There is a lack of information on homogeneity and distribution of ^{13}C and ^{15}N labeling in winter wheat. We conducted a dual labeling experiment to examine the variability of ^{13}C and ^{15}N enrichment in aboveground parts of labeled winter wheat. ^{13}C and ^{15}N labeling were performed on non-N fertilized ($-N$) and N fertilized ($+N$, 250 kg N ha⁻¹) winter wheat at elongation and grain filling stages. Aboveground parts of wheat were destructively sampled at 28 days after each labeling. As winter wheat growth progressed, $\delta^{13}\text{C}$ values of wheat ears significantly increased, whereas those of leaves and stems significantly decreased. At the elongation stage, N addition tended to reduce the aboveground $\delta^{13}\text{C}$ values through dilution of C uptake. At the two stages, upper (new) leaves were more highly enriched with ^{13}C compared with lower (old) leaves. Variability between individual wheat plants and among pots at the grain filling stage was smaller than that at the elongation stage, especially for the $-N$ treatment. Compared with ^{13}C labeling, differences of ^{15}N excess between aboveground components (leaves and stems) under ^{15}N labeling conditions were much smaller. We conclude that non-N fertilization and labeling at the grain filling stage may produce more uniformly ^{13}C -labeled wheat materials, while the materials were more highly ^{13}C -enriched at the elongation stage although the $\delta^{13}\text{C}$ values were more variable. ^{15}N -enriched straw tissues via urea fertilization were relatively uniformly labeled at the grain filling stage than at the elongation stage.

ABSTRACT

There is a lack of information on homogeneity and distribution of ^{13}C and ^{15}N labeling in winter wheat. We conducted a dual labeling experiment to examine the variability of ^{13}C and ^{15}N enrichment in aboveground parts of labeled winter wheat. ^{13}C and ^{15}N labeling were performed on non-N fertilized ($-N$) and N fertilized ($+N$, 250 kg N ha^{-1}) winter wheat at elongation and grain filling stages. Aboveground parts of wheat were destructively sampled at 28 days after each labeling. As winter wheat growth progressed, $\delta^{13}\text{C}$ values of wheat ears significantly increased, whereas those of leaves and stems significantly decreased. At the elongation stage, N addition tended to reduce the aboveground $\delta^{13}\text{C}$ values through dilution of C uptake. At the two stages, upper (new) leaves were more highly enriched with ^{13}C compared with lower (old) leaves. Variability between individual wheat plants and among pots at the grain filling stage was smaller than that at the elongation stage, especially for the $-N$ treatment. Compared with ^{13}C labeling, differences of ^{15}N excess between aboveground components (leaves and stems) under ^{15}N labeling conditions were much smaller. We conclude that non-N fertilization and labeling at the grain filling stage may produce more uniformly ^{13}C -labeled wheat materials, while the materials were more highly ^{13}C -enriched at the elongation stage although the $\delta^{13}\text{C}$ values were more variable. ^{15}N -enriched straw tissues via urea fertilization were relatively uniformly labeled at the grain filling stage than at the elongation stage.

KEY WORDS: $^{13}\text{CO}_2$ pulse labeling, ^{15}N labeling, homogeneity, winter wheat.

INTRODUCTION

The accurate quantification of carbon (C) and nitrogen (N) cycling in the plant–soil system requires the use of special techniques, especially for tracking above- and belowground residue C and N dynamics in soil (Shan *et al.*, 2012; Meng *et al.*, 2017; Zheng *et al.*, 2018; Xu *et al.*, 2019). This is because that small changes in soil organic C and N are difficult to detect on the background of large soil C and N pools (Felini *et al.*, 2007; Liang *et al.*, 2013; Sun *et al.*, 2018; Pausch and Kuzyakov *et al.*, 2018). Isotopic labeling of plants using ^{13}C and ^{15}N is a very powerful tool in tracking the fate of C and N derived from different plant parts in a soil-plant system when these ^{13}C and ^{15}N -labeled plant parts decompose simultaneously in situ (An *et al.*, 2015; Xu *et al.*, 2019) or laboratory (Meng *et al.*, 2017; Fang *et al.*, 2018) incubation. However, for obtaining unbiased conclusions from the fate of labeled straw C and N, quantitatively tracing the distribution of labeled straw C and N in various soil C and N pools require uniform ^{13}C or ^{15}N -labeled plant materials, since the calculations assume all plant parts become evenly labeled (Thompson, 1996; Girardin *et al.*, 2009; Nguyen Tu *et al.*, 2013; Soong *et al.*, 2014). It is therefore important to assess the variability and the degree of the ^{13}C or ^{15}N label enrichment among plant parts because different plant parts decompose at different rates, and the homogeneity of label signal in the labeled plant residues may impact the interpretation of quantification of the fractional contribution of soil organic matter and added plant material to plant uptake in subsequent decomposition studies.

Temporal ^{15}N variability among sources of N from soil and in allocation of N to different plant organs will produce labeled plant tissues with quite different ^{15}N contents (Wagger *et al.*, 1985; Crozier *et al.*, 1993). Production of more uniformly labeled tissue is a potential advantage of using a single source of N in a controlled growth system—for instance, in soil-free culture supplied with ^{15}N -fertilizer solution. The

homogeneous ^{15}N enrichment among different plant parts can be relatively easy to obtain through the growing crops fertilized with ^{15}N tracer (*Liang et al., 2013; Soong et al., 2014*), while the production of uniformly ^{13}C -labeled crop residues through $^{13}\text{CO}_2$ fixation poses a number of challenges (*Thompson, 1996; Girardin et al., 2009; Nguyen Tu et al., 2013; Soong et al., 2014*). This difficulty is because rates of C incorporation (photosynthesis) differ widely among plant compartments, which further increases ^{13}C isotope variation of the obtained plant tissues (*Thompson, 1996; Girardin et al., 2009; Nguyen Tu et al., 2013; Soong et al., 2014*). Pulse or continuous labeling of above-ground plant parts has frequently been used to the production of ^{13}C or ^{14}C -labeled plant parts. A continuous supply with either ^{14}C or ^{13}C presents an advantage over pulse labeling for uniformly label all plant parts, but it requires special facilities and was applied from first leaf emergence to harvest time, therefore it is not possible to use this approach under field conditions (*Zhu et al., 2014*). Field ^{13}C (or ^{14}C) and ^{15}N labeling has shown potential in investigating C and N dynamics derived from crop residues under actual field conditions, as affected by chemical composition and quantities of crop residue (*Berg et al., 1991; Tahir et al., 2018*). For instance, concentrations of phenolic compounds, which may alter decomposition rates (*Fox et al., 1990; Ranells and Waggar, 1992*), may be sensitive to differences in field, greenhouse, or growth-chamber UV light intensities (*Crozier et al., 1993*). For field isotopic labeling, pulse labeling is better than continuous labeling due to the advantage of being easier to handle and simple instrumentation (*Berg et al., 1991; Tahir et al., 2018*). However, most of the labeled crop residues that were used for C and N dynamic studies were labeled with ^{13}C (or ^{14}C) and ^{15}N tracer under controlled conditions.

