The scale of phenological research has expanded due to the digitization of herbarium specimens and volunteer based contributions. These data are status-based, representing the presence or absence of a specific phenophase. Modelling the progress of plant dormancy to growth and reproduction and back to dormancy requires estimating the transition dates from these status-based observations. There are several methods available for this ranging from statistical moments using the day of year to newly introduced methods using concepts from other fields. Comparing the proficiency of different estimators is difficult since true transition dates are rarely known. Here I use a recently released dataset of in-situ flowering observations of the perennial forb *Echinacea angustifolia*. In this dataset, due to high sampling frequency and unique physiology, the transition dates of onset, peak, and end of flowering are known to within 3 days. I used a Monte Carlo analysis to test eight different estimators across two scales using a range of sample sizes and proportion of flowering presence observations. I evaluated the estimators accuracy in predicting the onset, peak, and end of flowering at the population level, and predicting onset and end of flowering for individual plants. Overall a method using a Weibull distribution performed the best for population level onset and end estimates, but other estimators may be more appropriate when there is a large amount of absence observations relative to presence observations. For individual estimates a method using the midway point between the first flower presence and most prior flower absence, within 7 days, is the best option as long as the restriction does not limit the final sample size. Otherwise the Weibull method is adequate for individual estimates as well. These methods allow practitioners to effectively utilize the large amount of status-based phenological observations currently available.

# **Abstract**

The scale of phenological research has expanded due to the digitization of herbarium specimens and volunteer based contributions. These data are status-based, representing the presence or absence of a specific phenophase. Modelling the progress of plant dormancy to growth and reproduction and back to dormancy requires estimating the transition dates from these status-based observations. There are several methods available for this ranging from statistical moments using the day of year to newly introduced methods using concepts from other fields. Comparing the proficiency of different estimators is difficult since true transition dates are rarely known. Here I use a recently released dataset of in-situ flowering observations of the perennial forb *Echinacea angustifolia*. In this dataset, due to high sampling frequency and unique physiology, the transition dates of onset, peak, and end of flowering are known to within 3 days. I used a Monte Carlo analysis to test eight different estimators across two scales using a range of sample sizes and proportion of flowering presence observations. I evaluated the estimators accuracy in predicting the onset, peak, and end of flowering at the population level, and predicting onset and end of flowering for individual plants. Overall a method using a Weibull distribution performed the best for population level onset and end estimates, but other estimators may be more appropriate when there is a large amount of absence observations relative to presence observations. For individual estimates a method using the midway point between the first flower presence and most prior flower absence, within 7 days, is the best option as long as the restriction does not limit the final sample size. Otherwise the Weibull method is adequate for individual estimates as well. These methods allow practitioners to effectively utilize the large amount of status-based phenological observations currently available.

# Introduction

Plant phenology has a long history in ecological research and is a primary indicator of climate change (Scheffers et al. 2016, Chuine and Régnière 2017). Studies commonly document the long-term trends of the first flower or leaf out dates, apply various modelling approaches to infer the drivers of these transitions, or make forecasts using future climate conditions. Phenological models, such as predictive models or those used for long-term trends, use the transition dates as the variable of interest. Common transition dates are First Observed open flowers or new leaves on a plant, but can also include peak flower, fruit maturation, and leaf senescence. Historic datasets often use repeated observations to identify the true transition date (Wolkovich et al. 2012, Davis et al. 2015), yet this is susceptible to observer bias (Miller-Rushing et al. 2008). Most modern studies and collection protocols use status-based monitoring, where over time observers record the current state of a single plant (ie. leaves present or absent) regardless of recent or impending transitions. This includes research using herbarium records, where the presence or absence of flowers and other phenophases is inferred from their presence on a specimen (Willis et al. 2017). To make use of status-based data in most phenological models the transition date must first be estimated, and there are several methods available.

Two of the most common estimators are the First Observed and Mean Flowering methods, where either the first observation in a year or the mean dates for all observations within a year is used as an estimate for a phenophase transition and peak dates, respectively (Miller-Rushing et al. 2008, CaraDonna et al. 2014, Willis et al. 2017, Jones and Daehler 2018). The First Observed method has been shown to be biased in several instances, while the Mean Flowering date is considered a reliable estimator for the midpoint or peak of a phenophase (Miller-Rushing et al. 2008, Moussus et al. 2010, Bertin 2015). Recently more robust methods have been introduced. Templ et al. (2017) used survival modelling to estimate the median date of flowering

60 and Pearse et al. (2017) used an extinction model to estimate the first flowering date.  
 61 Using repeated observations of individual plants, as opposed to observations from  
 62 across a population, site, or region, allows for more reliable estimates. For example if  
 63 flowers are not present during one visit but present during the next, the transition of  
 64 flowers opening is constrained to the window between the two visits (Gerst et al. 2016).  
 65 Studies of bird migration phenology face similar challenges and several estimators have  
 66 been used to model the first arrival dates. Examples include logistic regression (Mayor  
 67 et al. 2017) and General Additive Models (GAMs) (Moussus et al. 2009, Newson et al.  
 68 2016, Lindén et al. 2017). To date no comparison has been made of these different  
 69 transition date estimators for plant phenology.

