# Short Title

## Molecular diagnostic of bacterial citrus diseases

### Abstract

#### Background:

In citrus cultures, three species of *Xanthomonas* are known to cause distinct diseases. *X. citri* subsp. *citri* pathotype A, *X. fuscans* subsp. *aurantifolii* pathotypes B and C, and *X. alfalfae* subsp. *citrumelonis*, are the causative agents of canker, A, B, C, and citrus bacterial spots, respectively. These species exhibit different levels of virulence and aggressiveness, and only limited alternatives are currently available for proper and early detection of these diseases in the field. The present study aimed to develop a new molecular diagnostic method based on genomic sequences derived from the four pathotypes of *Xanthomonas*.

#### Results:

Using comparative genomics approaches, primers were synthesized for the identification of the four causative agents of citrus diseases. These primers were validated for their specificity to their target DNA by both conventional and multiplex PCR. Upon evaluation, their sensitivity was found to be 0.02 ng/μl *in vitro* and  $1.5 \times 10^4$  CFU ml<sup>-1</sup> in infected leaves. Additionally, none of the primers were able to generate amplicons in 19 other genomes of *Xanthomonas* not associated with citrus and one species of *Xylella*, the causal agent of citrus variegated chlorosis (CVC). This denotes strong specificity of the primers for the different species of *Xanthomonas* investigated in this study.

#### Conclusions:

We demonstrated that these markers can be used as potential candidates for performing *in vivo* molecular diagnosis exclusively for citrus-associated *Xanthomonas*. The bioinformatics pipeline developed in this study to design specific genomic regions is capable of generating specific primers. It is freely available at <https://git.facom.ufms.br/bioinfo/specific-primers> and can be utilized for any other organism.

**Keywords:** Multiplex PCR; molecular diagnostic; citrus canker; *Xanthomonas*; comparative genomics analysis.

# Introduction

*Xanthomonas* is a genus of phytopathogenic Gram-negative bacteria that cause a variety of diseases in several agricultural commodities, including citrus [1]. These diseases cause huge economic losses to the agricultural sector. Consequently, bacteria from this genus have been targeted as an essential model of study in different pathosystems; for instance, *X. oryzae* in *Oryza* spp. (rice), *X. campestris* in *Brassica* spp. (cabbage), *X. vesicatoria* in *Solanum* spp. (potato), and *X. citri* in *Citrus* spp. (orange) [2–6]. Since *Xanthomonas* are quarantine pests in all these pathosystems and controlling them with agrochemicals is very expensive, early detection is of paramount importance for the control and management of the diseases caused by these bacteria.

The *Xanthomonas* and citrus pathosystem is composed mainly of the following three species: *X. citri* subsp. *citri* pathotype A (*XccA*), *X. fuscans* subsp. *aurantifolii* (*Xau*), and *X. alfalfae* subsp. *citrumelonis* (*Xacm*). These bacteria damage crops and consequently cause losses [7,8] (Table 1). Although the pathosystem as here defined contains only three species, control and eradication efforts are complicated by the genetic diversity of the pathotypes, with varying degrees of aggressiveness and virulence [9,10]. *XccA*, the causative agent of Asian citrus canker, is the most aggressive and virulent among the pathotypes. It infects all cultivated varieties of citrus hosts [11]. In addition to the pathotype A, two other variants, A\* (*XccA\**) and A<sup>W</sup> (*XccA<sup>W</sup>*) have been reported in previous studies [12,13]. Although they are genetically close to type A, these variants are associated with a smaller set of compatible hosts (Table 1) [9,13]. *Xau* is represented by two pathotypes known as B (*XauB*) and C (*XauC*). Pathotype B causes false citrus canker or cancrrosis B, a less aggressive disease than citrus canker that affects sour lemons (*Citrus limon*) severely [10,14]. Pathotype C is the cause of cancrrosis C, which is characterized by induction of hypersensitivity reaction in its hosts as described in ‘Galego’ acid lime (*C. aurantifolia*) [10] and ‘Swingle’ citrumelo (*Citrus paradisi* × *Poncirus trifoliata*) [15]. *Xacm*, or pathotype E, is the causative agent of citrus bacterial spot. It is not classified as cancrrosis since it does not cause typical corticosteroid lesions. However, citrus bacterial spot may be confused with cancrrosis, and pathotype E is pathogenic in ‘Swingle’ citrumelo [16–19].