For the production of the labeled crop residues, the field-labeling experiments that were developed in the past were mainly focused on the degree of ^{13}C and ^{15}N enrichment in crop residues with ^{13}C and ^{15}N . However, few researchers evaluated the homogeneity and distribution of ^{13}C and ^{15}N labels within the labeled plant

compartments, especially from winter wheat residues, one of the most important staple crops and frequently used plants in labeling studies (*Jia et al., 2011; Butterly et al., 2015; Chen et al., 2016; Sun et al., 2018*). In annual cereal crops, the plants grow vigorously and the enrichment of labeled C is higher at the early stage than at the mature stage (*Meng et al., 2013; Liu et al., 2015; Sun et al., 2018*). However, the majority of C labeling studies have been conducted at the early growth stages of wheat, e.g., 60 days after emergence by continuous labeling (*Liljeroth et al., 1994; Marx et al., 2007*) and <150 days after emergence by pulse labeling (*Martens et al., 2009; Butterly et al., 2015*), and few studies have compared the enrichment of labeled C for different labeling periods. In addition, heavy use of N fertilizer delayed senescence in wheat, which resulted in much nonstructural carbohydrate left in the straw and affected the photosynthesis (*Yang and Zhang, 2006*), might lead to changes in the enrichment degree of labeled C in straws. To assess uniformity of labeling within plants, the shoot of a single plant was divided into leaves and stem from three sections of equal length using the method described by *Thompson (1996)*. Thus, we set up a ^{13}C pulse-labeling and ^{15}N fertilization experiment for labeling winter wheat under field pot-grown conditions at different growth stages, and the objectives were: (i) to assess the homogeneity and the degree of ^{13}C and ^{15}N enrichment among different wheat organs and among different positions of identical organs such as stems and leaves; and (ii) investigate the impacts of wheat growth and N fertilization on the isotope variability among aboveground compartments after ^{13}C -labeling.

MATERIAL AND METHODS

Treatments and ^{15}N labeling procedure

In current study, we used winter wheat (*Triticum aestivum* L. ‘Luyuan 502’), one of the main staple crops grown in the world (Zhao *et al.*, 2016). To examine the impacts of wheat growth stages and N fertilization on the variation of ^{13}C enrichments of winter wheat, two N levels (0 mg N kg⁻¹ soil, -N; and 90 mg N kg⁻¹ soil, equivalent to 250 kg N ha⁻¹, +N) were applied, and wheat plants grown on a calcareous soil (fluvo-aquic sandy loam) were $^{13}\text{CO}_2$ pulse-labeled at elongation (168 days after sowing; (DAS)) and grain filling (205 DAS) stages (Figure 1a and b). To examine the variation degree of ^{15}N enrichment among aboveground compartments, the ^{15}N -labeled fertilizer was applied in the form of ^{15}N -labeled urea by directly adding N to soil for +N treatment (the atom% ^{15}N was 10.14%; about 10 US dollars per gram of ^{15}N labeled urea), which was provided by Shanghai Research Institute of Chemical Industry. Meanwhile, the other wheat plants were selected as ^{15}N natural abundance controls fertilized with unlabeled urea for +N treatment. Ten pre-germinated (24–48 h) winter wheat seeds were sown directly into pots (30 × 20 cm i.d.) containing 8.7 kg air-dried soil, and the soil was rewetted to 70% of the water holding capacity. One week after germination (October 20, 2014), all except the six strongest seedlings were removed (equivalent to a field planting density of 1.5 million plants ha⁻¹). The experiment was conducted under field pot-grown condition. For the N addition treatment (+N), half of the ^{15}N labeled or unlabeled urea was applied basally at sowing (0.84 g ^{15}N labeled or unlabeled urea was applied to each pot) and the other half was used to top-dress plants at the elongation stage (March 15, 2015). The wheat plants for the first $^{13}\text{CO}_2$ labeling were fertilized in only one basal application and received 45 mg N kg⁻¹ air-dried soil. The wheat plants for the second $^{13}\text{CO}_2$ labeling received a total of 90 mg N kg⁻¹ air-dried soil in two applications during the experiment (1.68 g ^{15}N labeled or unlabeled urea was applied to each pot; corresponding to a total fertilization of 250 kg N ha⁻¹), which was split into 2 × 45 mg N kg⁻¹ air-dried soil (basal urea N and topdressing urea N). KH_2PO_4 fertilizer was applied basally at a rate of 17 mg P

and 18 mg K kg⁻¹ air-dried soil (same to local agricultural practice). To produce plant litter similar to field-grown conditions in this study, we therefore applied ¹⁵N-urea to soil of field pot-grown winter wheat rather than supplying ¹⁵N-fertilizer solution to soil-free culture.

Growth conditions and ¹³C pulse labeling procedure

Soil was collected from plough layer of farmland (0–20 cm) near the Agro-Ecosystem Experimental Station of China Agricultural University, Hantai County, Shandong Province (36°57'N, 117°59'E, 18 m elevation). The soil of the experimental field was derived from alluvial sediments of Yellow River and was classified as aquic inceptisol (a calcareous, fluvo-aquic sandy loam; *Shi et al., 2013*). Soil properties were as follows: soil organic C = 8.4 g kg⁻¹, soil inorganic C = 5.2 g kg⁻¹, total N = 0.67 g kg⁻¹, NH₄-N = 1.6 mg kg⁻¹, NO₃-N = 17.2 mg kg⁻¹, pH = 8.2 (soil: water = 1: 2.5), available K = 174 mg kg⁻¹, and Olsen P = 5.2 mg kg⁻¹. After sampling, the soil was air-dried, homogenized, and sieved (5-mm screen) prior to the experiment. Each pot (height = 30 cm; inner diameter = 20 cm) for wheat-growing was filled with 8.7 kg of air-dried soil to a bulk density of 1.38 g cm⁻³. Wheat mainly concentrated in 0–20 cm soil layer and contributed the proportion to 0 to 100 cm total rooting weight were 57.6%–78.6% in typical farmland of Northern China Plain (*Hou, 2011*), hence pots with 30 cm soil layer was enough for wheat root development in this study. The pot-planted winter wheat seedlings were transferred to the field of the above-described Agro-Ecosystem Experimental Station. The PVC pots containing wheat plants were placed in cropland holes (30 cm in depth; 24 cm in diameter) to simulate local wheat-growing conditions. The total growth period was 230 days, with six different growth stages recognized: (i) seeding (0–17 DAS), (ii) tillering (18–150 DAS), (iii) elongation (151–179 DAS), (iv) anthesis (180–193 DAS), (v) grain filling (194–214 DAS), and (vi) dough ripening (215–230 DAS). The precipitation was 147 mm and soil temperature varied from -1.6 to 29.7 °C during the wheat season