70 Furthermore, there are no clear guidelines for using estimators across different spatial  
 71 scales. Over a latitudinal gradient the transition of a phenophase for a single species can  
 72 last several weeks to months, and even at the local scale can vary due to many factors  
 73 (Diez et al. 2012, Zhang et al. 2017). Studies which estimate transition dates have  
 74 combined observations from individual plants (Gerst et al. 2016, Taylor et al. 2019),  
 75 sites or populations of plants (Schaber and Badeck 2002, Linkosalo et al. 2008, Basler  
 76 2016), or entire regions (Calinger et al. 2013, Park 2014). How different phenological  
 77 estimators perform across spatial scales is currently unknown.

78 A comparison of estimators is difficult since, due to infrequent sampling, the true date  
 79 of transitions is rarely known. Previously Moussus et al. (2010) used simulated data to  
 80 test the ability of different estimators to detect shifts in phenological distributions. Here  
 81 I expand on this prior study by using a dataset of flowering observations from a single  
 82 population where, due to the unique physiology of the focal species, transition dates can  
 83 be calculated with high precision, and the efficacy of the different estimators directly  
 84 compared. To determine how these estimators perform using different sources of  
 85 phenological data, such as those from herbarium records or crowd-source applications, I  
 86 performed this analysis across two different scales (population and individual level

87 transition dates), with varying sample sizes, and with varying proportions of observed  
88 flowering presence.

## 89 **Methods**

### 90 **Phenological Data**

91 I used phenological observations of the perennial forb *Echinacea angustifolia* collected  
92 in Minnesota, U.S.A. in the years 1995-2015 (Waananen et al. 2018a, 2018b) to test the  
93 accuracy of different transition date estimators. The data consist of the start and end  
94 date of flowering (defined as the start and end of pollen production) for 286 individual  
95 plants in a 0.5 ha plot from the 11 years of sampling, where the sampling frequency was  
96 at least every 3 days during pollen production. The flowering of *E. angustifolia* is such  
97 that the true start date of flowering can be inferred very precisely for an individual plant.  
98 The flowering heads of *E. angustifolia* consist of 80-250 disk flowers in several rows.  
99 The bottom most row flowers first, with each adjacent row flowering every day  
100 afterwards. This pattern was used to determine the date of first flowering for an  
101 individual to within 2 days for flowering onset and 3 days for flowering end (Wagenius  
102 2004, Waananen et al. 2018b). With this information a true start and end date of  
103 flowering for the entire population can be approximated.

104 Different interpretations of phenological metrics can yield different results (Renzi et al.  
105 2019), thus with the *E. angustifolia* dataset I used strict definitions in calculating the  
106 true values used in the analysis. For each year I calculated the following  
107 population-level metrics: 1) the start of flowering as defined by the day of year (DOY)  
108 of the first observed flower, 2) peak flower defined as the DOY when the most flowers  
109 were observed in a given year, 3) the end of flowering as defined by the last DOY a  
110 flower was observed. I also calculated two individual level metrics: 1) the start and 2)

111 end DOY of flowering for each individual plant in each year.

112 To simulate status-based data of a plant population I first determined the flowering  
 113 status (either present or absent) for every individual plant on every DOY 1-365, then  
 114 randomly sampled from these dates. Thus an observation could be of flowers present or  
 115 absent. Flowering absence observations are possible throughout the year as no  
 116 individual flowers for the full duration of the season. I performed a Monte Carlo  
 117 analysis, where for every year I repeated this 1000 times with varying sample sizes (10,  
 118 50, and 100 observations) and varying levels of flowering presence being observed  
 119 (25%, 50%, and 75%). For example, with flowering presence set to 25% using 100  
 120 observations only 25 observations were allowed to be of flower presence while the rest  
 121 were of flower absence, all being randomly chosen from the full calendar year. The  
 122 variation in sample size and ratio of flowering presence observations simulate patterns  
 123 seen in non-systematic phenological datasets, such as the those from herbarium records  
 124 or volunteer contributions. These patterns stem from biases in the time of year of  
 125 sampling, infrequent or sporadic sampling, or variations in observer effort (Dickinson et  
 126 al. 2010, Willis et al. 2017, Daru et al. 2018).

127 For individual level flowering estimates I performed the same random sampling routine  
 128 for every individual in every year using sample sizes of 5, 10, and 20 observations, and  
 129 flowering presence ratios of 25%, 50%, and 75%. I only used individuals which were in  
 130 flower for more than 20 days, since below that there would not be enough data in the  
 131 lowest sample size and flowering presence classes. I repeated this 20 times for each  
 132 individual in every year in the Monte Carlo analysis.

133 Each estimator, described below, was fit to each random sample (Table 1). For the  
 134 population estimates this resulted in 11,000 estimates for each estimator, and sample  
 135 size/flowering presence combination. For the individual estimates this resulted in 4840  
 136 estimates for each estimator and sample size/flowering presence combination.

137 Estimators were compared using the  $R^2$  value between estimated and observed dates of

138 metrics, and by examining the density of errors from all Monte Carlo estimates.

## 139 **Estimators**

140 The First Observed method uses the earliest DOY of flowering as the estimate for the  
141 start of flowering. Analogous to this is the Last Observed DOY for estimating the end of  
142 flowering. These were used in both the population and individual level analysis.

143 The Midway method uses the midway date between the First Observed flowering date  
144 and the most prior observation of flowering absence for an individual plant. This can be  
145 improved by applying a restriction whereas only individuals with an observed absence  
146 within 7 days of the First Observed presence are used (Gerst et al. 2016). Applying this  
147 restriction reduces the final sample size available for modelling though. The Midway  
148 method was used to estimate onset and end in the individual analysis (Midway and  
149 Midway 7-Day), and in the population analysis by using the mean onset date from all  
150 individuals (Mean Midway and Mean Midway 7-Day). For all cases I noted the rate at  
151 which this could not be calculated due to inadequate sampling (ie. if no individuals have  
152 an absence observation within 7 days prior to the first presence, than no estimate can be  
153 made).