Due to this considerable diversity in the characteristics of infection and disease spread, these bacteria are one of the main phytosanitary problems that affect and decimate Brazilian orange orchards. As they are cosmopolitan pathogens, they not only harm the economy of Brazil, a major citrus producer, but also the world [20]. Since the management of the plants during cultivation and export are different for each infecting strain, correct diagnosis of the pathogen may reduce damages [9].

Molecular diagnosis is a cost-effective option for identifying pathogens with great genetic proximity. Molecular biology techniques have been extensively used for identifying various species of the genus *Xanthomonas* [21–30]. The genetic diversity of the *Xanthomonas* pathotypes that infect citrus makes their correct identification a challenging task. The low sensitivity and false negative cases of serological tests [13, 31], and false positive amplifications of the molecular tests,

demonstrate the need for new detection tests that are specific and that discriminate the different variants of this class of plant pathogens [32]. Thus, this study aimed to develop a molecular detection method from unique genomic sequences, identified by comparative genomics, which can distinguish different *Xanthomonas* pathotypes infecting *Citrus* spp. These sequences are intended to be used only for detecting *Xanthomonas* isolates obtained from *Citrus* spp..

## Materials and methods

For a better understanding of the methodological steps involved in this study, a flowchart of actions was established (Fig. 1).

### *Comparative Genomics for identification of pathotype-specific regions*

In order to identify the pathotype-specific regions, we have built a very simple 4-step pipeline. The input for the method is the set of nucleotide FASTA sequences from the four genomes of the genus *Xanthomonas*, belonging to each of the disease-causing-pathotypes in citrus obtained from NCBI (Table 2). The first step is to pre-process sequences, to concatenate all contigs of each genome, in case of being in a draft condition, and also to concatenate all FASTA genome files in a unique one. This file is the input for the second step, where mauveAligner, from the Mauve package [33], is used to build a multiple sequence alignment. MauveAligner outputs unique regions defined as regions that are present in one genome but absent from at least one of the other genomes. We call these unique regions ‘Mauve islands’, and they are the input to a custom Perl script to pick out specific regions from each genome. The third step is to post-process data just to separate all specific regions in distinct FASTA files. The candidate regions found at this point are double-checked in the fourth step, using BLASTn [34]. BLASTn is then performed on each candidate region from genome *G* against the set of all genomes except *G*. The final output of this workflow consists of the list of all unique regions with no hits in this BLASTn run. This comparative genomics pipeline is freely available at <https://git.facom.ufms.br/bioinfo/specific-primers>, including a short and simple tutorial for installation and using, and can be used for any set of genomes in a regular Linux system.

Other specific regions finders are available in the literature, for instance Insignia [35]. Insignia is a web application where the user can find specific regions from a genomic sequence, but only against sequences available currently in the previously populated database by the authors. On the other hand, our tool is a very easy-to-install and easy-to-use stand-alone tool where the user can find specific regions against any set of genomes (available in databases or not), even draft ones.

### *Selection of specific sequences and production of primers*

The sets of unique regions determined for each genome were used as a reference for the selection of the primers using Primer-BLAST tool [36]. To verify the specificity of each primer to their target DNA, each generated primer was subjected to local alignment against *Xanthomonas* pathotypes that infect citrus using BLASTn. Primers that demonstrated specificity and ability to form amplicons of different sizes among the analyzed pathotype were selected for *in vitro* empirical verification.