(Zhao *et al.*, 2017). The soil water content of each pot, which was controlled gravimetrically to simulate local wheat production and was adjusted daily to 65% (during the seedling stage), 70% (tillering), 80% (elongation), 80% (anthesis) and 70%–75% (grain-filling) of the field water-holding capacity, according to the amount of rainfall and evaporation.

The $^{13}\text{CO}_2$ labeling was performed at elongation and grain filling stages (i.e., 168 and 205 DAS). On each occasion, four pots were randomly selected for $^{13}\text{CO}_2$ labeling under -N treatment, and four pots were also randomly chosen for $^{13}\text{CO}_2$ labeling under +N treatment (^{15}N labeling with ^{15}N -urea), with an additional eight pots selected as $^{13}\text{CO}_2$ unlabeled controls and maintained separately from the labeled plants. Hence, we used 32 pots in this experiment with three replicates for each N treatment, for destructive sampling at 28 days after labeling during each of the growth stages (three from four pots per sampling for each treatment): 8 pots were labeled with dual ^{13}C and ^{15}N labeling in +N treatment; 8 pots were labeled with single ^{13}C labeling for -N treatment; and an additional 16 pots were selected as unlabeled controls (8 pots for -N and 8 pots for +N). We considered each pot as the technical replicate for each treatment (three from four pots per sampling for each treatment), and took each plant within pot as the biological replicate (three plants chosen within the pot). A chamber (0.6 m long \times 1.0 m high; Figure 1c) adapted from Swinnen *et al.* (1994) and Meng *et al.* (2013) was used for the $^{13}\text{CO}_2$ labeling. On the previous day, the soil surface was covered with a PVC board and sealed with silicon, including around stems. To remove all $^{12}\text{CO}_2$ before labeling, the air inside the chamber was continuously circulated for 30 min through a 10 M NaOH solution using a membrane pump. The ^{13}C labeled $\text{Na}_2^{13}\text{CO}_3$ at 98 atom% ^{13}C (about 100 US dollars per gram of $\text{Na}_2^{13}\text{CO}_3$) was provided by Shanghai Research Institute of Chemical Industry. A beaker containing $\text{Na}_2^{13}\text{CO}_3$ (8.0 g of $\text{Na}_2^{13}\text{CO}_3$ for each labeling occasion) was placed inside the chamber. To determine CO_2 concentrations within the chamber using an infrared gas

analyzer (CI301PS; CID Bio-Science, Camas, WA, USA), an unlabeled control treatment with an additional four pots was set up in another chamber under the same conditions except that Na_2CO_3 was used to produce non-labeled CO_2 . This arrangement was used because of the different wavelengths for maximum absorption of $^{13}\text{CO}_2$ and $^{12}\text{CO}_2$ in the infrared detector (Meng *et al.*, 2013). If the rate of CO_2 concentration decline slowed considerably (below $200 \mu\text{L L}^{-1}$) in the chamber containing the unlabeled control treatment, 1 M H_2SO_4 was injected until CO_2 concentrations increased to approximately $360 \mu\text{L L}^{-1}$. The same amount of H_2SO_4 solution was also injected into the chamber housing the plants being labeled. A fan was used to homogenize the atmosphere within each chamber. After 7 h of labeling, plants were removed from the chamber to prevent the re-assimilation of shoot-respired $^{13}\text{CO}_2$.

Sampling and chemical analyses

^{13}C -labeled winter wheat and soils were destructively sampled 28 days after each labeling. There was no significant difference between the mean weights of the aboveground and root biomass of the ^{13}C pulse labeled plants and the unlabeled control plants when they were harvested 28 days after labeling during each of the growth stages. This indicated that ^{13}C pulse labeling and did not affect plant growth. To examine the uniformity of labeling within a wheat plant, individual entire wheat plants were collected at final harvest and their shoots (stem and leaves) were divided into three equal-length portions (upper, middle and lower portion; Figure 1d). Separate analyses of ^{13}C and ^{15}N enrichment were undertaken on leaf and stem portions as well as the ears. Three plants per pot were assessed for the variation of ^{13}C and ^{15}N enrichments. Shoots (stems and leaves) and ears were oven-dried at 60°C to a constant weight. All samples were ground to a fine powder ($<500 \mu\text{m}$) in a ball mill (Restol MM2000, Retsch, Haan, Germany) prior to analysis.

The ^{13}C and ^{15}N values of wheat plant materials were determined using isotope ratio mass spectrometry (DELTAplus XP, ThermoFinnigan, Bremen, Germany). The abundance of ^{13}C was expressed as parts per thousands (‰) relative to the international standard (Pee Dee Belemnite, PDB; 0‰) expressed as delta units (δ) (Craig, 1953). The ^{15}N enrichment of ^{15}N labeled plant parts fertilized with labeled urea was reported as atom% ^{15}N excess calculated by subtracting the ^{15}N natural abundance control samples fertilized with unlabeled urea (Coplen, 2011).