154 The Weibull method fits a Weibull distribution to only the flowering presence  
155 observations, thus is advantageous when no absence observations are available. The  
156 flexible Weibull distribution can model a variety of shapes, and is commonly used to  
157 used to estimate the start or end of a process. The estimated date of first flowering is the  
158 sum of the dates of all flowering weighted by the joint Weibull distribution and is  
159 equivalent to estimating an extinction date (Roberts and Solow 2003, Pearse et al. 2017).  
160 This was used for both population and individual level estimates. Code for this in the R  
161 language was obtained from Pearse et al. (2017) and is provided in the code repository.

162 The Logistic method fits a generalized linear model to both presence and absence

163 observations using a binomial distribution, where the DOY was used to explain the  
 164 presence or absence of flowering ( $\text{glm}(\text{flowering} \sim \text{doy}, \text{family}=\text{binomial})$ ). Prior to  
 165 fitting all flowering absence observations after the last observed flowering presence  
 166 were excluded. The expected probability of observing a flower was calculated for all  
 167 DOYs 1-365, and the estimated onset of flowering was the first DOY in the season in  
 168 which the expected probability exceeded a given threshold. The inverse of this is used to  
 169 estimate the end of flowering. All absence observations prior to the First Observed  
 170 flowering date were excluded, the expected probability was calculated for all DOYs  
 171 1-365, and the first DOY where the probability of flowering falls below the threshold  
 172 was the estimate for the end of flowering. I evaluated a range of probability thresholds  
 173 (0.05, 0.25, 0.50, 0.75, and 0.95) and used the one with the highest  $R^2$  for each  
 174 combination of metric, sample size, and flowering presence ratio. This method was used  
 175 in both the population and individual level analysis.

176 The GAM method is unique in that it can potentially estimate the full flowering  
 177 phenology for a season (onset, peak, and end) using smoothing splines. Similar to the  
 178 Logistic method, a general additive model was fit with a binomial distribution and DOY  
 179 explaining the presence or absence of flowers, where the DOY was a thin plate  
 180 regression spline ( $\text{gam}(\text{flowering} \sim \text{s}(\text{doy}, \text{bs}=\text{'tp'}), \text{family}=\text{binomial})$ ). The expected  
 181 probability of flowering was calculated for all DOYs 1-365. The estimated onset date  
 182 was the first DOY in which the probability exceeded a given threshold. The estimated  
 183 peak flowering date was the DOY with the maximum probability in a given year. The  
 184 estimated end of flowering was the first DOY, after the peak, in which the probability  
 185 fell below the threshold. As in the Logistic method I evaluated five probability  
 186 thresholds and chose the one with the highest  $R^2$  for each metric and scenario. Results  
 187 showing the best probability thresholds for the GAM and Logistic are available in  
 188 Figure S4. The GAM method was used for estimating onset and end in both the  
 189 population and individual level analysis, and for estimating peak flowering in the

190 population analysis.

191 The Survival method uses a Kaplan–Meier model, which is commonly used to estimate  
 192 the survival of medical patients. Patient survival (alive or dead) observed in the years  
 193 following a treatment is used in the model to estimate overall survival probability, with  
 194 median survival rate, in years, used as a common summary statistic. In a phenology  
 195 context observations of non-flowering and flowering can be ascribed to alive or dead,  
 196 respectively, and the DOY, instead of year, of observation used as the time (Templ et al.  
 197 2017). The median survival rate can then be interpreted as the median time for  
 198 flowering. I used the survfit function in the R package survival using right censoring  
 199 (Therneau 2015). This method was used to estimate peak flowering in the population  
 200 analysis.

201 Finally, the Mean Flowering method uses the average DOY of all flowering presence  
 202 observations from throughout the year. This was used to estimate peak flowering in the  
 203 population analysis.

204 All analysis was done using the R programming language (version 3.6.0, R Core Team  
 205 2017). Packages used during the analysis included dplyr (version 0.8.1, Wickham et al.  
 206 2017), tidyr (version 0.8.3, Wickham and Henry 2018), ggplot2 (version 3.1.1,  
 207 Wickham 2016), mgcv (Wood 2003, version 1.8.28, 2011), survival (version 2.44.1.1,  
 208 Therneau 2015), testthat (version 2.1.1, Wickham 2011), ggridges (version 0.5.1, Wilke  
 209 2018), and lubridate (version 1.7.4, Grolemund and Wickham 2011). Code to fully  
 210 reproduce this analysis is available on GitHub  
 211 ([https://github.com/sdtaylor/phenology\\_estimators](https://github.com/sdtaylor/phenology_estimators)) and archived on Zenodo  
 212 (<https://doi.org/10.5281/zenodo.3234913>).

Table 1: Estimators used in this analysis. *p* indicates the estimator uses only presence observations as opposed to both presence and absence observations.