#### *In silico* evaluation of possible false positive amplifications

To verify false positive amplifications from other *Xanthomonas* species or other plant-associated microorganisms whose DNA could be extracted from infected plant tissue, the primers were compared against all sequences available at GenBank (using BLASTn against NT database).

#### *Bacterial strain and growth conditions*

For the biological assays, 16 strains belonging to the pathotype *XccA* (7 strains), *XauB* (2 strains), *XauC* (5 strains), and *Xacm* (2 strains) were selected. These strains came from culture collections maintained by the Agronomy School of the University of São Paulo (ESALQ) and by the Faculty of Agrarian and Veterinary Sciences of the State University of São Paulo (Campus Jaboticabal), both in the state of São Paulo, Brazil. The isolates were reactivated in nutrient agar medium - NA (5 g/l peptone, 3 g/l beef extract, 15 g/l agar, pH 6.8-7.0) and incubated at 28°C for 48 hours for *XccA* and *Xacm* strains and 96 hours for *XauB* and *XauC* strains. Then, a colony was grown in nutrient broth medium (NB; NA without agar) under agitation at 250 rpm at 28 °C for 12 hours.

In addition to the citrus-pathogenic *Xanthomonas* isolates, the markers have also been tested against other *Xanthomonas* strains that are not known to infect citrus: *X. axonopodis* pv. *vignicola* FDC 1701 (IBSBF 1739), *X. axonopodis* pv. *vesicatoria* 1387 (IBSBF 1387), *X. axonopodis* pv. *vesicatoria* FDC 1689 (IBSBF 331), *X. axonopodis* pv. *allii* 1770 (IBSBF 1770), *X. axonopodis* pv. *phaseoli* IAC 11280, *X. alfalfae* subsp. *alfalfae* FDC 1711 (IBSBF 3174), *X. axonopodis* pv. *passiflorae* M89, *X. axonopodis* pv. *patelli* FDC 1727 (IBSBF 3181), *X. axonopodis* pv. *coracanae* FDC 1729 (IBSBF 3187), *X. axonopodis* pv. *manihotis* 1954 (IBSBF 1954), *X. axonopodis* pv. *phaseoli* var. *fuscans* IAC13755, *X. citri* pv. *rhynchosiae* FDC 1721 (IBSBF 3184), *X. axonopodis* *vasculorum* 2008 (IBSBF 2008), *X. axonopodis* pv. *axonopodis* FDC 1696 (IBSBF 1444), *X. axonopodis* pv. *dieffenbachiae* 1478 (IBSBF 1478), *X. axonopodis* pv. *glycines* FDC 1694 (IBSBF 333), *X. citri* pv. *cajani* FDC 1718 (IBSBF 3180), *X. citri* pv. *sesbaniae* FDC 1719 (IBSBF 3179), and against *Xylella fastidiosa* strain 9a5c [37], a phytopathogenic bacterium that is disseminated by insects among citrus.

# *Extraction of DNA from isolates*

The DNA of the isolates was extracted with the *Spin Tissue*<sup>™</sup> *Core Kit* (Qiagen Biosciences, MD, USA) following the manufacturer's recommendations.

# *Inoculation of the isolates in the leaves and genomic DNA extraction from bacterial cells in exudate*

The bacteria were inoculated into Hamlin-type orange leaves with a needleless syringe. The syringe was pressed lightly into the abaxial part of the leaf to allow entry of the phytopathogen into the intercellular space of the leaf. A leaf from the same plant was inoculated likewise with ultrapure water as a negative control. Immediately after the inoculation, the inoculated area was cut into small pieces, and bacterial exudation was carried out.

To mimic the condition of naturally infected plants, spray inoculation methods were also used. Spray inoculation was performed in 'Pera-rio' orange leaves according to the methods described by Yan and Wang [38]. After 30 days of inoculation, leaves containing lesions were detached from the plants and each lesion was cut into small pieces to get the exudate with bacteria. The inoculated area/lesions were submerged in 1 mL of ultrapure water for 30 min and agitated for 5 min to facilitate bacterial exudation from the leaf. After agitation, genomic DNA extraction from bacterial cells in the exudate was performed with a rapid manual DNA extraction protocol. The exudate was centrifuged at 16,000 x g for 4 min at 4 °C and washed twice with an isotonic solution (33 mM KH<sub>2</sub>PO<sub>4</sub>, 60 mM K<sub>2</sub>HPO<sub>4</sub>, 7.6 mM (NH<sub>4</sub>)<sub>2</sub>SO<sub>4</sub>, 3.3 mM sodium citrate, and 4.0 mM MgSO<sub>4</sub>). The pellet was resuspended in lysis buffer (10 mM Tris-HCl 1 M, pH 8.0; 100 mM EDTA 0.5 M, pH 8.0; 10 mM NaCl 5 M; 0.5% of 10% SDS), and isotonic solution with subsequent extraction with phenol and incubation with RNase (5 mg/ml) for 1 hour at 37 °C. After further extraction with phenol, the DNA was precipitated with ethanol and sodium acetate (7.5 M, pH 7.4) and then diluted in Tris-EDTA buffer 10:0.1.

# *PCR Conditions*

PCR amplifications were carried out in a final volume of 25 µl. The final concentrations of the reagents in the reaction were: 2 mM MgCl<sub>2</sub>, 200 µM dNTPs, 0.2 µM of each primer (Forward and Reverse), 1 unit of Taq DNA polymerase<sup>™</sup> (CellCo, SP, Brazil) and 0.4 ng of the DNA sample from the isolates grown in medium or 1 µl of the total DNA extracted from the exudates. The initial denaturation temperature was 94 °C for 3 min, followed by 30 cycles of denaturation at 94 °C for 45 seconds, annealing at 59 °C for 45 seconds and extension at 72 °C for 45 seconds, followed by a final extension at 72 °C for 5 min. Verification of PCR amplicons was established by applying 10 µl of the PCR product in 3.0% (w/v) agarose gel.

204

## 205 *Multiplex PCR*

206 Multiplex PCR amplifications (mPCR) were also performed in final volumes of 25  $\mu$ l. The final  
207 concentration of the reagents in the reaction was the same as on the conventional PCR, except for  
208 increasing the concentration of dNTPs to 400  $\mu$ M and using 0.2  $\mu$ M of each primer (Forward and  
209 Reverse) of all four primer pairs (XccAm, XauBm, XauCm, and Xacmm) in the same reaction.

210

## 211 *Sensitivity of PCR*

212 To verify the sensitivity of the PCR reaction *in vitro*, progressive dilutions of DNA from the  
213 isolates were performed until the amplification checked the minimal DNA concentration  
214 detectable by PCR. The isolates used in this test were *XccA* strain 306 (*XccA306*), *XauB* strain  
215 FDC 1561 (*XauB1561*), *XauC* strain FDC 1559 (*XauC1559*), and *Xacm* strain 1510 (*Xacm1510*).  
216 For leaf testing, sensitivity was found from minimal inoculations of leaf bacteria ( $1.5 \times 10^7$ ,  
217  $1.5 \times 10^6$ ,  $1.5 \times 10^5$ ,  $1.5 \times 10^4$ ,  $1.5 \times 10^3$  CFU ml<sup>-1</sup>) with consequent lower extraction of DNA from the  
218 exudate.

219

## 220 *In-silico PCR*

221 The *in-silico* PCR was performed using the tool ‘*In silico* PCR amplification’ [39] available at  
222 <http://insilico.ehu.eus/>.

223

## 224 Results

### 225 Specific sequences and selection of primers

226 Mauve found 5,217 islands. From these, 173 candidates for specific regions of *XccA306*, 59 of  
227 *XauB1561*, 55 of *XauC1559* and 38 of *Xacm1510* were identified. After the BLAST refinement  
228 step, we found 135 specific regions of *XccA306*, 23 of *XauB1561*, 12 of *XauC1559*, and 33 of  
229 *Xacm1510*. From the sequences, a pair of primers were developed for each *Xanthomonas*  
230 pathotype. Each marker was developed using a different amplicon size, allowing its differentiation  
231 from the other pathotypes. The primer sequences and their respective amplicons are described in  
232 Table 3. Primer XccAm appears to amplify part of a hypothetical gene and a transcriptional  
233 activator FtrA, generating a 509bp amplicon. Primer XauBm amplifies an intergenic region  
234 (434bp); primer XauCm amplifies part of a hypothetical gene (160bp) and primer Xacmm  
235 amplifies part of a gene encoding a D-alanyl-D-alanine synthetase A (115bp). Due to the

intraspecific genetic proximity between *Xanthomonas*, a reference genome was used for each target pathotype.

BLASTn analysis of the primers against NCBI's non-redundant sequence database NT revealed high sequence specificity (100% identity) for the citrus-associated *Xanthomonas* pathotypes in all cases, and also for other non-citrus-associated *Xanthomonas* species (80 to 100% identity). However, *in silico* analysis of the possible amplicons generated in the non-citrus-associated species indicated different sizes from those expected for the defined targets. Only one pair of primers (*XauC*) indicated possible amplification in the case of *Stenotrophomonas maltophilia*, a bacterium that lives in aqueous environments, soil, and plants. However, the coverage of the *XauCm* forward and reverse primers on the genome of *Stenotrophomonas maltophilia* is not complete and the size of *in silico* amplicon is not similar to that of previously predicted amplicon for *XauC*.

#### Specificity of molecular markers and sensitivity of PCR

The specificity for citrus-associated *Xanthomonas* verified *in silico* was confirmed as shown in Fig. 2. Primer *XccAm* generated an amplicon of size 509 bp, primer *XauBm* generated an amplicon of 434 bp, primer *XauCm* generated an amplicon of 160 bp, and primer *Xacmm* generated an amplicon of 115 bp for their corresponding pathotypes. All markers generated unique amplicons for their respective target DNAs without cross-amplifications for other investigated strains. Progressive dilutions of the target DNA verified the *in vitro* sensitivity. The minimum concentrations that allowed PCR amplification were 0.02 ng/μl for *XccA* (~70 cells), 0.03 ng/μl for *XauB* (~100 cells), 0.12 ng/μl for *XauC* (~400 cells), and 0.07 ng/μl *Xacm* (~ 200 cells) (Fig. 3).

These results were reproducible when the markers were subject to multiplex PCR with their respective target DNAs and with the DNAs of the four pathotypes (Fig. 4). Despite the findings *in silico*, when tested with the other 18 species of *Xanthomonas* that do not infect citrus, the markers developed for *XccA*, *XauB*, and *XauC* did not demonstrate amplification with any of these isolates (Fig. 5). In contrast, *Xacmm* amplified a weak fragment for five of the investigated strains (*X. axonopodis* pv. *vesicatoria* 1689, *X. axonopodis* pv. *passiflorae* M89, *X. axonopodis* pv. *manihotis* IBSBF1954, *X. axonopodis* pv. *axonopodis* 1696, and *X. axonopodis* pv. *glycines* 1694), but with a different amplicon size (~125 bp) without correspondence to the established standards for citrus-associated xanthomonads. Although now empirically shown, this result does not affect detection since none of these strains with false positive amplification infects citrus. Finally, no amplicons were generated due to cross-amplification with DNA from *Xylella*, a plant pathogen that also infects citrus.

*In vivo* assays replicated the results obtained *in vitro*. The markers were specific for the inoculated bacterium (Fig. 6) and citrus canker lesions (Fig. 7) without cross-reaction with any other DNA

that may have been extracted from exudate, including endophytic DNA. Additionally, the plants inoculated with water did not amplify with any marker tested, confirming the specificity for bacteria of the genus *Xanthomonas* (Fig. 6). For the exudate, the minimum concentrations that allowed PCR amplification were approximately  $1.5 \times 10^4$  CFU mL<sup>-1</sup> for *XccA*,  $1.5 \times 10^5$  CFU mL<sup>-1</sup> for *XauB*,  $1.5 \times 10^5$  CFU mL<sup>-1</sup> for *XauC*, and  $1.5 \times 10^4$  CFU mL<sup>-1</sup> for *Xacm* (Fig. 6).

## Discussion

Currently, the citrus disease of greatest concern to citrus growers worldwide is greening, also known as Huanglongbin (HLB) [40]. However, citrus canker still is a problem for the citrus industry due to its virulence and rapid propagation characteristics [41]. Coupled with deficiencies in maintaining legislation and inspecting contaminated orchards, citrus canker causes great losses to farmers worldwide [42]. Thus, the correct identification of the pathogen is crucial to restrain this disease, given that the management of plants during cultivation and export may differ with each infecting strain [9].

Due to its high virulence and host range, the development of diagnostics is aimed towards the detection of *XccA* strains, the causative agent of Asian citrus canker. Currently, field detection is performed through rapid tests based on the immune-identification of its proteins as Xcc ImmunoStrip® Test, Agdia, Inc. (Catalog number: STX 92200), but there are several studies that have developed serological diagnoses for *XccA* [14,28,43–47]. However, these tests have low sensitivity, and in some cases, false negative results have already been reported in phenotypically different strains of *XccA* [13,31]. Additionally, its high cost per sample is a significant disadvantage when compared to methods based on molecular biology techniques.

Some studies have already demonstrated the potential of molecular diagnosis for *Xanthomonas*, more specifically for *XccA* strains, based on several techniques such as conventional PCR, multiplex PCR, real-time PCR (qPCR), nested-PCR, loop-mediated isothermal amplification (LAMP-PCR), droplet digital polymerase chain reaction (ddPCR), BOX-PCR, and FISH [22–27,29,30,48–53]. The wide variety of techniques used in the molecular diagnostics developed for citrus canker solved the problem of cost and low sensitivity presented by serological methods. However, the false-positive amplifications already highlighted among strains of genetically close variants, such as *XccA* and *Xau*, once again reveal the need for new detection methods that are specific and that distinguish the different pathotypes of these plant pathogens [32]. Thus, to the best of our knowledge, this is the first study that presents a single method that simultaneously distinguishes the four pathotypes of *Xanthomonas* that infect citrus. In this method, each of these four pathotypes will have its own distinct amplicon.

It is important to emphasize that the method presented here is not a general method for identifying the *Xanthomonas* strains discussed here with respect to other bacterial isolates. The application setting for which the detection tool was designed is for strains isolated from citrus trees only.

The specificity verified in the results enables the adoption of individualized management for each pathotype, which could reduce cultivation losses. Although BLASTn analysis of primer sequences against genomes deposited in NCBI has shown that non-specific binding to other *Xanthomonas* genomes may occur, two factors must be considered with respect to false positives: a) a possible PCR product generated for other species of *Xanthomonas* would likely have a different size from that observed for citrus pathotypes; b) as far as we know, the only members of the *Xanthomonas* genus that infect citrus are the ones considered here. Therefore we think that the probability of amplification of false positives in samples from diseased trees is small, which is corroborated by the analyses presented in Fig. 5.

The sensitivity of the PCR *in vivo* tests shows the potential of its usage as a preventive detection tool since it can detect as little as  $10^4$  CFU of bacteria, allowing the pathogen to be screened during the colonization and survival phase of its life cycle, avoiding its later dissemination and infection of healthy plants. Remaining canker lesions under favorable conditions have a concentration of up to  $10^7$ - $10^8$  CFU of viable bacteria for a new infection [54,55].

Another potential benefit of the correct detection of *Xanthomonas* strains presented here is its use on seedlings that will be distributed to rural producers, since the introduction of infected seedlings in orchards is one of the mechanisms of dissemination of the bacteria to healthy plants [10,19,56]. Additionally, our method can be used for a biogeographic survey of the pathotypes, to trace the distribution profile among citrus orchards throughout the world. This becomes important for epidemiological surveillance of this phytopathogen, as this type of analysis is typically hampered by the lack of adequate molecular typing techniques for surveillance and outbreak investigation [25].

Our approach is based on conventional PCR because it is an accessible and inexpensive technique, without compromising the quality of the analysis. Furthermore, the present study has established the detection of all pathotypes in the same PCR reaction, as demonstrated in the results of multiplex PCR. This technique increases the importance of the detection method, since the same sample can be submitted to a PCR reaction with all the primers, reducing the time for obtaining the result. Another technique used in our study, which could enhance the speed of detection, was the extraction of total DNA from the exudate of the leaves. This extraction takes less than four hours to be carried out; thus, there is no need to wait for several days for bacterial growth from its lesion isolation.

Collectively, both experimental procedures make the methodology feasible on a large scale and at a reduced cost. It is important to highlight that the variable size of the PCR products for each pathotype was established to facilitate its identification, and the use of PCR-RFLP would only be justifiable to verify genetic diversity within species, which is not the objective of this study. Moreover, although we did not use the TaqMan system to verify the potential of these molecular markers in the identification of these pathogens, it is likely that the use of this system would only make detection sensitivity higher than that observed by conventional PCR, as described for other

organisms [57–59]. However, the cost of analysis would be higher, which could significantly burden large-scale analyses.

Thus, our results not only allow the correct identification of the four pathotypes of *Xanthomonas* that infect citrus, but they also point to a possible bioinformatics pipeline for the production of species-specific molecular markers for any set of genomes defined by the user. The high specificity and sensitivity obtained demonstrated the effectiveness of our bioinformatics analysis.

## Conclusions

In summary, the identification of unique sequences from different genomes, using comparative genomics, allowed the development of specific molecular markers. This is the first conventional or multiplex PCR-based method that discriminates four different citrus-associated *Xanthomonas* pathotypes. This study further describes an effective pipeline for the generation of species-specific molecular markers.

## Author's contributions

NFA, GPT, DA, AMV, JCS, and LMM designed and implemented the comparative genomics workflow.

LMM, JAF and JBJ select the strains.

NFA, DA, NPF, and LMM designed and selected the pathotypes specific primers.

NPF, EBF, WLC, ABS, IFC, and RABA performed *in vitro* assays.

FMSC, CGLB, NFP performed *in vivo* assays.

NPF, NFA, and LMM analyzed the results and drafted an initial version of the manuscript.

AMV, RABA, GPT, NFA, JCS, and LMM wrote the final version of the manuscript.

## Acknowledgments

Thanks to all members of the Laboratory of Biochemistry and Molecular Biology (LBBM, Federal University of Ouro Preto, UFOP) and the Laboratory of Biochemistry and Molecular Biology of Faculty of Agrarian and Veterinary Sciences UNESP, Jaboticabal campus for their support. Thanks, Dr. Fabrício Jaciani, FUNDECITRUS researcher, for the critical help in finalizing this paper.

Figure captions

**Figure 1: Experimental design.** Stages and procedures from the development of the *in silico* stages to the validation of the molecular results of the plant diagnosis.

**Figure 2: Specificity of molecular markers *in vitro*.** Conventional PCR electrophoresis using Xcc-specific oligonucleotides for *Xanthomonas citri* subsp. *citri* pathotypes A (*XccA*) and A\* (*XccA*\*) with a 509 bp amplicon, (A) *Xanthomonas fuscans* subsp. *aurantifolii* pathotype B (*XauB*) with 434 bp amplicon, (B) *Xanthomonas fuscans* subsp. *aurantifolii* pathotype C (*XauC*) with 160 bp amplicon, (C) *Xanthomonas alfalfae* subsp. *citrumelonis* (*Xacm*) with an amplicon of 115 bp, and (D) MW: molecular weight (ladder 100 bp).