Data processing and statistical analysis

To estimate the weight-average ^{13}C and ^{15}N values of the aboveground and three equal-length portions (upper, middle and lower portion) of shoot in the winter wheat, a simple isotopic mass balance mixing equation was used (Thompson, 1996):

$$\delta^{13}\text{C}_{\text{aboveground}} = \delta^{13}\text{C}_{\text{ear}} \times F_{\text{ear}} + \delta^{13}\text{C}_{\text{leaves}} \times F_{\text{leaves}} + \delta^{13}\text{C}_{\text{stem}} \times F_{\text{stem}} \quad (1)$$

$$^{15}\text{N}_{\text{aboveground}} = ^{15}\text{N}_{\text{ear}} \times F_{\text{ear}} + ^{15}\text{N}_{\text{leaves}} \times F_{\text{leaves}} + ^{15}\text{N}_{\text{stem}} \times F_{\text{stem}} \quad (2)$$

$$1 = F_{\text{ear}} + F_{\text{leaves}} + F_{\text{stem}} \quad (3)$$

where $\delta^{13}\text{C}_{\text{aboveground}}$, $\delta^{13}\text{C}_{\text{ear}}$, $\delta^{13}\text{C}_{\text{leaves}}$, and $\delta^{13}\text{C}_{\text{stem}}$ is C isotope values (δ) for aboveground, ear, leaves, and stem of winter wheat, respectively; $^{15}\text{N}_{\text{aboveground}}$, $^{15}\text{N}_{\text{ear}}$, $^{15}\text{N}_{\text{leaves}}$, and $^{15}\text{N}_{\text{stem}}$ is ^{15}N excess in atom% for aboveground, ear, leaves, and stem of winter wheat, respectively; and F_{ear} , F_{leaves} , and F_{stem} is the total aboveground dry weight of winter wheat in the respective ear, leaves and stem fractions.

$$\delta^{13}\text{C}_{\text{i portion}} = \delta^{13}\text{C}_{\text{i leaves}} \times F_{\text{i leaves}} + \delta^{13}\text{C}_{\text{i stem}} \times F_{\text{i stem}} \quad (4)$$

$$^{15}\text{N}_{\text{i portion}} = ^{15}\text{N}_{\text{i leaves}} \times F_{\text{i leaves}} + ^{15}\text{N}_{\text{i stem}} \times F_{\text{i stem}} \quad (5)$$

$$1 = F_{\text{i leaves}} + F_{\text{i stem}} \quad (6)$$

where $\delta^{13}\text{C}_{i\text{portion}}$ and $^{15}\text{N}_{i\text{portion}}$ is C isotope values (δ) and ^{15}N excess in atom% for upper, middle and lower portion of shoot of winter wheat, respectively; and $F_{i\text{leaves}}$ and $F_{i\text{stem}}$ is the respective leaves and stem fractions in the same portion of shoot.

Statistical analysis was carried out with SPSS (version 11.0, 2002, SPSS, Chicago, Illinois, USA). Two-way analysis of variance was performed to analyze the effect of N fertilization and/or growth stage on ^{13}C and ^{15}N distribution in different aboveground wheat components. The LSD test was used to examine differences in ^{13}C and ^{15}N isotope values between N treatments or different aboveground components. A level of 0.05 was chosen to indicate statistical significance.

RESULTS

Wheat biomass, total C and N

The interactive effect of plant age and N fertilizer treatment on increasing the biomass of the ear and whole wheat was at a significant level (Table 1 and Figure 2a), indicating that the effect of N fertilization tend to be more profound as wheat growth progressed. Straw, ear and whole wheat plant biomass were significantly higher in the +N treatment than in the -N at the elongation and grain filling stages (Figure 2a). With plant growth, the C and N content of wheat straw and ear significantly increased (Table 1 and Figure 2b, c), whereas no significant differences in roots were observed from the elongation to grain filling stages (Table 1 and Figure 2a). Compared with -N, N fertilization significantly decreased the C content of straw, and significantly increased the N content of wheat straw and ear at the elongation and grain filling stages (Table 1 and Figure 2b, c).

$\delta^{13}\text{C}$ values of aboveground components of winter wheat

In the ^{13}C labeled wheat plants, $\delta^{13}\text{C}$ values in leaves were the highest, followed by stems and ears at the elongation stage; however, significantly higher ^{13}C enrichment was observed in the ears than in the other aboveground parts at the grain filling stage (Table 2). As growth progressed, $\delta^{13}\text{C}$ values of ears significantly increased, by 130% and 170% for $-N$ and $+N$ treatments, respectively; in contrast, $\delta^{13}\text{C}$ values of leaves and stems significantly decreased, by 82.3% ($-N$) and 72.2% ($+N$) in leaves and 72.4% ($-N$) and 65.5% ($+N$) in stems. This indicated that growth stage had a significant impact on ^{13}C distribution among ears, leaves, and stems (Table 3). N fertilization decreased $\delta^{13}\text{C}$ values of aboveground wheat components at the elongation stage and had no significant effects at the grain filling stage; however, the change was only significant in leaves at the elongation stage (36.9%; Tables 2 and 3).

Shoots (leaves and stems) of single wheat plants were divided into three equal-length portions (upper, middle, and lower), to analysis the labeled ^{13}C distribution within the shoot. Following pulse labeling at the elongation stage, $\delta^{13}\text{C}$ values of leaves and stems in different portions was significantly different: the leaves of lower portion was least ^{13}C enriched for both $+N$ and $-N$ treatments, and ^{13}C enrichment was highest in the middle and upper portions under $-N$ and $+N$ treatments, respectively; however, $\delta^{13}\text{C}$ values of stems were highest in the lower portion, followed by middle and upper portions, both under $-N$ and $+N$ conditions (Figure 3). A significant difference was observed at the grain filling stage: for both leaves and stems, $\delta^{13}\text{C}$ values were significantly highest in the upper portion, with no significant differences between middle and lower portions (Figure 3).

When we combined $\delta^{13}\text{C}$ values from the same portions of leaves and stems, at elongation stage, we observed that there were no significant differences among different portions for $+N$ treatment, and $\delta^{13}\text{C}$ values of upper and middle portions was significantly higher than that of lower portion for $-N$ treatment; at the grain

filling stage, the $\delta^{13}\text{C}$ values of upper portion was the highest, followed by that in the middle and lower portions under both $-N$ and $+N$ conditions (Table 4).

Labeled plants had coefficients of variation (CVs) for intra-pot (between individual plants) $\delta^{13}\text{C}$ of 9.4%–76.4% and 6.3%–31.5% at elongation and grain filling stages, respectively, while inter-pot CVs (among plants across different pots) for $\delta^{13}\text{C}$ ranged from 16.5%–59.0% at the elongation stage and 3.8%–70.9% at the grain filling stage (Table 5). Generally, CVs at the grain filling stage were lower than those at the elongation stage, and N addition tended to increase $\delta^{13}\text{C}$ variation, particularly at the grain filling stage.

^{15}N enrichment variation in aboveground components of winter wheat

Following ^{15}N -labeling, the order of ^{15}N excess (in atom%) of ears, leaves, and stems were similar at elongation and grain filling stages, with ^{15}N excess highest in ears, followed by stems and leaves (Table 2). In regard to the three shoot portions (without ears), combined ^{15}N excess of leaves and stems were similar among different portions at both elongation and grain filling stages (Table 4). ^{15}N excess of stems and leaves were similar at the elongation stage, but were highest in the upper portion and lowest in the lower portion at the grain filling stage (Figure 4). As growth advanced, i.e., with the increase in biomass, ^{15}N excess were increased by 32.1%–41.8% (Table 2). Stage had a significant impact on ^{15}N excess for all shoot components except lower portions of leaves (Table 3). Labeled wheat exhibited an intra-pot CV of 7.7%–18.1% at both elongation and grain filling stages; the inter-pot CV was 1.7%–23.4% at the elongation stage, with much smaller variation at the grain filling stage (0.1%–6.2%; Table 5). At both stages, the variation in ^{15}N excess was smaller than that of $\delta^{13}\text{C}$. For both ^{15}N excess and $\delta^{13}\text{C}$ values, intra-pot and inter-pot CVs were comparable, showing similar levels of variation for ^{13}C and ^{15}N distributions.

DISCUSSION

Variation in ^{13}C enrichment

Average total $\delta^{13}\text{C}$ values of aboveground wheat parts resulting from $^{13}\text{CO}_2$ release from $\text{Na}_2^{13}\text{CO}_3$ (98 atom% ^{13}C) in the field labeling chamber ranged from 81‰ to 295‰ (Table 2). Because most studies involving pulse labeling of wheat used ^{14}C rather than ^{13}C , we compared our findings with those of studies using ^{13}C labeling in other plants. By injection of $^{13}\text{CO}_2$ gas (90 atom% ^{13}C) in a field labeling chamber, *Tahir et al.* (2018) produced a large amount of wheat with a final $\delta^{13}\text{C}$ enrichment of 493‰ in leaves and 357‰ in stems, while *Meng et al.* (2013) enriched maize shoots to approximately 125‰–178‰ via $^{13}\text{CO}_2$ release from $\text{Ba}^{13}\text{CO}_3$ (98 atom% ^{13}C) in a laboratory labeling chamber. The direct $^{13}\text{CO}_2$ labeling method has also been used for the production of very highly ^{13}C -enriched crop plants such as rice (533‰–927‰) (*Liu et al.*, 2015) and clover (>1000‰) (*Thompson*, 1996). The ^{13}C enrichment of plant materials is dependent on both the quantity of ^{13}C per gram dry weight of plant labeled, which is influenced by the quantity of ^{13}C added to the labeling chamber, and net ^{12}C and ^{13}C assimilation rates.

The development of winter wheat ear during the entire growth season was clearly reflected in the increasing allocation of ^{13}C to that reproductive organ. As growth advanced, $\delta^{13}\text{C}$ values of ears significantly increased, whereas those of leaves and stems significantly decreased (Tables 1, 2). This pattern, i.e., an increase in the carbohydrate sink during plant development, is typical of cereal crops. In a ^{14}C pulse-labeling experiment, *Swinnen et al.* (1994) found that up to 85% of the ^{14}C allocated to aboveground parts was recovered in the ears at the ripening stage. In our study, the proportion in ears relative to all aboveground portions increased from 30% at the elongation stage to 50% at the grain filling stage (Figure 2a). Among aboveground components, $\delta^{13}\text{C}$ values were also the highest in ears at grain filling stage (Table 2). At the grain filling stage, the ears were conditioned by the size and availability of C pools. At the grain filling stage, the

main C sources for wheat ears are mainly from the remobilization of labeled photosynthesized C from leaves and stems, and the photosynthesis by the ears itself (Palta *et al.*, 1997; Aranjuelo *et al.*, 2013; Zhou *et al.*, 2016). Several studies using the natural abundance of ^{13}C and ^{13}C labeling techniques have proved that ear photosynthesis may account for 40% to 80% of the C accumulated in the ears (Palta *et al.* 1997; Aranjuelo *et al.* 2011; Sanchez-Bragado *et al.* 2014). The fact that the leaves and stems had the lowest labeled C in wheat is also indicative that these organs acted as a C source for grain filling, with ears as sink having more labeled C. This result is in agreement with previous C pulse labeling study for wheat during grain filling (Aranjuelo *et al.*, 2013). However, at the elongation stage, the larger ^{13}C -enriched values of shoots (leaves and stems) was observed in this study (Table 2). This suggested that shoots acted as major labeled C sinks due to the poor sink strength of ears at the elongation stage, while ears represented the major labeled C sink that competed with the shoots as C sink at the grain filling stage (Palta *et al.*, 1994; Aranjuelo *et al.*, 2013; Zhou *et al.*, 2016).

At the elongation stage, N addition tended to reduce $\delta^{13}\text{C}$ values of aboveground components through a dilution effect (Table 2). Compared with the -N treatment, net ^{13}C assimilation in plant biomass increased by 7.8% under the +N treatment (76 mg ^{13}C pot⁻¹ for -N vs. 82 mg ^{13}C pot⁻¹ for +N), while the increase in plant biomass was 35% (Figure 2a). Another likely relevant factor was the reduced carbohydrate accumulation under over-supplied N conditions, i.e., under the +N treatment in the current study (Palta, 1991; Gooding and Davies, 1992). At the grain filling stage, N addition tended to increase $\delta^{13}\text{C}$ values of aboveground components (Table 2). This result was probably due to the presence of more green leaves for the +N treatment at the later stage of maturity (grain filling), which have a stronger photosynthetic capacity and hence can affect the ^{13}C -isotopic signature of aboveground components.

At both labeled stages, ^{13}C enrichment was higher in upper (new) leaves than in lower (old) leaves (Figure 3), which may be explained by the more rapid uptake of $^{13}\text{CO}_2$ by younger leaves. Leaf age influences photosynthetic capacity, and also the ^{13}C -isotopic signature of plant leaves (*Girardin et al., 2009*). In addition, young expanded leaves provide most labeled C assimilates for stem growth (*Ryle and Powell, 1972; Subrahmanyam and Rathore, 2004*). Other factors, such as light intensity (*Ryle and Powell, 1972; Subrahmanyam and Rathore, 2004*), air temperature (*Meharg and Killham, 1989*), and relative humidity (*Farquhar et al., 1982*), are also known to influence photosynthetic rates and change the C-isotopic signature. Wheat leaves had higher $\delta^{13}\text{C}$ values than stems (Table 2), which is in agreement with previous $^{13}\text{CO}_2$ pulse-labeling studies such as that of grain sorghum (*Berg et al., 1991*). Leaf and stem positions (upper, middle, and lower) also influence the $\delta^{13}\text{C}$ values of aboveground components (*Thompson, 1996*). In our study, upper leaves tended to be more enriched in ^{13}C compared with upper stems, whereas lower leaves were generally less ^{13}C -enriched than stems at a similar position (Table 2) (*Thompson, 1996*). This result was due to the remobilization of photosynthate and more recently fixed C from leaves to stems during reproductive (grain filling) and vegetative (elongation) stages. The great variation in $\delta^{13}\text{C}$ values in leaves and stems indicated that a single $^{13}\text{CO}_2$ pulse-labeling did not produce uniformly ^{13}C -labeled plant material. Repeat-pulse labeling has been suggested to overcome the technical constraints of continuous labeling and the high variation issues of single-pulse labeling approach, and may obtain adequate homogeneous ^{13}C -labeled plant material (*Roper et al., 2013; Tahir et al., 2018*).

With respect to isotope signals, labeled plants also exhibited different patterns of variation among individual plants within a pot and among the three replicate pots (Table 5). Approximately 75% of leaf and stem components had a CV for intra-pot $\delta^{13}\text{C}$ higher than 30% at the elongation stage, while 67% had a CV

less than 20% at the grain filling stage. This result demonstrates that the variability between individual wheat plants at the grain filling stage was smaller than that at the elongation stage, especially for the -N treatment. The ^{13}C -enrichment variation in different portions of shoot at the elongation stage are much higher than that of the grain filling stage, which may explain that young leaves are the most frequently labeled wheat organs (*Girardin et al., 2009; Nguyen Tu et al., 2012*). The stronger labeling of starch is related to its rapid synthesis during leaves photosynthesis compared with that of stems during vegetative growth stages, while the redistribution of labeled C from source organs (leaves and stems) toward sink organs (ears) of C assimilated during the grain filling period (*Aranjuelo et al., 2013; Zhou et al., 2016*) may lead to a less extent of variations of ^{13}C -enrichment among plant organs. Such different variations between +N and -N were because C and N remobilization starts earlier and stronger when plants are under low N fertilization compared to high N fertilization condition (*Aranjuelo et al., 2013*). Approximately 83% of leaf and stem components had an inter-pot $\delta^{13}\text{C}$ CV higher than 20% at the elongation stage, while 67% had an intra-pot $\delta^{13}\text{C}$ CV lower than 20% at the grain filling stage (Table 5). This result might indicate that the photosynthesized C in leaves and stem has many destinations at the elongation stage, whereas the reallocation of labeled C from leaves and stem mainly goes to the ears at the grain filling stage (*Palta et al., 1994; Aranjuelo et al., 2013; Zhou et al., 2016*). We therefore suggest that labeling of winter wheat at the grain filling stage without N fertilization may produce more uniformly ^{13}C -labeled materials, while labeling of winter wheat at the elongation stage without N fertilization may produce more highly ^{13}C -enriched plant materials albeit it can be more variable.

Variation in ^{15}N enrichment

Compared with ^{13}C labeling, differences in ^{15}N excess between aboveground components under ^{15}N labeling conditions were much smaller (Table 2). Variation among individual plants (intra-pot) and among

different pots (inter-pot) was also much lower (Table 5). No significant differences in ^{15}N excess were observed among wheat aboveground components; the greatest difference, between ears and leaves, was only 11% at the grain filling stage (Table 2). This result suggests that the ^{15}N -enriched urea application used in this study can produce relatively uniformly labeled straw tissues at the late (grain filling) stage in wheat. It is because N is a very mobile nutrient in the plant, because there are other nutrients (i.e., C) that do not move so easily inside the plant. This outcome is due to the fact that N is utilized as a nutrient by plants, whereas C is a basic element of plant photosynthesis. In contrast to plant ^{13}C labeling, which requires complex environmental conditions, such as temperature, humidity, and $^{13}\text{CO}_2$ concentration, to be maintained throughout the labeling period (Soong *et al.*, 2014), ^{15}N labeling is relatively easy to achieve through ^{15}N fertilization. Ideally, studies of straw tissue decomposition rate should be conducted, both to select uniformly enriched materials (Crozier *et al.*, 1993; Soong *et al.*, 2014) and to choose straw tissue similar to that of actual field-grown plant tissues (Crozier *et al.*, 1993). The chemical composition of straw tissue at late maturity differs substantially from that at an early stage of maturity. For instance, most plant N at later stages of maturity is associated with higher proteins, nucleic acids, and amino sugars (Waggar *et al.*, 1985). Some components may exist in a form more resistant to microbial decomposition, such as N associated with cell wall material (Waggar *et al.*, 1985).

As wheat growth progressed, i.e., with an increase in biomass, ^{15}N excess increased by 30.4%–41.1% (Table 2), indicating that plant N demand was satisfied by available soil N derived from ^{15}N fertilizer between elongation and grain filling stages. N demand per plant is largely met through N uptake by roots pre-anthesis, with ear N content also supplemented by the amount of N absorbed by root systems between anthesis and ear maturity (Kichey *et al.*, 2007).

The ^{15}N enrichment of shoots and ears were different at different wheat stages. At the elongation stages, there was no significant differences of ^{15}N enrichment among leaves, stems and ears. This result may be explained by the fact that the redistribution of labeled N from source organs to ears was low level and the heading ears N was mainly taken up from the soil during vegetative growth stages (Aranjuelo *et al.*, 2013). However, at the grain filling stage, wheat ears labeled with ^{15}N tended to accumulate a significantly higher ^{15}N compared with other aboveground components (Table 2). Other researchers have described similar phenomena following ^{15}N labeling, such as in wheat (Ladd *et al.*, 1981; Palta *et al.*, 1994) and in winter wheat and grain sorghum (Waggar *et al.*, 1985). The ears was a critical pool of N sink that influenced the N accumulation in the ears during the grain filling, while the shoots and roots serve to feed the ears (Palta *et al.*, 1994; Aranjuelo *et al.*, 2013; Zhou *et al.*, 2016; Sun *et al.*, 2018; Zhou *et al.*, 2018). In the same experiment, we found that 65% of total N of grains was remobilized from the N accumulation in the shoots and roots during vegetative growth stage, while the remaining 35% was derived from the N taken up from the soil during grain filling stage (Sun *et al.*, 2018). Although ears exhibited a significantly higher ^{15}N enrichment compared with leaves and stems in winter wheat at the grain filling, the differences of ^{15}N enrichment between leaves and stems were only slight (Table 2), thereby suggesting relatively uniform labeling in the plants because N accumulation and redistribution in grain occurs many days after N accumulation in leaves and stems (Jha and Ladd, 1985; Waggar *et al.*, 1985).

CONCLUDING REMARKS

Weight-average ^{13}C values of aboveground wheat components resulting from $^{13}\text{CO}_2$ release from $\text{Na}_2^{13}\text{CO}_3$ (98 atom% ^{13}C) in the field labeling chamber ranged from 81‰ to 295‰. ^{13}C labeling of winter wheat at the grain filling stage without N fertilization may produce more uniformly ^{13}C -labeled materials,

while the materials were more highly ^{13}C -enriched at the elongation stage although the ^{13}C values of the wheat materials were more variable. The photosynthesized C in leaves and stems has many destinations at the elongation stage, whereas at the grain filling stage, the reallocation mainly goes to the ears. The presence of more green leaves for the +N treatment than for -N at the grain filling stage had a stronger photosynthesis capacity and led to a higher variation of ^{13}C -isotopic signature of aboveground components. The pulse labeling did not produce uniformly ^{13}C -labeled plant materials. Different from ^{13}C labeling, which asks for the control of various environmental conditions throughout the labeling period, such as temperature, humidity and $^{13}\text{CO}_2$ concentration, a uniform ^{15}N labeling is relatively easier to achieve through ^{15}N fertilization; differences in isotope excess among aboveground wheat components were much smaller under ^{15}N labeling than under ^{13}C labeling condition. The application of ^{15}N -enriched urea as carried out in this study may produce more uniformly labeled wheat straw at the grain filling stage than at the elongation stage.

Figure 1 Winter wheat growth 168 days after sowing (elongation stage) (a) and 205 days after sowing (grain filling stage) (b). Field labeling chamber for winter wheat (c). Schematic diagram of the three sampled portions of wheat shoots (d). -N = no N addition; +N = N addition.

Figure 2 Biomass (a), C content (b), and N content (c) of different wheat components. Error bars indicate standard errors ($n = 4$). -N = no N addition; +N = N addition.

Figure 3 $\delta^{13}\text{C}$ (‰) values of different wheat components. Different lowercase letters denote significant differences (LSD, $p < 0.05$) among wheat components at the same stage. Error bars indicate standard errors ($n = 9$). -N = no N addition; +N = N addition.

Figure 4 ^{15}N excess in atom% of different wheat components with ^{15}N labeling. Different lowercase letters denote significant differences among wheat components at the same stage (LSD, $p < 0.05$). Error bars indicate standard errors ($n = 9$).

Figure 1

Winter wheat growth 168 days after sowing (elongation stage) (a) and 205 days after sowing (grain filling stage) (b). Field labeling chamber for winter wheat (c). Schematic diagram of the three sampled portions of wheat shoots (d).

