (van Etten et al. 2007). This polymorphism has been implicated in the response to PEG-IFN therapy and several chronic liver diseases including autoimmune hepatitis and HCC in patients with chronic HBV infection (Mostafa-Hedeab et al. 2018; Vogel et al. 2002; Yao et al. 2013). The present study found an association between the *FokI* polymorphism and advanced liver fibrosis in patients with chronic HCV infection. The *FokI* polymorphism genotypic frequencies in a healthy Thai population have been reported to be 15.7% for TT, 43.6% for TC, and 40.7% for CC (Sangkaew et al. 2018). These frequencies are consistent with our results showing frequencies of 20.9% for TT, 48.9% for TC, and 30.2% for CC in Thai patients with chronic HCV infection.

Our study had several limitations. We did not investigate the relationship between the baseline serum VD level and response to PEG-IFN-based therapy because it is influenced by many confounding factors such as sunlight exposure, nutritional status, and liver function. In addition, *VDR* variants can modulate their effects independently of serum VD status (Uitterlinden et al. 2004). Additionally, our study was a retrospective study, and pre-treatment serum samples were

not collected for most of the participants. However, we still attempted to assess associations between the *VDR* variants and clinical outcomes in patients with chronic HCV infection.

CONCLUSIONS

The present study demonstrates an association between the *VDR* bAt (CCA) haplotype and poor response to PEG-IFN plus ribavirin therapy and associations between the *VDR FokI* rs2228570 TC/CC genotypes and advanced liver fibrosis in Thai patients with chronic HCV infection. These results provide helpful clinical information for understanding the causation between *VDR* polymorphisms and clinical outcomes. Further studies are required to elucidate the detailed molecular mechanisms.

- Rujipat Wasitthankasem performed the experiments, approved the final draft.
- Yong Poovorawan contributed reagents/materials/analysis tools, authored or reviewed drafts of the paper, approved the final draft.
- Piyawat Komolmit conceived and designed the experiments, contributed reagents/materials/analysis tools, prepared figures and/or tables, authored or reviewed drafts of the paper, approved the final draft.

Ethics

The study protocol was approved by the Institutional Review Board of the Faculty of Medicine, Chulalongkorn University (IRB number 562/54) and Khon Kaen University (HE561177).

Data Availability

The following information was supplied regarding data availability:
