**Background:** Esophageal squamous cell carcinoma (ESCC) is a subtype of esophageal cancer with high incidence and mortality. Due to the poor five-year survival rates of patients with ESCC, exploring novel diagnostic markers for early ESCC is emergent. Collagen, the abundant constituent of extracellular matrix, plays a critical role in tumor growth and epithelial-mesenchymal transition. However, the clinical significance of collagen genes in ESCC has been rarely studied. In this work, we systematically analyzed the gene expression of whole collagen family in ESCC, aiming to search for ideal biomarkers.

**Methods:** Clinical data and gene expression profiles of ESCC patients were collected from The Cancer Genome Atlas (TCGA) and the Gene Expression Omnibus (GEO) databases. Bioinformatics methods, including differential expression analysis, survival analysis, gene sets enrichment analysis (GSEA) and co-expression network analysis, were performed to investigate the correlation between the expression patterns of 44 collagen family genes and the development of ESCC.

**Results:** 22 genes of collagen family were identified as differentially expressed genes (DEGs) in both the two datasets. Among them, COL1A1, COL10A1 and COL11A1 were particularly up-regulated in ESCC tissues compared to normal controls, while COL4A4, COL6A5 and COL14A1 were notably down-regulated. Besides, patients with low COL6A5 expression or high COL18A1 expression showed poor survival. In addition, a 7-gene prediction model was established based on collagen gene expression to predict patient survival, which had better predictive accuracy than the tumor-node-metastasis (TNM) staging based model. Finally, GSEA results suggested that collagen genes might be tightly associated with PI3K/Akt/mTOR pathway, p53 pathway, apoptosis, cell cycle, etc.

**Conclusion:** Several collagen genes could be potential diagnostic and prognostic biomarkers for ESCC. Moreover, a novel 7-gene prediction model is probably useful for predicting survival outcomes of ESCC patients. These findings may facilitate early detection of ESCC and help improves prognosis of the patients.

## 20 Abstract

21 **Background:** Esophageal squamous cell carcinoma (ESCC) is a subtype of esophageal cancer  
22 with high incidence and mortality. Due to the poor five-year survival rates of patients with ESCC,  
23 exploring novel diagnostic markers for early ESCC is emergent. Collagen, the abundant  
24 constituent of extracellular matrix, plays a critical role in tumor growth and epithelial-  
25 mesenchymal transition. However, the clinical significance of collagen genes in ESCC has been  
26 rarely studied. In this work, we systematically analyzed the gene expression of whole collagen  
27 family in ESCC, aiming to search for ideal biomarkers.

28 **Methods:** Clinical data and gene expression profiles of ESCC patients were collected from The  
29 Cancer Genome Atlas (TCGA) and the Gene Expression Omnibus (GEO) databases.  
30 Bioinformatics methods, including differential expression analysis, survival analysis, gene sets  
31 enrichment analysis (GSEA) and co-expression network analysis, were performed to investigate  
32 the correlation between the expression patterns of 44 collagen family genes and the development  
33 of ESCC.

34 **Results:** 22 genes of collagen family were identified as differentially expressed genes (DEGs) in  
35 both the two datasets. Among them, COL1A1, COL10A1 and COL11A1 were particularly up-  
36 regulated in ESCC tissues compared to normal controls, while COL4A4, COL6A5 and COL14A1  
37 were notably down-regulated. Besides, patients with low COL6A5 expression or high COL18A1  
38 expression showed poor survival. In addition, a 7-gene prediction model was established based on  
39 collagen gene expression to predict patient survival, which had better predictive accuracy than the  
40 tumor-node-metastasis (TNM) staging based model. Finally, GSEA results suggested that collagen  
41 genes might be tightly associated with PI3K/Akt/mTOR pathway, p53 pathway, apoptosis, cell  
42 cycle, etc.

43 **Conclusion:** Several collagen genes could be potential diagnostic and prognostic biomarkers for  
44 ESCC. Moreover, a novel 7-gene prediction model is probably useful for predicting survival  
45 outcomes of ESCC patients. These findings may facilitate early detection of ESCC and help  
46 improves prognosis of the patients.

47

## 48 Introduction

49 Esophageal cancer is the seventh most commonly diagnosed cancer and the sixth leading cause of  
50 cancer death (Bray et al. 2018). It is classified into two histological subtypes, esophageal  
51 adenocarcinoma (EAC) and esophageal squamous cell carcinoma (ESCC), the latter of which is  
52 the predominant type worldwide (Pennathur et al. 2013). Despite the effective treatments (e.g.  
53 surgery, chemotherapy and radiotherapy) for ESCC, the 5-year survival rates of patients with  
54 advanced ESCC are still less than 20% (Codipilly et al. 2018). However, the survival rates could  
55 be improved to over 80% if patients were diagnosed with an early stage (Lao-Sirieix & Fitzgerald  
56 2012; Wang et al. 2004). Although a few tumor markers, carcinoembryonic antigen (CEA),  
57 carbohydrate antigen (CA) 19-9, and squamous cell carcinoma (SCC) antigen, have been used in  
58 the diagnosis of ESCC, they are not suitable for early detection due to the lack of sensitivity

59 (Kosugi et al. 2004). Thus, it is urgent to search for novel biomarkers to help early detection of  
60 ESCC and improve survival rates of the patients.

61 Collagen is the most abundant extracellular matrix protein that promotes cell growth and  
62 provides mechanical resilience of connective tissues (Sorushanova et al. 2018). The collagen  
63 family comprises 28 types with different  $\alpha$  Chains encoded by more than 40 genes (Ricard-Blum  
64 2011). It has been reported that the expression of collagen-encoding genes was significantly related  
65 to the prognosis of certain types of cancers (Giussani et al. 2018; Liu et al. 2018; Rong et al. 2018;  
66 Shen et al. 2016; Zhang et al. 2018c). In addition, a couple of collagen genes, such as COL11A1  
67 and COL6A1, were expressed aberrantly in ESCC tissues and possibly affected the progression of  
68 ESCC (Fan et al. 2012; He et al. 2017; Zhang et al. 2018a). However, most of these works focused  
69 on specific collagen genes, and the potential roles of other members remain to be clarified.

70 Here we provided a systematic analysis of gene expression of the whole collagen family and its  
71 corresponding clinical significance in ESCC. Clinical data and gene expression profiles of ESCC  
72 patients were extracted from The Cancer Genome Atlas (TCGA) and the Gene Expression  
73 Omnibus (GEO), two public databases with substantial information about cancers. Different  
74 bioinformatics methods, including differential expression analysis, survival analysis, pathway  
75 analysis and co-expression network analysis were used to analyze the data to sift important hits  
76 possibly involved in the initiation and development of ESCC. According to collagen family genes,  
77 we also established a prediction model with high performance to predict the prognosis of ESCC  
78 patients. Collectively, our works mainly explored the relation of collagen gene expression to ESCC  
79 and illuminated the potential mechanism.

80

## 81 **Materials & Methods**

### 82 **Patient data**

83 Basic data of ESCC patients were downloaded from the TCGA database  
84 (<https://portal.gdc.cancer.gov/>) and the GSE53625 dataset of the GEO database  
85 (<https://www.ncbi.nlm.nih.gov/geo/query/acc.cgi?acc=GSE53625>), 95 cases from TCGA and 179  
86 cases from GSE53625. Univariate and multivariate Cox regression analyses were carried out to  
87 investigate the correlation between overall survival and clinicopathological characteristics of the  
88 patients by SPSS (v23.0). The relations between collagen family gene expression and  
89 clinicopathological characteristics of the patients were examined using Pearson correlation  
90 analysis via SPSS.

91

### 92 **Differential expression analysis**

93 Gene expression profiles of tumor and adjacent normal tissues in ESCC patients were also obtained  
94 from the two datasets. 81 of 95 patient cases in TCGA and all patient cases in GEO had RNA-  
95 sequence data. In total, 81 tumor samples with 11 normal controls from TCGA and 179 tumor  
96 samples with 179 normal controls from GEO (Li et al. 2014) were included in analysis (each  
97 sample was taken from a different patient). Differential expression analysis was conducted using  
98 the edgeR (Robinson et al. 2010) and the limma (Ritchie et al. 2015) packages respectively for

99 TCGA and GEO data by R software (<https://www.r-project.org/>, v3.5.3). Gene expression levels  
100 were normalized by the `calcNormFactors` function in `edgeR` (Law et al. 2016) and by the  
101 `normalizeBetweenArrays` function in `limma` (Smyth & Speed 2003), to make the expression  
102 distributions of each sample are similar across the entire matrix. Then based on the exact test in  
103 `edgeR` which is analogous to Fisher's exact test (Robinson et al. 2010) and the Empirical Bayes  
104 statistical test in `limma` (Phipson et al. 2016), fold change (FC),  $P$  value and false discovery rate  
105 (FDR) (or adjusted  $P$  value) were figured out to show the expression difference between tumor  
106 and normal samples. Genes with  $P < 0.05$  and  $FDR < 0.05$  were considered as differentially  
107 expressed genes (DEGs). Accordingly, DEGs of collagen family were identified. Then heatmaps,  
108 boxplots and Venn diagram were drawn by R software.

109

### 110 **Survival analysis**

111 First, hazard ratio (HR) and  $P$  value of each DEG of collagen family were figured out based on  
112 gene expression and overall survival of patients by the univariate Cox regression model with the  
113 `survival` package through R software. The HR is an estimate of the ratio of the hazard rate in the  
114 treated versus the control group (Spruance et al. 2004), while in this study it is defined as the  
115 hazard in the high expression group divided by the hazard in the low expression group.  $HR > 1$   
116 and  $HR < 1$  mean higher expression of the gene is associated with worse and better overall survival  
117 respectively. Survival curves were plotted according to the Kaplan-Meier method and compared  
118 by the log-rank test using the `survival` and the `qvalue` packages in R.  $P < 0.05$  was considered  
119 statistically significant.

120

### 121 **Prediction models**

122 Prediction models were established to predict patient survival based on gene expression of 22  
123 DEGs of collagen family and overall survival of patients by the multivariate Cox regress analysis  
124 with the `survival` package via R software. Several candidate genes were eventually selected out by  
125 the analysis to form the model, with a formula calculating the risk score of each patient. The  
126 general formula is given below:

127

$$\text{Risk score} = \sum_{i=1}^n \text{Coef}_i \times \text{Exp}_i \quad (1)$$

128 where  $n$ ,  $\text{Coef}$ , and  $\text{Exp}$  indicate the number of included genes, the coefficient of each gene, and  
129 gene expression level, respectively. The coefficients were estimated based on the relative  
130 contributions of each collagen gene. A patient's risk score was calculated as the sum of the  
131 expression levels of each gene multiplied by its corresponding coefficient. Similar methods have  
132 been adopted by earlier studies (Beer et al. 2002; Lossos et al. 2004; Wang et al. 2018). Then  
133 receiver operating characteristic (ROC) curves were plotted based on the risk scores and overall  
134 survival of patients by the `survivalROC` package in R, with area under curve (AUC) values which  
135 represented the accuracy of predicting 3-year survival. Also, survival curves were obtained by  
136 dividing the patients into high- and low-risk groups according to the median risk score using the  
137 `survival` package.

138

### 139 **Pathway analysis**

140 Potential mechanism of collagen family genes was explored by the gene sets enrichment analysis  
141 (GSEA), a method to determine whether members of a previously defined gene set are correlated  
142 with the phenotypic class distinction (Subramanian et al. 2005). GSEA was conducted using the  
143 gene expression profiles of patients' tumor samples via javaGSEA software  
144 (<http://software.broadinstitute.org/gsea/downloads.jsp>), and the patient samples were divided into  
145 high- and low-risk groups in half according to the risk scores obtained by the collagen-DEGs-  
146 based prediction models (Chai et al. 2018; Zhang et al. 2017; Zhao et al. 2017). Oncogenic  
147 Signatures Gene Sets (v6.2), Hallmark Gene Sets (v6.2) and KEGG Gene Sets (v6.2)  
148 (<http://software.broadinstitute.org/gsea/msigdb/collections.jsp>) were respectively used as  
149 references. Based on these gene sets databases, the expression profiles were analyzed to find out  
150 if a set of genes were mostly up-regulated (or down-regulated) in the high-risk group (or low-risk  
151 group). Normalized enrichment score (NES) reflected the degree to which a gene set was  
152 overrepresented in the groups, and gene sets in the results with  $P < 0.05$  and  $FDR < 0.25$  were  
153 considered as significant ones (Subramanian et al. 2005).