	Population			Individual	
	Onset	Peak	End	Onset	End

Mean Flowering		✓ <i>p</i>			

## Results

### Population Onset Estimates

For population level flowering onset the Weibull method produced estimates with the lowest error for most scenarios (Fig. 1). Excluding the scenario where the proportion of flowering presence was 25% and with a sample size of 10, the Weibull method had  $R^2$  values from 0.34 - 0.79 and median error rates of 3 - 4 days (upper and lower bound errors range from -20 - -1 and 15 - 8 for the 0.025 and 97.5 quantiles, respectively).

220 With a flowering proportion presence of 25% and sample size of 10 the First Observed  
221 method had the highest  $R^2$ , but still overestimated the true dates by 11 days on average.  
222 With higher sample sizes the First Observed method performed comparable to, but  
223 always slightly worse than, the Weibull method.

224 The Logistic and GAM methods had the highest  $R^2$ , and similar median errors to the  
225 Weibull method, when the sample size was high (50-100) and ratio of flowering  
226 presence low (25%). In the scenarios where they had the highest  $R^2$ , the best threshold  
227 for estimating onset was 0.25 and 0.50 for the GAM and Logistic methods, respectively  
228 (Fig. S4). As the proportion of flowering presence increased, and relative amount of  
229 absences decreased, the Logistic and GAM methods tended to perform worse (Fig. 1).  
230 This was due to larger time gaps in the data since flowering presence observations occur  
231 during a short time window. The gaps resulted in overfit models which increasingly  
232 underestimated flowering onset as the proportion of flowering absences decreased (Fig  
233 S5).

234 The Mean Midway and Mean Midway 7-Day methods were never the best performing  
235 methods for estimating population onset. The Mean Midway method did not improve  
236 by increasing the sample size or by increasing the proportion of flowering presence  
237 observations. Results from the Mean Midway 7-Day method using a sample size of 10  
238 were excluded due to less than 1% of random samples resulting in a usable estimate.  
239 This was due to the requirement of each individual plant having at least one presence  
240 and one prior absence observation. The usable number of estimates for the remaining  
241 scenarios ranged from 2-10% (Fig. S1). With a sample size of 10 the GAM method  
242 only produced estimates 27-81% of the time because of too few absence observations,  
243 and 100% of the time in all other scenarios.

Figure 1: The error distribution of all estimators for population onset. The density curves are each derived from 11,000 randomly drawn observations, with sample size and presence proportion stated, across eleven years of phenological data. Text values represent the median error and the 95% quantile range in parenthesis.

## Population End Estimates

The end of flowering for the entire population was more difficult to estimate than the onset of flowering. The highest  $R^2$  for a given scenario in estimating population onset was always higher than the same scenario in population end estimates. For end estimates the Weibull method had the highest  $R^2$  in 4 of 9 scenarios, including all three scenarios where the proportion of flowering presence was 75%, as well as when the proportion was 50% with a sample size of 10 (Fig. 2, B,C,F,I). With a sample size of 50 and 100 and a presence proportion of 50% and 25% the Logistic and GAM methods had the highest  $R^2$  (Fig. 2, D,E,G,H). Where it performed the best the Logistic method used a threshold of 0.25 or 0.50 for estimating flowering end, while the GAM method used a threshold of 0.05 (Fig. S4). As in estimating population onset, the Logistic and GAM methods performed worse with increasing flowering presence due to large gaps in the absence data (Fig. S5).

With a sample size of 10 and presence proportion of 25% the Last Observed method had the highest  $R^2$ , but still underestimated the end date of flowering by 17 days the majority of the time (Fig. 2,A). The Midway method, both with and without the 7-day restriction, were never the best performing estimators. Without the 7-day restriction the method consistently overestimated the end date. With the 7-day restriction the method consistently underestimated the end date. Neither Midway method improved with either increasing sample size or increasing proportion of flowering presence. As in the population onset the results from the Mean Midway 7-Day method were excluded due to less than 1% of estimates being usable, and the GAM method had a low proportion (27-81%) of usable estimates with a sample size of 10 (Fig. S1).

Figure 2: The error distribution of all estimators for population end. The density curves are each derived from 11,000 randomly drawn observations, with sample size and presence proportion stated, across eleven years of phenological data. Text values represent the median error and the 95% quantile range in parenthesis.

## Population Peak Estimates

All three methods to estimate peak flowering had median error rates of 1 day except in one instance, using the GAM method for a sample size of 10 and proportion of flower presence 75% (Fig. 3, C). The Mean Flowering method had the highest  $R^2$  in all scenarios except three where it had  $R^2$  values equal to the Survival Curve method. For the Mean and Survival Curve methods, errors improved with both increasing sample size and increasing proportion of flowering presence. For the GAM method errors improved with increasing sample size, but worsened with increasing proportion of flowering presence.

## Individual Onset and End Estimates

For individual plant onset estimates the Midway 7-Day method performed the best in 7 of 9 scenarios (Fig. 4, A-C,D,E,G,H). In two scenarios, when the sample size was 15 and 20 with a proportion of flowering presence observations of 75%, the First Observed method had slightly higher  $R^2$  and lower median error rates than the Midway 7-Day method (Fig. 4, F,I). The Midway 7-Day method was able to produce usable individual estimates only 3-17% of the time due to its restrictive nature, while the Midway method produced usable estimates 70-100% of the time (Fig. S2).

The Weibull, Midway, Logistic, and GAM methods never produced the best estimate for any scenario in estimating individual plant flowering onset. The Weibull method did improve with increasing sample size and increasing proportion of flowering presence. Though, since the Weibull method does not use absence observations, increasing the flowering proportion effectively just increases the sample size. At effective sample sizes of 10 or more the Weibull method produced estimates only slightly worse than the Midway 7-Day and First Observed method. The Midway, Logistic, and GAM methods improved slightly with increasing sample size but worsened with increasing proportion

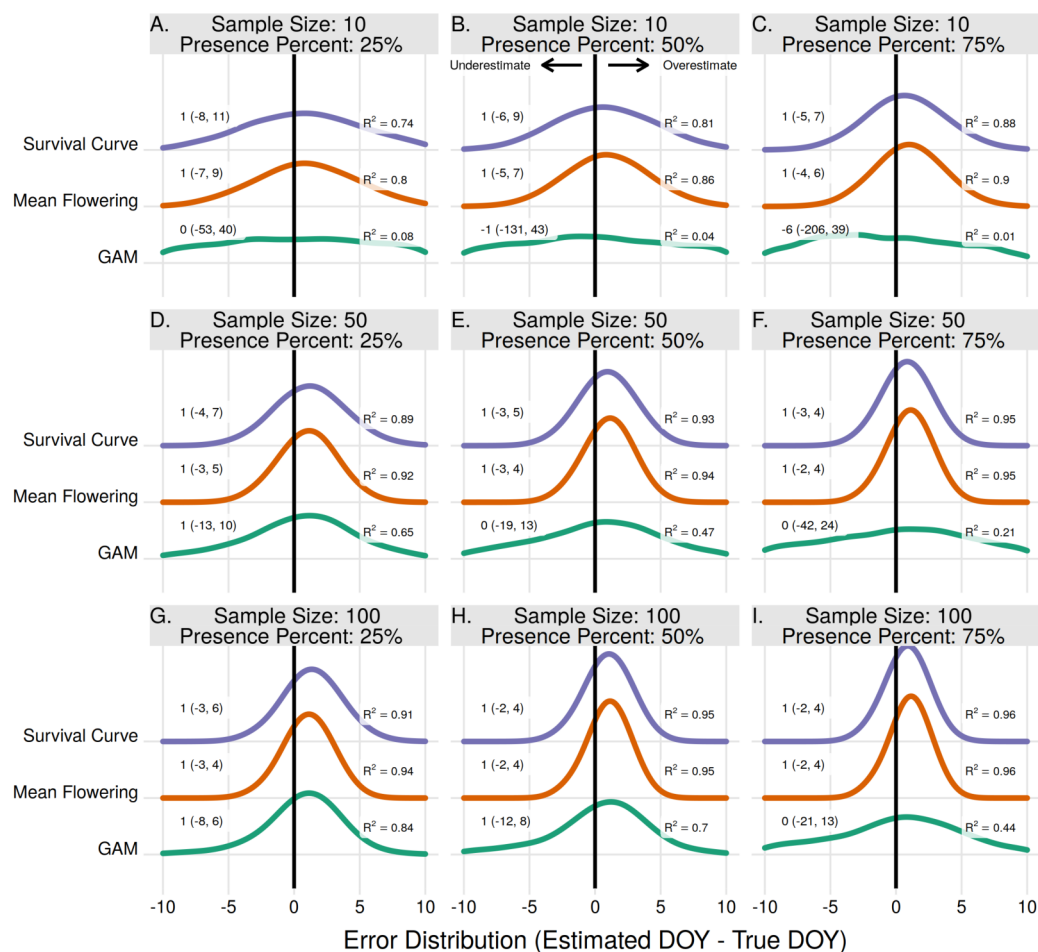

Figure 3: The error distribution of all estimators for population peak. The density curves are each derived from 11,000 randomly drawn observations, with sample size and presence proportion stated, across eleven years of phenological data. Text values represent the median error and the 95% quantile range in parenthesis.

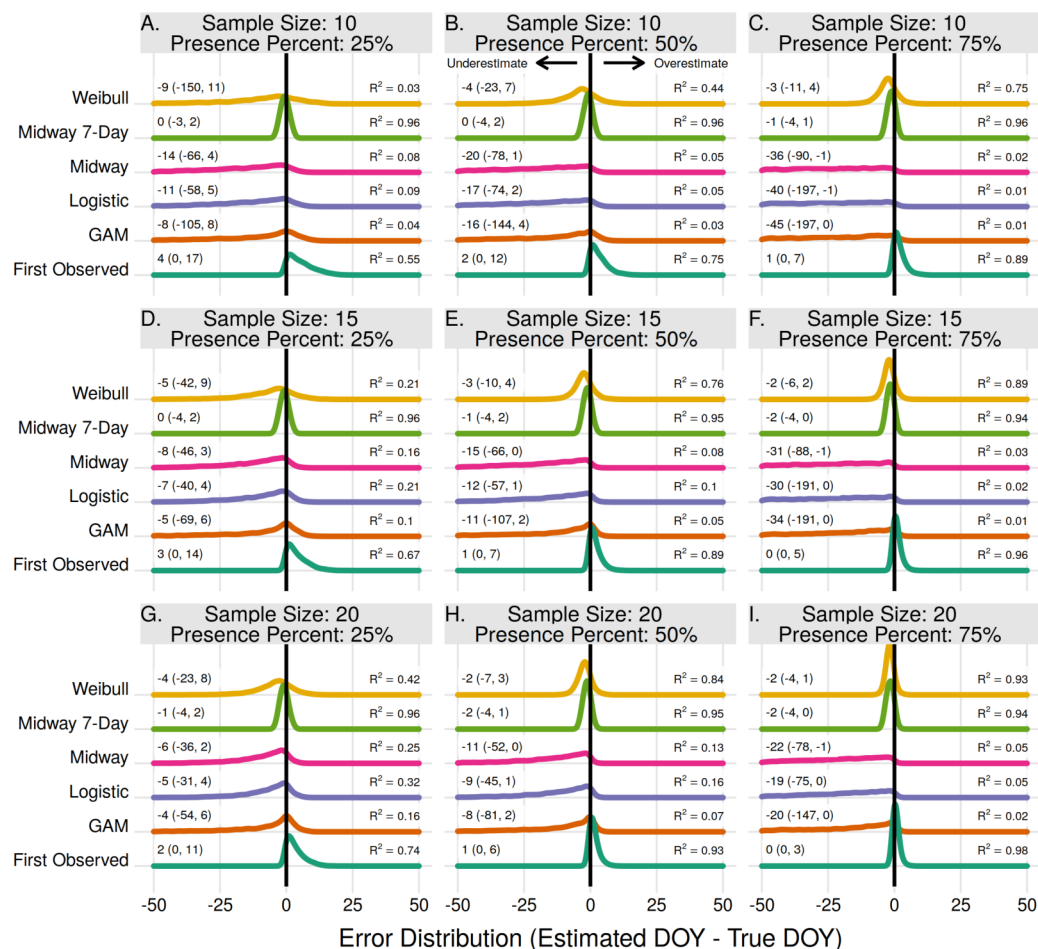

Figure 4: The error distribution of all estimators for individual onset. The density curves are each derived from 4840 randomly drawn observations, with sample size and presence proportion stated, across eleven years of phenological data for 286 individual plants. Text values represent the median error and the 95% quantile range in parenthesis.

of flowering presence.

The errors from individual end estimates were nearly identical to individual onset errors, thus the model performance outcomes were the same. Individual end errors are supplied in the supplement (Fig. S3).

# Discussion

## Overall findings

This comparison of phenological estimators using a dataset with known onset, peak, and end of flowering dates confirmed biases in some estimators and shows the strength of newer ones. Overall the Weibull method predominantly outperformed all other methods for estimating the onset and end of flowering populations. The Mean Flowering method produced better, or equal, estimates than other methods for flowering peak. The Midway 7-Day method outperformed other methods in estimating onset and end of individuals flowering, albeit with limitations on the usable sample size. Exceptions to these stem mainly from differences in sample size but also the shape of the flowering distribution.

The Weibull method was the best overall for estimating population onset and end with two exceptions. First, when the total number of flowering presence observations were extremely low (ie. with a total sample size of 10 and percent presence observations 25%) using just the first or last observed flowering date produced better estimates. Yet with such a low  $R^2$  values this method cannot be recommended, and along with other studies I recommend not estimating flowering onset or end with extremely low sample sizes (Miller-Rushing et al. 2008, Moussus et al. 2010, Bertin 2015). Second, using a larger sample size (50-100) and a small proportion of flowering presence the Logistic and GAM methods performed slightly better than the Weibull method. This suggests the Logistic and GAM methods effectively utilize flowering absence observations, but require a large amount of them, relative to presence observations, to accurately describe the phenology. Exploring the GAM and Logistic methods further showed that regular sampling, especially during the non-flowering season may also be important. Absence observations are rare in herbarium data due to a bias toward growing season sampling (Rich and Woodruff 1992, Daru et al. 2018), but more common in datasets with status-based protocols (Denny et al. 2014, Elmendorf et al. 2016). Given that flowering

322 absence observations could prove useful when presence observations are low, absence  
323 observations should be emphasized in future data collection efforts.

324 For estimating the peak of flowering populations the Mean Flowering method  
325 consistently produced the best estimate, even when the sample size and proportion of  
326 flowering presence was low, 10 and 25%, respectively. This method has the advantage  
327 over the Survival Curve and GAM method of not requiring flowering absence  
328 observations. As noted in other studies the Mean Flowering method is a reliable method  
329 for estimating peak flowering (Miller-Rushing et al. 2008, Moussus et al. 2010, Bertin  
330 2015).

331 For estimating the start and end of flowering for individual plants the Midway 7-Day  
332 method was the best in most cases. The Weibull method performed similarly when the  
333 absolute number of flowering presence observations was greater than 10, and the First  
334 Observed method also performed well with a high amount of presence observations.  
335 The First Observed method can be advantageous as it ensures no underestimate of the  
336 onset date (or no overestimate of the end date if using Last Observed). In the vast  
337 majority of cases (83-97% depending on the scenario, Fig. S2) it was not possible to use  
338 the Midway 7-Day method due to lack of individuals with an absence observation  
339 within 7 days of the first presence observation. With large enough datasets using this  
340 method is still possible even with the restriction (Gerst et al. 2016), and it can also be  
341 relaxed with a 15 or 30 day minimum to increase sample size if needed (Taylor et al.  
342 2019). If an insufficient number of individuals results from applying the restriction  
343 using the Midway method, then the Weibull or First Observed methods are preferable  
344 for estimating onset in an individual given enough flowering presence observations.  
345 While the Midway 7-Day method was the best for estimating flowering for individual  
346 plants, using the mean of those estimates from a population (Mean Midway 7-Day) did  
347 not provide the best population level estimates even with a large sample size. The onset  
348 of flowering for individuals is staggered over time and the mean of these start times is

not equivalent to the population onset date (Ison and Wagenius 2014, Keyzer et al. 2017, Renzi et al. 2019).

## **Prior study comparison**

Moussus et al. (2010) found GAM's to be among the best estimators for detecting phenological shifts among different seasons, yet here the GAM method performed best only in scenarios with a large proportion of flowering absences. Differences in analysis include Moussus et al. (2010) using a poisson distribution with simulated count data, while here I used a binomial distribution and observed presence/absence data. Moussus et al. (2010) also did not evaluate the Weibull estimator, which outperformed the GAM method in many scenerios in the current study. Here the performance of the GAM method was influenced by the proportion of absence observations, where their relative amount affected the best threshold to use as well as the highest accuracy attainable (Fig. S5). Future studies could potentially adjust the GAM model specifications to better accommodate scenarios with a low proportion of absence observations. It is also possible that the output for the GAM model used here, the probability of observing a flower, is not analogous to the total abundance of flowers. General additive models have substantial flexibility (Wood 2017, Simpson 2018, Pedersen et al. 2018) and further exploration into their use for plant phenology would be beneficial.

## **Drivers of estimator performance**

The shape of the flowering distribution affected the proficiency of the estimators. The number of *E. angustifolia* flowers observed over time resembles a skewed distribution, with a quick onset, peak, and gradual decline in number of flowers. The long tail made end estimates more difficult as the probability of observing a flower close to the true end was low. The best performing estimators also tended to overestimate onset and

underestimate end of population flowering, as the majority of randomly sampled observations came from the center of the flowering period. The likeness to a normal distribution allowed for very accurate estimates of peak flowering using the Mean Flowering method. Flowering distributions for many species are thought to have similar properties (Forrest and Miller-Rushing 2010, Clark and Thompson 2011), but the methods used here may not be appropriate for other phenophases, especially ones which can last significantly longer (ie. leaves lasting several months on the tree). Flowering is also expected to have non-uniform shifts from changing drivers (Ogilvie and Forrest 2017, Theobald et al. 2017). Other phenophases which do not have a distinct transition or cannot be easily modelled using presence and absence, such as fruit maturation, may not be well described by the methods used here. In these cases models integrating the continuous cycle of phenology would likely need to be developed, such as using integrated process based models (Chaine and Régnière 2017) or hierarchical bayesian models (Clark et al. 2014).

The outcomes for estimating the end of individuals flowering was essentially identical to estimates for the onset. The flowering of an individual *E. angustifolia* plant over time approximates a uniform distribution. Thus, unlike the skewed population flowering over time, estimators for the onset and end of individuals perform equally. This may not be the case when the study species are larger in size and/or contain numerous flowers which can be counted (Renzi et al. 2019). In these cases the phenology over time may be more similar to a population, with a flowering peak and potentially skewed distribution (while *E. angustifolia*, being in the family Asteraceae, can have one or more flowering heads each with numerous florets, here I treated each individual plant as a single unit).

## Recommendations

Results from this study can be applied to two common sources of large-scale status-based phenological observations, herbarium data and citizen science data. Data from herbarium specimens represent spatially diffuse observations at the population scale or larger, with a bias toward flowering presence (Willis et al. 2017, Daru et al. (2018)). The best onset estimator for these data depends on the type and amount of data available. With a low sample size (less than 10 observations) I recommend not estimating onset as it can lead to high errors (Miller-Rushing et al. 2008, Moussus et al. 2010, Bertin 2015). With larger sample sizes the Weibull method will be appropriate in most cases as herbarium data are mostly presence observations, but when there are a large amount of absences the GAM or Logistic methods should be explored. With a very large sample size (greater than 50) the First Observed method can be just as accurate as the Weibull, but note that this accuracy will likely decrease for longer lasting phenophases such as leaves or fruit. For estimating the end of a phenophase the same recommendations apply, with the caveat that the minimum sample size will need to increase if the phenophase distribution has a long tail. As herbarium specimens do not represent repeated observations of the same individual, individual level estimates are not applicable.

Citizen science phenological data can be subset into two types: 1) those from social media applications using geotagged images (ie. Twitter or iNaturalist, Silva et al. 2018), and 2) those from observing networks and consisting of repeated observations of the same site or individual plant (ie. the USA National Phenology Network or Pan European Phenological database, Denny et al. 2014, Templ et al. 2018). For the former the same recommendations as from herbarium specimen data apply. For the latter, if estimates for individual plants are needed then the Midway-7 Day method is most suitable as long as absence observations are available and the final usable amount of data is adequate. Without absences, or to provide more usable data, the First Observed