**Figure 3: Progressive DNA dilutions demonstrating the sensitivity of PCR.** (A) *XccA* (0.02 ng/μl, ~70 cells), (B) *XauB* (0.03 ng/μl, ~100 cells), (C) *XauC* (0.12 ng/μl, ~400 cells), and (D) *Xacm* (0.07 ng/μl, ~200 cells). MW: molecular weight (ladder 100 bp).

**Figure 4: Multiplex PCR of *Xanthomonas* that infect citrus.** (A) Multiplex PCR electrophoresis containing the combination of the DNA of one species with all pairs of specific primers generating only their amplicon (lines 2 to 5). MP - Combination of DNAs of all pathotypes with all primers (line 6). MW: molecular weight (ladder 100 bp) and (B) Theoretical electrophoresis of multiplex PCR.

**Figure 5: Multiplex PCR electrophoresis of *Xanthomonas* spp. that do not infect citrus.** (1701) - *X. axonopodis* pv. *vignicola* strain 1701; (1387) - *X. axonopodis* pv. *vesicatoria* strain IBSBF1387; (1689) - *X. axonopodis* pv. *vesicatoria* strain 1689; (1770) - *X. axonopodis* pv. *allii* strain IBSBF1770; (11280) - *X. axonopodis* pv. *phaseoli* strain IAC11280; (1711) - *X. alfalfae* subsp. *alfalfae* strain 1711; (M89) - *X. axonopodis* pv. *passiflorae* strain M89; (1727) - *X. axonopodis* pv. *patelli* strain 1727; (1729) - *X. axonopodis* pv. *coracanae* strain strain 1729; (1954) - *X. axonopodis* pv. *manihotis* strain IBSBF 1954; (13755) - *X. axonopodis* pv. *phaseoli* var. *fuscans* strain IAC13755; (1721) - *X. citri* pv. *rhynchosiae* strain 1721; (2008) - *X. axonopodis* pv. *vasculorum* strain IBSBF 2008; (1696) - *X. axonopodis* pv. *axonopodis* strain 1696; (1478) - *X. axonopodis* pv. *dieffenbachiae* strain IBSBF 1478; (1694) - *X. axonopodis* pv. *glycines* strain 1694; (1718) - *X. citri* pv. *cajani* strain 1718; (1719) - *X. citri* pv. *sesbaniae* strain 1719; (Xf) *Xylella fastidiosa* strain 9a5c. MW: molecular weight (ladder 100 bp).

663

664 **Figure 6: Specificity and sensitivity of amplification by *in vivo* PCR.** Conventional PCR of  
 665 bacterial exudate using the specific markers for *XccA*, *XauB*, *XauC*, and *Xacm*. The minimum  
 666 concentration detected by PCR (A) for *XccA* was  $1.5 \times 10^4$  CFU ml<sup>-1</sup>, (B) for *XauB* was  $1.5 \times 10^5$   
 667 CFU ml<sup>-1</sup>, (C) for *XauC* was  $1.5 \times 10^5$  CFU ml<sup>-1</sup>, and (D) for *Xacm*  $1.5 \times 10^4$  CFU ml<sup>-1</sup>. PC: positive  
 668 control. NC: negative control of leaves inoculated with water. MW: molecular weight (ladder 100  
 669 bp).

670

671 **Figure 7: Specificity of the markers in exudate samples from leaves inoculated by spraying**  
 672 **with *XccA* strain.** PC: Positive control *in vitro* DNA extraction; *XccA*, *XauB*, *XauC*, and *Xacm*  
 673 PCR using *XccAm*, *XauBm*, *XauCm*, and *Xacmm* specific markers respectively, for exudate  
 674 samples of citrus canker lesions induced by *XccA306*. MW: molecular weight (ladder 100 bp).