154

### 155 **Co-expression network analysis**

156 Patients' tumor samples from TCGA were separated into high- and low-risk groups by the risk  
157 scores calculated by the 7-gene prediction model. Risk-score-based DEGs that were differentially  
158 expressed between the two groups were determined using the gene expression profiles of tumor  
159 samples by the same method as differential expression analysis. Then the relationships between  
160 collagen family genes and the risk-score-based DEGs as well as the representative enriched gene  
161 sets from GSEA were assessed by the Weighted Gene Co-Expression Network Analysis  
162 (WGCNA) with the WGCNA package through R software, which is a method to describe the  
163 correlation patterns among genes across different samples (Langfelder & Horvath 2008). Genes of  
164 each gene set were extracted from <http://software.broadinstitute.org/gsea/msigdb/genesets.jsp>.  
165 Finally, the genes co-expressed with collagen family genes were obtained, and the networks of  
166 them were drawn via Cytoscape (<http://www.cytoscape.org/>, v3.7.1).

167

## 168 **Results**

### 169 **Clinicopathological information of the ESCC patients**

170 A total of 95 patient cases in TCGA and 179 cases in GEO were collected and analyzed by  
171 univariate and multivariate Cox regression analyses. As a result, poor overall survival was  
172 significantly correlated with sex, TNM stage and N stage in TCGA ( $P = 0.020$ ,  $P = 0.015$ , and  $P$   
173  $= 0.012$ , respectively) (Table 1), and was notably associated with age, TNM stage and N stage in  
174 GEO ( $P = 0.021$ ,  $P < 0.001$ , and  $P = 0.030$ , respectively) (Table 2). Besides, investigation into the  
175 correlation between collagen family gene expression and the clinicopathological characteristics  
176 revealed that the expression of several collagen genes was significantly related to advanced TNM  
177 stages or tumor grades. (Table 3 and Table 4).

178

### 179 **Identification of DEGs of collagen family in ESCC tissues**

180 Differential expression analysis showed that more than 2/3 of the 44 collagen family genes were  
 181 up-regulated in tumor tissues in both TCGA and GEO (Tables S1 and S2). 22 members in TCGA  
 182 and 35 members in GEO were identified as DEGs, and their expression patterns were shown by  
 183 heatmaps (Figs. 1A and 1B). Then the Venn diagram demonstrated that there were 22 mutual  
 184 DEGs between the two datasets (Fig. 1C), which meant the DEGs observed in TCGA were also  
 185 DEGs in GEO. Obviously from the heatmaps, COL1A1, COL10A1 and COL11A1 ranked in the  
 186 top five among the up-regulated DEGs in both datasets (Figs. 1D-1I), further presented by  
 187 boxplots. Likewise, COL4A4, COL6A5 and COL14A1 were the most down-regulated candidates  
 188 (Figs. 1J-1O).

189

### 190 **Survival analysis of collagen family genes in ESCC patients**

191 HRs and *P* values of the 22 DEGs were calculated and shown by heatmaps (Figs. 2A and 2B).  
 192 Among them, HRs of COL6A5 and COL18A1 were the lowest and highest respectively. Survival  
 193 curves of the DEGs were plotted according to the Kaplan-Meier method. Consistently, COL6A5  
 194 and COL18A1 were the two genes most relevant to the overall survival of ESCC patients. Patients  
 195 with lower COL6A5 expression exhibited poorer overall survival (*P* = 0.008 in TCGA, Fig. 2C; *P*  
 196 = 0.060 in GEO, Fig. 2D). By contrast, patients with higher COL18A1 expression had worse  
 197 overall survival (*P* = 0.393 in TCGA, Fig. 2E; *P* = 0.009 in GEO, Fig. 2F). These results suggested  
 198 that COL6A5 and COL18A1 are tightly associated with the prognosis of ESCC.

199

### 200 **DEGs-based prediction models to predict the prognosis of ESCC patients**

201 ROC curves have been extensively used to evaluate the predictive effect of one or more genes.  
 202 The AUC value represents predictive accuracy and usually makes sense when it exceeds 0.60  
 203 (Ludemann et al. 2006; Metz 1978; Obuchowski 2003). ROC curves of COL6A5 and COL18A1  
 204 indicated that good predictive performance could only be attained by COL6A5 in TCGA  
 205 (AUC=0.679, Fig. S1A), while COL18A1 had no predictive ability (Figs. S1C and S1D),  
 206 suggesting that a single gene is not suitable for survival prediction of ESCC patients. Therefore,  
 207 we established multi-gene prediction models based on expression levels of the DEGs to assess the  
 208 joint effect of selected collagen genes on patient survival. There were 7 genes in TCGA and 9  
 209 genes in GEO finally included to form the models respectively, and risk scores of the patients were  
 210 calculated according to the below formulas:

$$211 \text{ Risk score (TCGA)} = (1.528 * \text{COL1A1}_{\text{Exp}}) + (0.265 * \text{COL4A4}_{\text{Exp}}) + (-0.539 * \text{COL6A5}_{\text{Exp}}) + (-$$

$$212 0.638 * \text{COL11A1}_{\text{Exp}}) + (-1.193 * \text{COL12A1}_{\text{Exp}}) + (-0.244 * \text{COL19A1}_{\text{Exp}}) + (0.417 * \text{COL24A1}_{\text{Exp}}).$$

$$213 \tag{2}$$

$$214 \text{ Risk score (GEO)} = (7.700 * \text{COL1A1}_{\text{Exp}}) + (-8.800 * \text{COL1A2}_{\text{Exp}}) + (-5.800 * \text{COL3A1}_{\text{Exp}}) +$$

$$215 (6.320 * \text{COL5A1}_{\text{Exp}}) + (-0.708 * \text{COL6A5}_{\text{Exp}}) + (-0.790 * \text{COL11A1}_{\text{Exp}}) + (1.990 * \text{COL14A1}_{\text{Exp}}) +$$

$$216 (1.300 * \text{COL22A1}_{\text{Exp}}) + (2.400 * \text{COL24A1}_{\text{Exp}}).$$

$$217 \tag{3}$$

217 For instance, the positive coefficient for COL1A1 suggests that higher expression of COL1A1  
 218 was associated with worse survival. The negative value allocated to COL6A5 means that higher  
 219 expression of COL6A5 was related to prolonged survival, in agreement with the survival analysis

220 (Fig. 2). Notably, AUCs on the ROC curves of the DEGs-based models in TCGA and GEO reached  
221 0.86 and 0.68 respectively (Figs. 3A and 3C), which were higher than those of the prediction  
222 models based on TNM staging in the two datasets with AUCs of 0.625 and 0.646 respectively  
223 (Figs. 3E and 3G). The TNM staging system is a generally recognized standard for classifying the  
224 spreading extent of cancer (D'Journo 2018) and is commonly used to predict prognosis of cancer  
225 in clinical application. The prediction models respectively based on T-stage and N-stage were also  
226 examined but the AUCs were all less than 0.6 (Fig. S2). Furthermore, survival curves showed that  
227 patients with high risk were significantly correlated with poor survival (Figs. 3B, 3D, 3F and 3H).  
228 The 7-gene model in TCGA with true positive rate of 86% was more accurate than that of the  
229 TNM staging-based model, whereas predictive accuracy of the 9-gene model in GEO exhibited no  
230 difference. Therefore, the model in TCGA was used for our further studies. Finally, a heatmap was  
231 plotted to show the expression patterns of the 7 genes in TCGA between high-risk and low-risk  
232 groups (Fig. 3I). The risk score distribution was exhibited in ascending order, and patients were  
233 divided into high- and low-risk groups by the median point (Fig. 3J). Overall, it can be seen that  
234 patients with high risk score had higher mortality rates and shorter survival time than those with  
235 low risk score (Fig. 3K). Taken together, above results indicated that the 7-gene model could be  
236 more accurate to predict patient survival.

237

### 238 **Pathway analysis of collagen family genes**

239 GSEA results showed that most of the gene sets were up-regulated in the high-risk group, and the  
240 top twenty enriched gene sets were given in Tables S3-S8. The gene sets that were closely  
241 associated with tumorigenesis were shown in Fig. 4. For instance, gene sets of PDGF, RB/P107,  
242 AKT/MTOR and p53 were significantly up-regulated according to Oncogenic Signatures Gene  
243 Sets (Figs. 4A-4F). Based on Hallmark Gene Sets, the enriched gene sets included p53 pathway,  
244 oxidative phosphorylation, apoptosis, mitotic spindle, G2/M checkpoint and notch signaling (Figs.  
245 4G-4L). Using KEGG Gene Sets as reference, the high-risk group was tightly correlated with  
246 oxidative phosphorylation, renal cell carcinoma, bladder cancer, small cell lung cancer, adherens  
247 junction and cell cycle (Figs. 4M-4R).

248

### 249 **Co-expression network analysis**

250 WCGNA was performed to find out the genes that were co-expressed with collagen family genes  
251 in ESCC tissues. Risk-score-based DEGs that were differentially expressed between high- and  
252 low-risk groups were determined and presented by the volcano plot (Fig. S3). The co-expression  
253 network of collagen genes and the risk-score-based DEGs were given in several modules (Fig. 5).  
254 Collagen family genes were displayed as red nodes, and the genes included in the 7-gene prediction  
255 model in TCGA were marked as bigger red nodes. The blue nodes represented the co-expressed  
256 genes. Another network was drawn to show the association between collagen family genes and  
257 seven representative enriched gene sets (PDGF, RB/p107, PI3K/Akt/mTOR pathway, p53  
258 pathway, oxidative phosphorylation, apoptosis and cell cycle) from the GSEA results (Fig. S4).  
259 The red nodes were the collagen family genes with close connections to those gene sets. A big  
260 blue circle represented a gene set and the blue nodes were genes included in each set. Genes closer

261 to the center were more tightly associated with the collagen genes.

262

## 263 **Discussion**

264 Although extensive research efforts have been focused on this field in past decades, efficient  
265 detection methods for early ESCC and accurate prediction against complicated ESCC patients still  
266 remain an open issue. Recently, studies have found that the expression of certain genes, such as  
267 MCT4, ZNF750, Gli1, etc. was highly related to the occurrence and development of ESCC, and  
268 they might be applied as ideal biomarkers for ESCC (Cheng et al. 2018; Li et al. 2018; Nambara  
269 et al. 2017; Yang et al. 2017; Zhang et al. 2018b). In addition, the aberrant expression of a few  
270 collagen family genes has also been reported to be significantly associated with the prognosis of  
271 ESCC patients. However, most works only focused on single or limited genes, and the predictive  
272 ability was barely satisfactory. Herein, we provided a more systematic analysis of the whole  
273 collagen family gene expression to evaluate the potential roles and clinical significance of collagen  
274 genes in ESCC.

275 We found that most of the collagen genes were up-regulated in ESCC tissues when compared  
276 to normal controls, half of which were identified as DEGs (Figs. 1A and 1B). Among them, the  
277 expression of COL1A1, COL10A1 and COL11A1 was particularly higher, and that of COL4A4,  
278 COL6A5 and COL14A1 was especially lower in tumor tissues, indicating their possible roles as  
279 diagnostic markers for ESCC. Consistently, several studies have shown that COL1A1, COL10A1  
280 and COL11A1 were notably overexpressed in ESCC compared to normal tissues (Fang et al. 2019;  
281 He et al. 2017; Karagoz et al. 2016; Senthebane et al. 2018; Zhang et al. 2018a). Also, COL4A4  
282 was also found to be down-regulated in esophageal tumor tissues (Chattopadhyay et al. 2009).  
283 Additionally, among the DEGs, COL7A1 was observed to be up-regulated in ESCC tissues (Kita  
284 et al. 2009). In our works, COL6A5, COL14A1 and some other collagen genes were reported to  
285 be significantly up- or down-regulated in ESCC tissues for the first time.

286 In the survival analysis, COL6A5 and COL18A1 were validated to be significantly related to  
287 overall survival of ESCC patients. Previous studies demonstrated that the COL6A5 expression was  
288 significantly associated with depressed behavior and atopic dermatitis (Soderhall et al. 2007; Zhan  
289 et al. 2017), but no articles manifested its correlation with cancer. In addition, COL18A1 has been  
290 proved to be a promising biomarker for ovarian cancer and was possibly involved in the  
291 progression of bladder cancer (Fang et al. 2013; Peters et al. 2005). In this study, ESCC patients  
292 with low COL6A5 expression or high COL18A1 expression showed poor overall survival (Figs.  
293 2C-2F), implying the expression of COL6A5 or COL18A1 as a potential indicator for the  
294 prognosis of ESCC patients. Moreover, the variations that affect the expression of COL6A5 and  
295 COL18A1 possibly have effects on the progression of ESCC. Activating COL6A5 or inhibiting  
296 COL18A1 might improve the therapeutic efficiency and the life-span of ESCC patients.

297 Because the expression of one gene is usually influenced by various factors, ideal effect may  
298 not be attained by using a single gene as a predictor. Indeed, COL6A5 achieved an AUC value  
299 over 0.60 only in TCGA (Fig. S1), making the requirement of another more powerful prediction  
300 method. Based on the selected collagen DEGs (7 genes in TCGA and 9 genes in GEO, both

301 including COL6A5), we established two new prediction models. Importantly, such DEGs-based  
302 models exhibited better predictive ability than conventional prognostic models according to TNM  
303 staging. The 7-gene model in TCGA had especially higher predictive accuracy of 86%. One  
304 possible reason was that the RNA sequencing technology applied to TCGA was more accurate  
305 than the gene chip technology used in GEO. In summary, this 7-gene prediction model is greatly  
306 promising to predict the prognosis of ESCC patients and help determine next therapeutic regimens.

307 Furthermore, GSEA was used to identify significantly enriched gene sets and potentially  
308 relevant pathways (Fig. 4). The results showed that based on Oncogenic Signatures Gene Sets,  
309 gene sets of PDGF, RB/P107 and AKT/MTOR were significantly enriched in the high-risk group.  
310 It has been reported that PDGF receptor-beta increased the expression of COL1A2 through  
311 Akt/mTORC1 signaling pathway (Das et al. 2017). According to Oncogenic Signatures Gene Sets  
312 and Hallmark Gene Sets, the high-risk group was significantly related to p53 and p53 pathway,  
313 which suggested that collagen genes might be highly associated with the p53 or its related pathway  
314 in ESCC. Earlier studies proved that enhanced expression of ectopic p53 in dermal fibroblasts  
315 inhibited basal and TGF-beta-stimulated collagen gene expression, and the absence of cellular p53  
316 was correlated with increased transcriptional activity of the Type I collagen gene (COL1A2) and  
317 collagen synthesis (Ghosh et al. 2004). Moreover, the type IV collagen expression was inversely  
318 related to p53 in malignant tumors (Bar et al. 2004). Oxidative phosphorylation related genes were  
319 found to be up-regulated in the high-risk group by both Hallmark Gene Sets and KEGG Gene Sets.  
320 Indeed, some reports demonstrated that oxidative phosphorylation signature occurred when  
321 collagen density was decreased, and the change of collagen density microenvironment regulated  
322 the metabolism of cancer cells (Mah et al. 2018; Morris et al. 2016). As for apoptosis, an earlier  
323 study has shown that Type IV collagen could stimulate cancer cell proliferation, migration, and  
324 inhibit apoptosis (Ohlund et al. 2013). Additionally, the gene sets of mitotic spindle, G2/M  
325 checkpoint and cell cycle were enriched in the high-risk group as well, implying that collagen  
326 might regulate the cell cycle of ESCC cells. Furthermore, it was indicated that the high-risk group  
327 was markedly associated with renal cell carcinoma, bladder cancer and small cell lung cancer.  
328 These results were consistent with previous studies that collagen gene expression was correlated  
329 with the poor prognosis of those cancers (Koskimaki et al. 2010; Wan et al. 2015; Xu et al. 2017;  
330 Zeng et al. 2018).

331 As shown by the co-expression network (Fig. 5), a few collagen family genes such as COL1A1,  
332 COL11A1, COL6A6, and COL19A1, were co-expressed with NETO1, NEUROD2, and NRG3,  
333 which are the genes involved in neural functions. These findings could be verified by earlier  
334 articles to some extent (McCarthy & Hay 1991; Perris et al. 1993a; Perris et al. 1993b). COL11A1  
335 was also observed to be co-expressed with tumor suppressor candidate 7 (TUSC7), further  
336 validating the possible role of COL11A1 in the occurrence of ESCC. Beyond that, some potassium  
337 channel related genes (KCNA2, KCNE1B, KCNH1, KCNJ4, and KCNK4) were co-expressed  
338 with collagen genes in a way, revealing that collagen genes might be correlated with the regulation  
339 of potassium channels in ESCC. As for the two potential prognostic biomarkers, COL18A1 only  
340 showed close relations with collagen family members, while COL6A5 was associated with two  
341 other genes in this network, ROBO2 and MIR548A3. ROBO2 has been identified as a candidate

342 tumor suppressor (Trifonov et al. 2013), and the alteration of its expression might play a role in  
343 malignant tumors of digestive tract including gastric and colorectal cancers (Je et al. 2013).

344 Apart from what is aforementioned, there are still some limitations of this research. For instance,  
345 the prediction model was comprised of several genes, making it difficult to conduct cellular  
346 experiments by targeting a single gene to confirm its predictive effect. Aside from it, the  
347 characteristics of patient samples, as well as the methodology utilized in TCGA, were somewhat  
348 different from that in GEO, which may explain the different results coming from the two datasets.  
349 For example, TCGA uses the RNA sequence technology while GEO applies the gene chip  
350 technology to detect gene expression of patient tissues. Besides, TCGA mainly collected data from  
351 white people, whereas the majority of patients in GEO (GSE53625) were Asian. Therefore, there  
352 was no a single gene that exhibited significant  $P$  values in both datasets in the survival analysis,  
353 and the selected genes driving the prediction model in one dataset were not completely identical  
354 to those in another dataset. Further validation of these outcomes requires more clinical information  
355 and biological experiments in the future.

356

## 357 **Conclusions**

358 In summary, this study identified 22 collagen family genes that were significantly expressed higher  
359 or lower in ESCC compared to normal tissues. Among them, COL1A1, COL10A1, COL11A1,  
360 COL4A4, COL6A5 and COL14A1 were the most distinct ones and possessed the potential in  
361 ESCC diagnosis. Besides, COL6A5 and COL18A1 showed strong correlations with overall  
362 survival of ESCC patients and might be robust prognostic biomarkers for ESCC. Furthermore, we  
363 established a 7-gene prediction model with high performance to predict the prognosis of ESCC  
364 patients. In terms of the underlying mechanism, collagen genes might be associated with  
365 PI3K/Akt/mTOR pathway, p53 pathway, oxidative phosphorylation, apoptosis and cell cycle  
366 during the progression of ESCC. Our works may further benefit the diagnosis, prognosis and  
367 treatments for ESCC patients.

# Figure 1

Differential expression analysis of collagen family genes between ESCC and normal tissues.

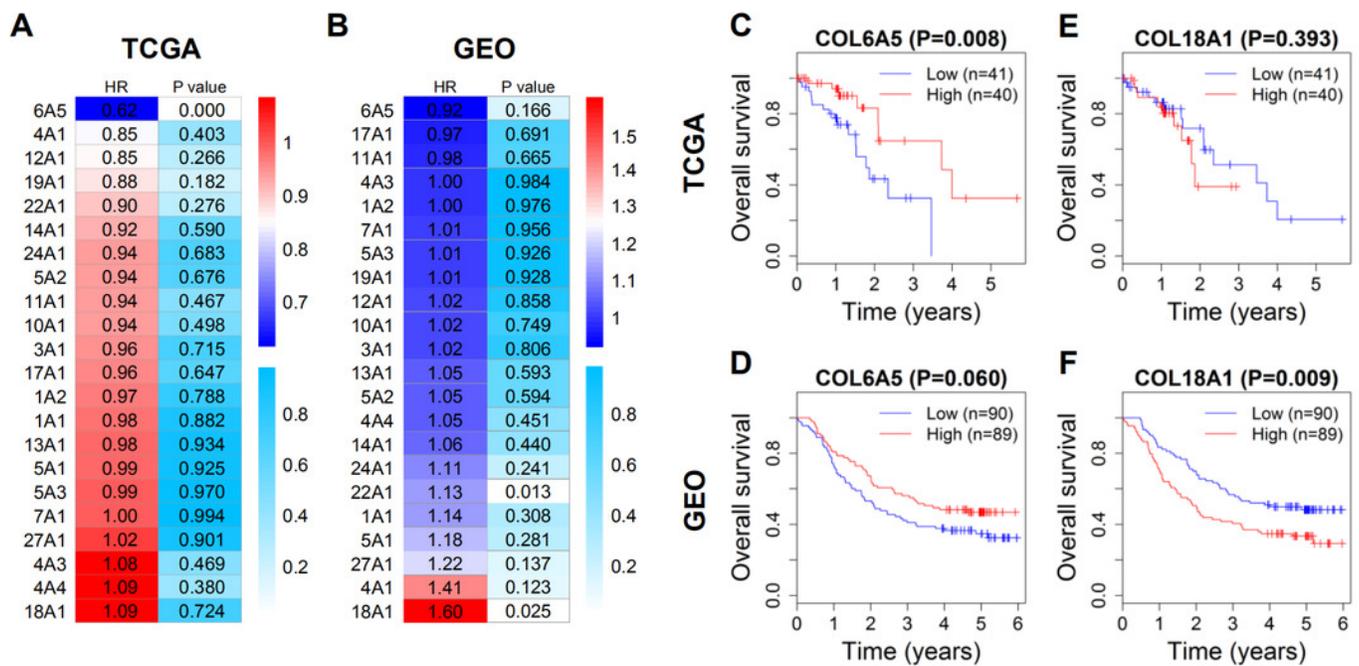

(A) and (B) Heatmaps of the DEGs in TCGA and GEO in descending order of logFC. The red and blue colors represent high and low expression, respectively. \*  $P < 0.05$ ; \*\*  $P < 0.01$ ; \*\*\*  $P < 0.001$ . (C) The Venn diagram showing the overlapped DEGs between the two datasets. (D-I) Boxplots of three representative up-regulated genes, COL1A1, COL10A1 and COL11A1 in TCGA and GEO. (J-O) Boxplots of three representative down-regulated genes, COL4A4, COL6A5 and COL14A1 in TCGA and GEO. DEG, differentially expressed gene; FC, fold change.

## Figure 2

Survival analysis of the DEGs of collagen family in ESCC patients.

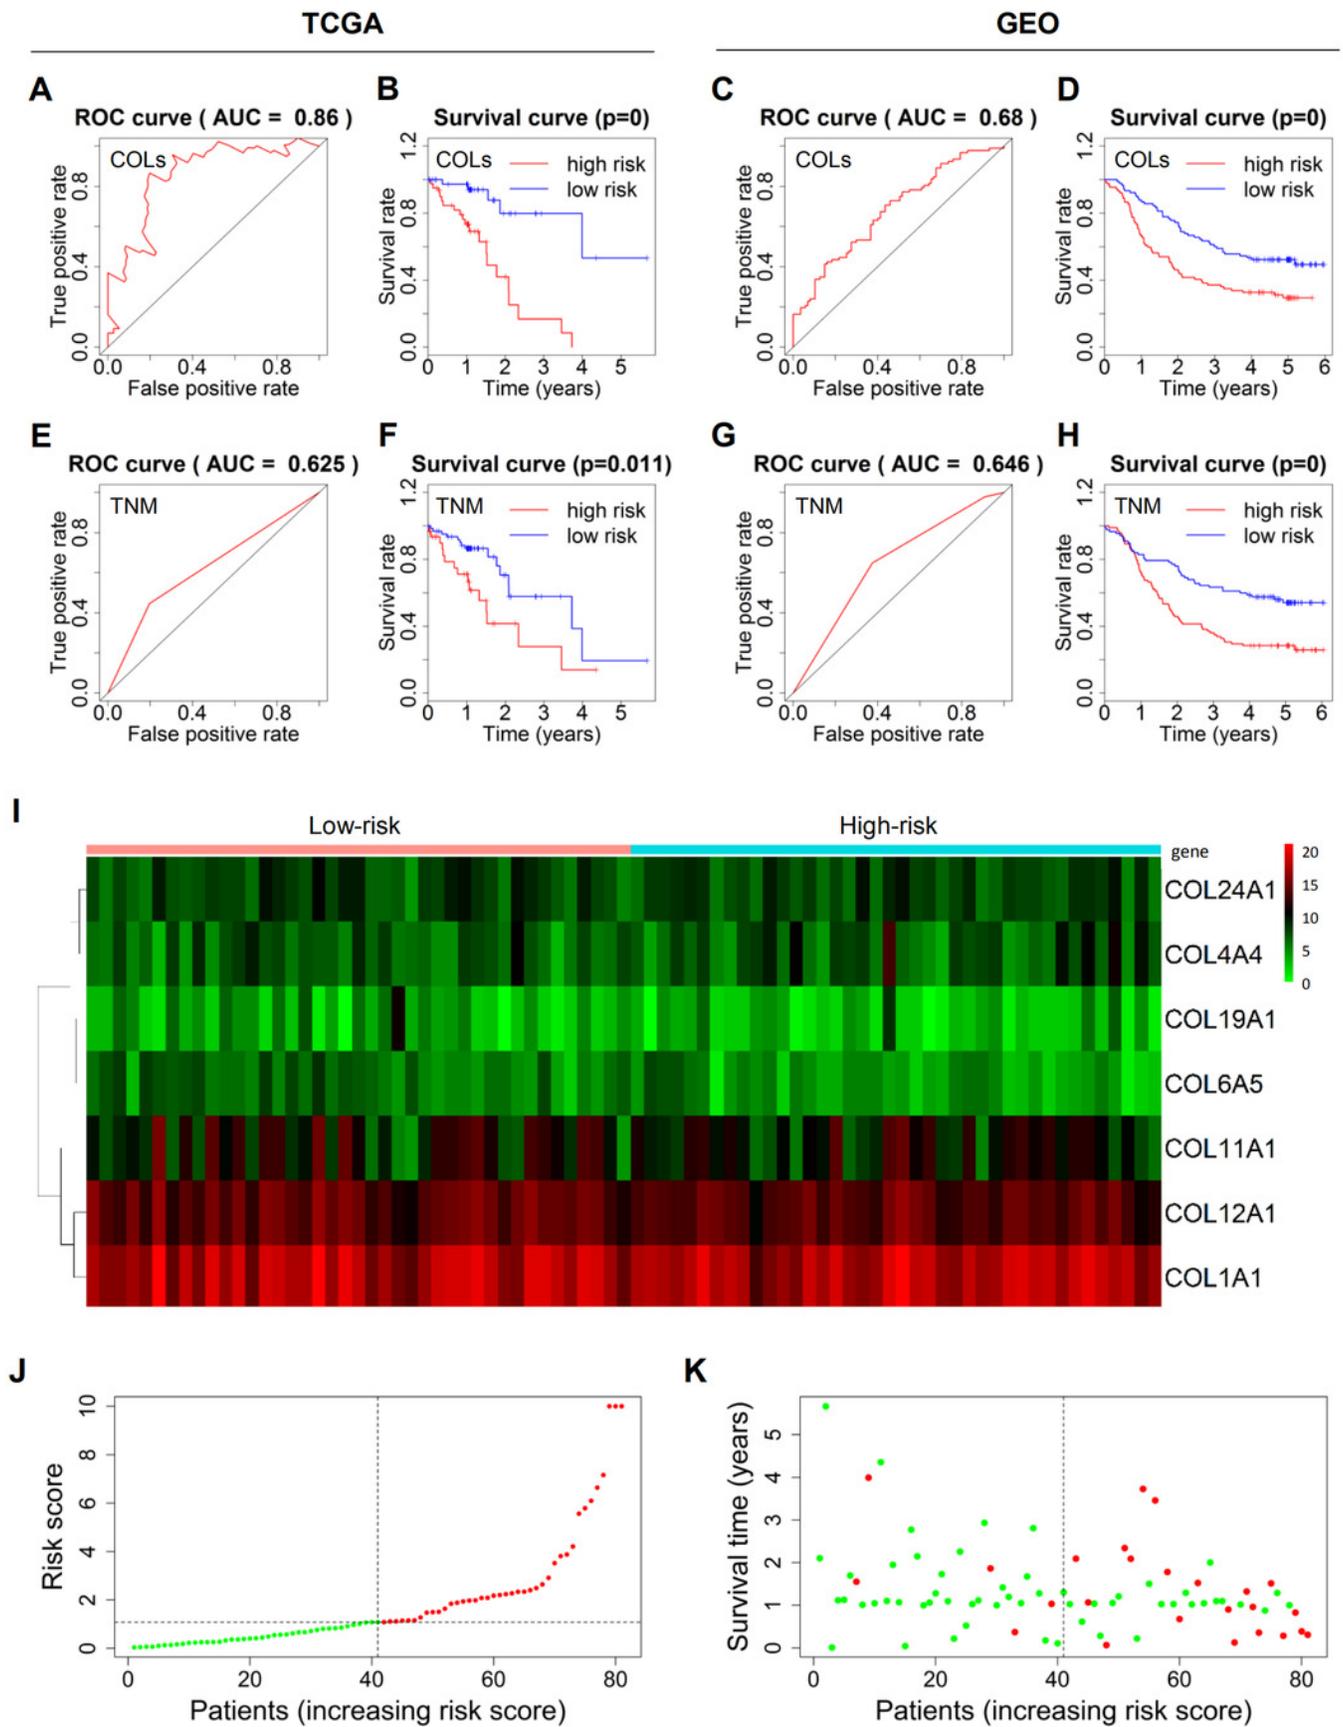

(A) and (B) HRs and *P* values of the DEGs related to overall survival in ascending order of HR in TCGA and GEO. (C) and (D) Kaplan-Meier survival curves of COL6A5 in TCGA and GEO. (E) and (F) Kaplan-Meier survival curves of COL18A1 in TCGA and GEO. DEG, differentially expressed gene; HR, hazard ratio.

## Figure 3

Prediction models to predict the survival of ESCC patients.

(A-D) ROC and survival curves of the models based on expression of 7 and 9 collagen DEGs respectively in TCGA and GEO. (E-H) ROC and survival curves of the models according to TNM staging in TCGA and GEO. (I) A heatmap showing the expression patterns of the 7 genes driving the prediction model in TCGA. (J) Risk score distribution of the patients in ascending order and divided into low-risk (green) and high-risk (red) in TCGA. (K) Survival time and status of the patients in order of increasing risk scores in TCGA. The red and green dots represent dead and alive, respectively. ROC, receiver operating characteristic; AUC, area under curve; DEG, differentially expressed gene; COL, collagen; TNM, tumor-node-metastasis.

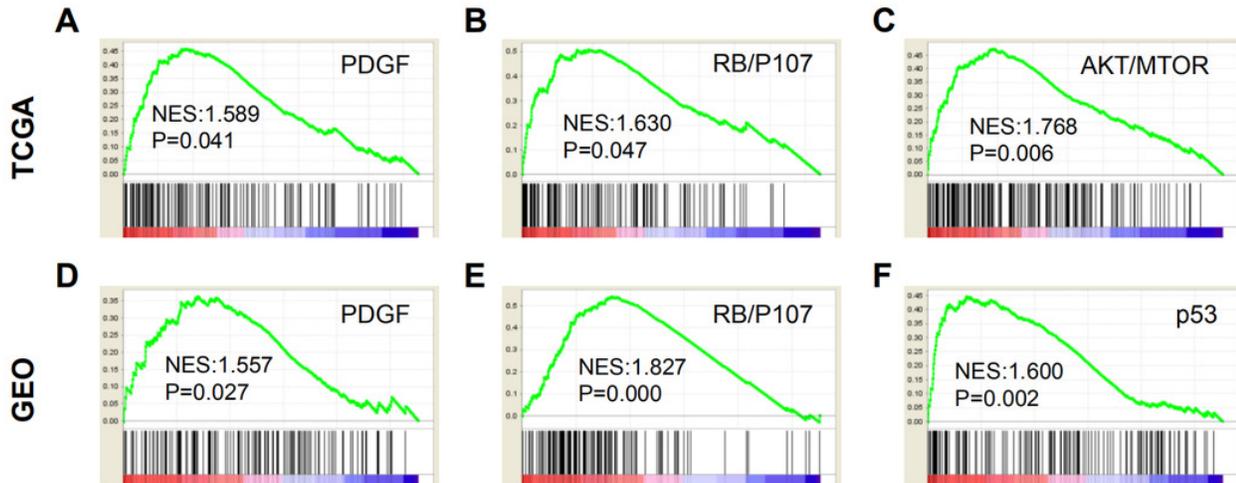

## Figure 4

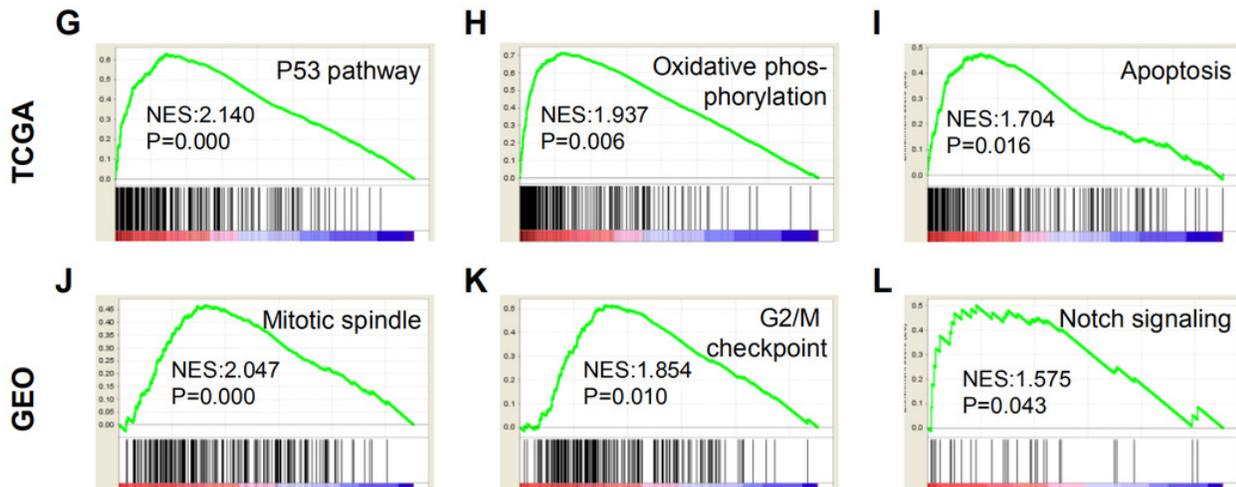

GSEA results based on patient risk scores calculated by the prediction models in TCGA and GEO

(A-F) Representative enriched gene sets according to Oncogenic Signatures Gene Sets. (G-L) Representative enriched gene sets according to Hallmark Gene Sets. (M-R) Representative enriched gene sets according to KEGG Gene Sets. GSEA, gene sets enrichment analysis. NES, normalized enrichment score.

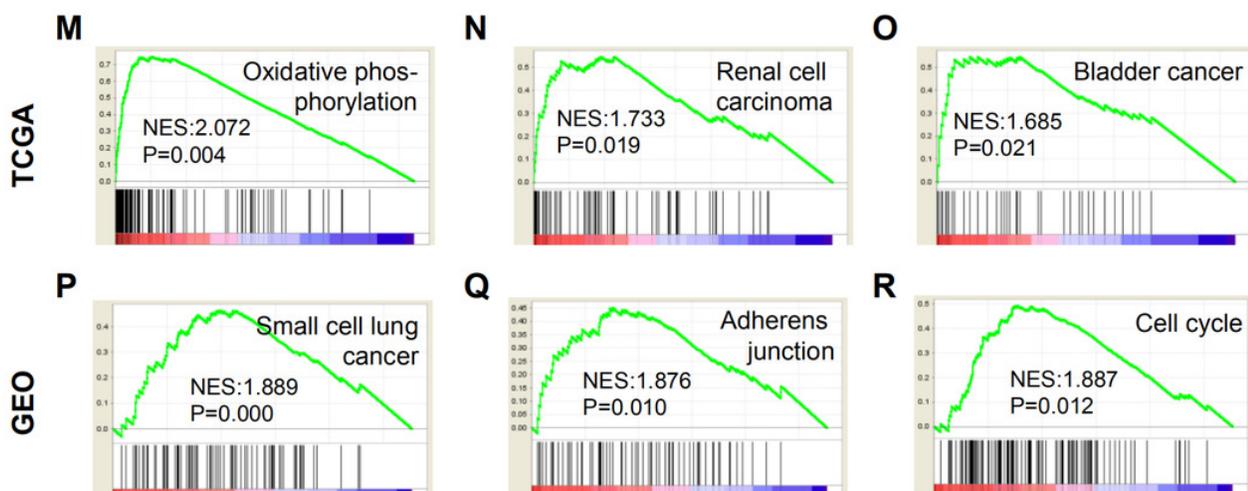

### Oncogenic Signatures Gene Sets

### Hallmark Gene Sets

### KEGG Gene Sets

## Figure 5

Co-expression network of collagen family genes.

Visualization of the co-expression between collagen family genes and the risk-scores-based DEGs. The red nodes are collagen family genes, and the bigger ones are the genes included in the 7-gene prediction model in TCGA. The blue nodes are the co-expressed genes. DEG, differentially expressed gene.