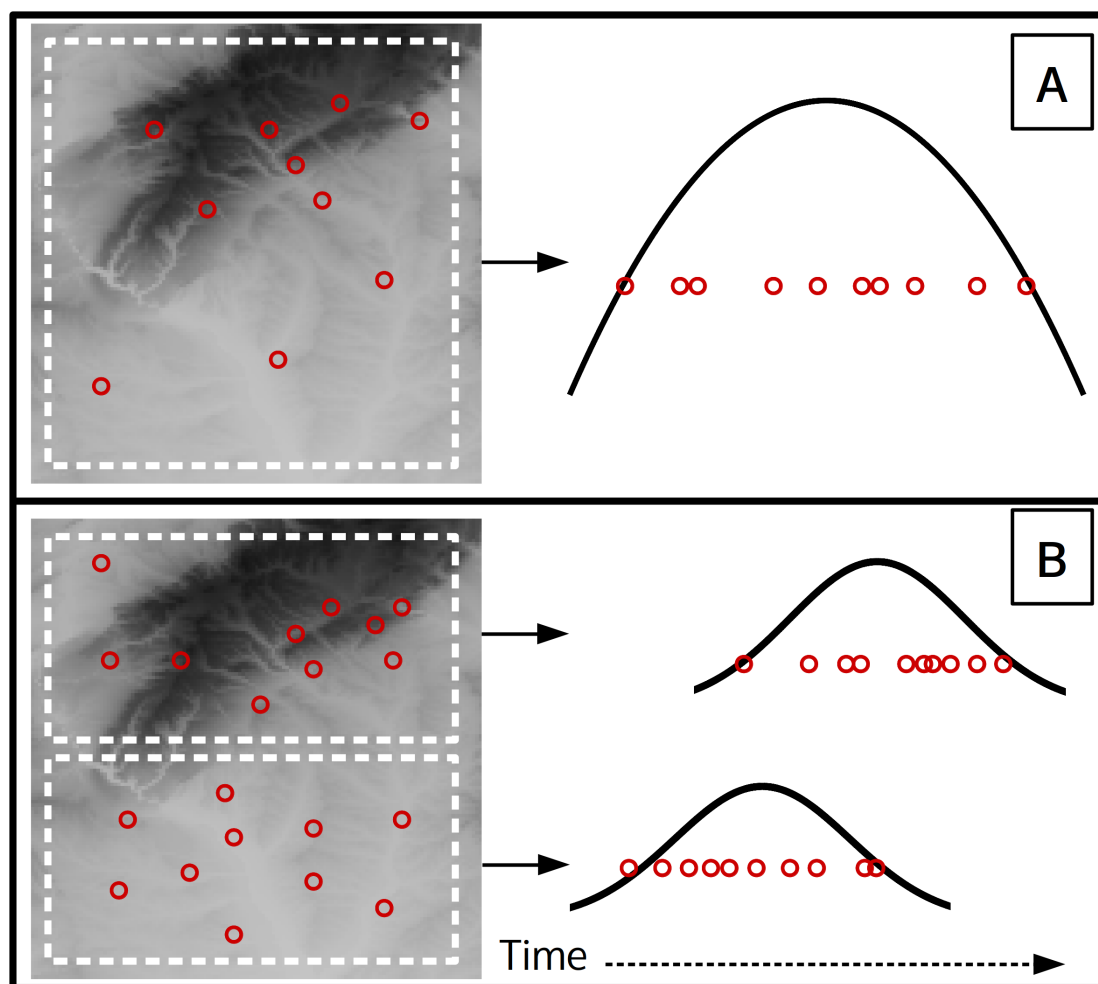

Figure 5: A theoretical scenario where 10 flowering observations are used to estimate onset across a landscape (A), and a second scenario where onset is estimated at a finer spatial grain on the same landscape (B). Curves indicate the theoretical flowering distribution over time for the respective area.

method can be used as long as the sample size is adequate, and the Weibull method should be considered regardless due to its ability to generate confidence intervals (Pearse et al. 2017).

This analysis used data from a single site, yet with herbarium or citizen science data observations more commonly represent a large spatial extent. At these larger scales the underlying phenology of a species is affected by an array of biotic and abiotic factors which can cause different flowering times at distant locations (Diez et al. 2012, Keyzer et al. 2017, Prev  y et al. 2017). When combining phenological observations from

different locations any transition estimates will be for some subset of the full flowering phenology across the species entire range (ie. the universal curve, Keyzer et al. (2017)). The spatial extent and grain of the analysis will affect the minimum sample size needed and also what the estimates represent due to the modifiable areal unit problem (Jelinski and Wu 1996). For example consider a case where 10 observations of flowering from a single year are used to estimate onset (Fig. 5A), which represents flowering onset for the entire landscape. If the same landscape is subset to a finer spatial grain (Fig. 5B), then each of the two smaller spatial units could have an independent onset estimate, but would each require an adequate sample size. Also note that the onset estimate for the larger grain (Fig. 5A) will likely approximate the onset estimate of the earlier of the two smaller grain estimates, while the larger grain end estimate will approximate the later of the smaller grain estimates. Previous studies used political boundaries as the spatial unit (Park 2014, Pearse et al. 2017), though the optimal spatial grain and observation density needed likely depends on the species being analysed and the large-scale gradients over which it occurs. Future studies should examine these relationships between spatial scales and phenology more closely.

## Conclusion

In summary I have used a precise flowering phenological dataset to confirm that naively using the first flowering observation is biased, and estimates using the Mean Flowering reliable for estimating flowering peak. I have also shown how the recently introduced Weibull method can produce reliable estimates given an adequate sample size. The Logistic and GAM methods can be useful with large datasets having low amounts of flowering presence, and future collection efforts should emphasize absence observations for this reason. Additionally, estimating transition dates of individual plants is best done with the Midway method using a 7 day restriction, and the Weibull method if the restriction results in a low number of final samples. These estimators are needed for

458 translating status-based phenological data into distinct transition dates used to track  
459 changing seasonal patterns.

## 460 **Acknowledgements**

461 I thank Amy Waananen and the team of the Echinacea Project  
462 (<http://echinaceaproject.org/>) for providing the phenology data set. I thank Amy  
463 Waananen and Janet Prev  y for providing feedback on early versions of the manuscript.