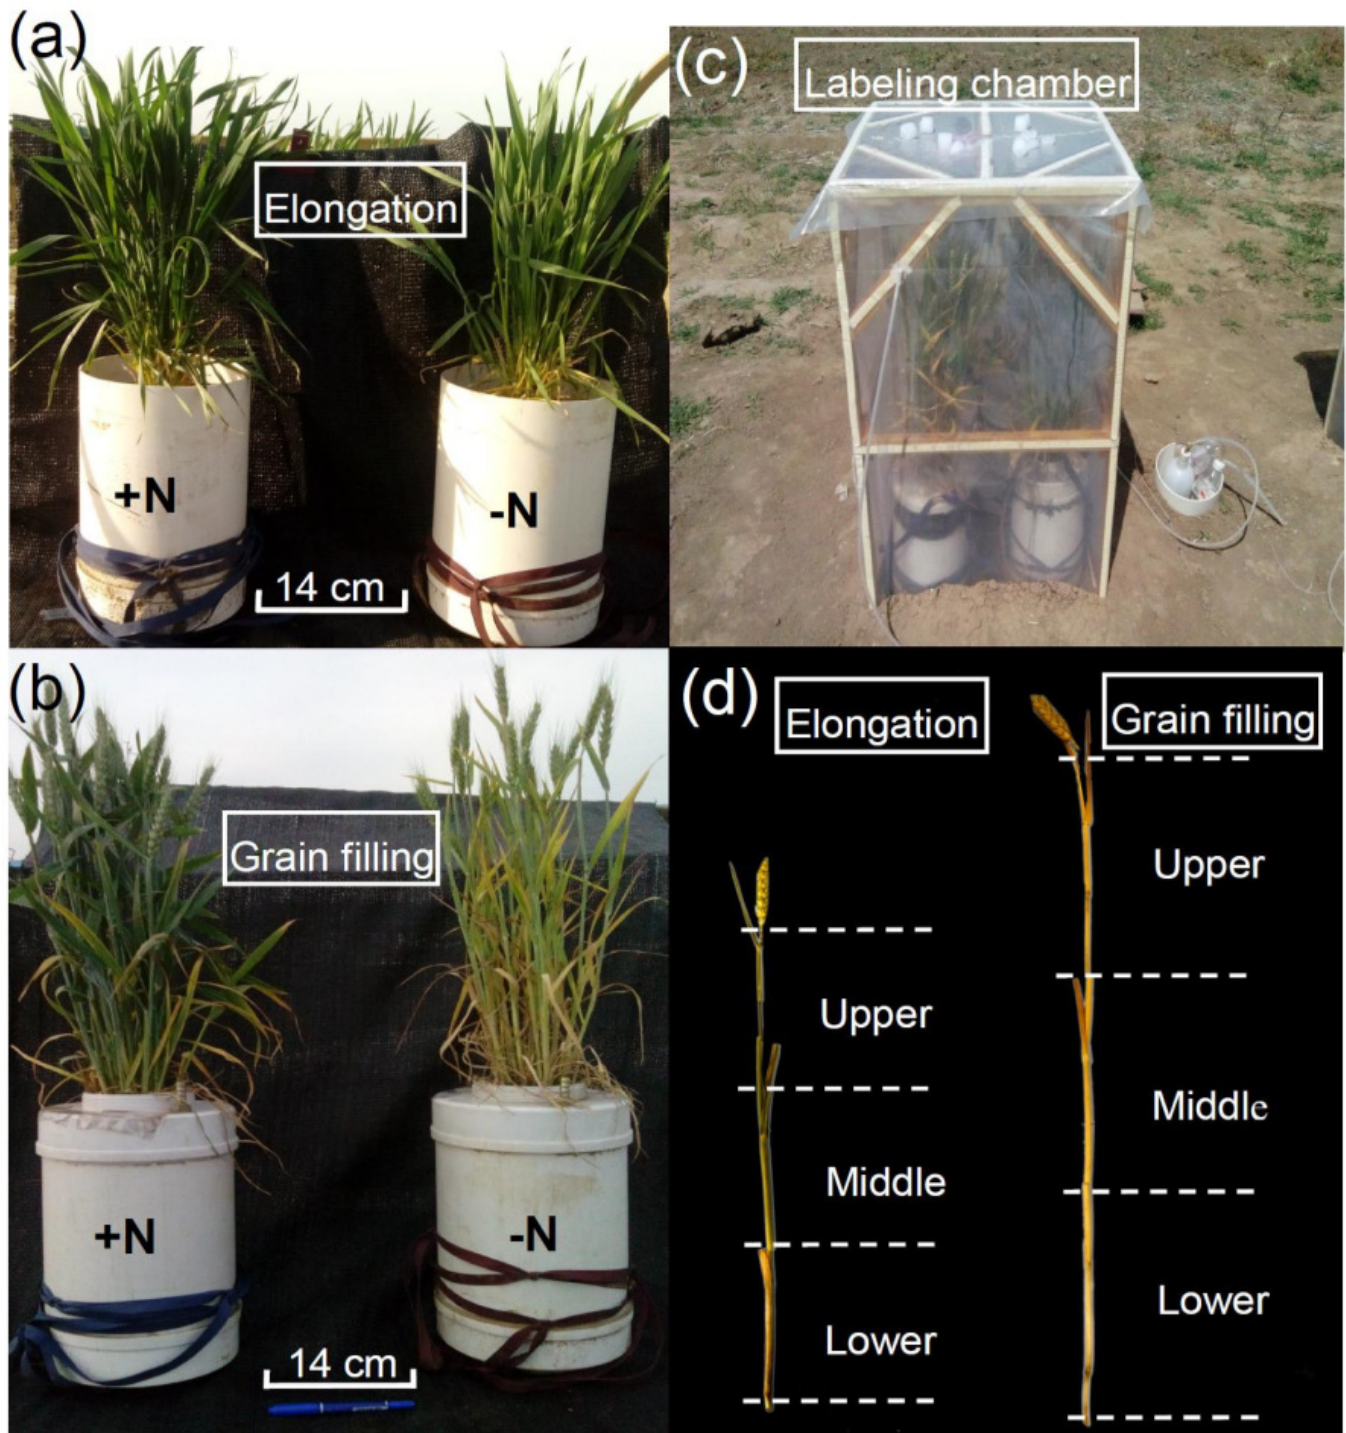

Figure 2

Biomass (a), C content (b), and N content (c) of different wheat components.

Error bars indicate standard errors ($n = 4$). -N = no N addition; +N = N addition.

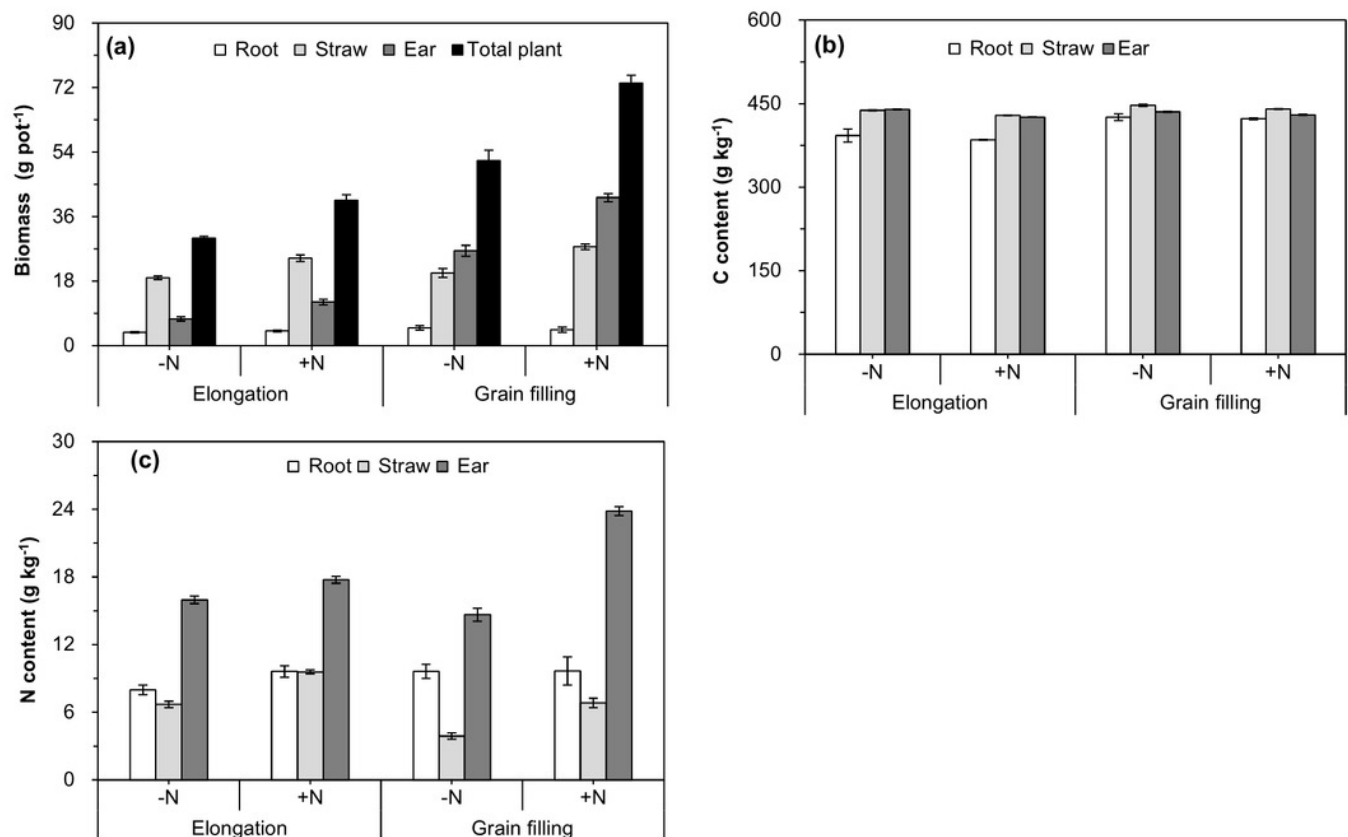

Figure 3

$\delta^{13}\text{C}$ (‰) values of different wheat components.

Different lowercase letters denote significant differences (LSD, $p < 0.05$) among wheat components at the same stage. Error bars indicate standard errors ($n = 9$). -N = no N addition; +N = N addition.

Figure 4

¹⁵N excess in atom% of different wheat components with ¹⁵N labeling.

Different lowercase letters denote significant differences among wheat components at the same stage (LSD, $p < 0.05$). Error bars indicate standard errors ($n = 9$).

Table 1(on next page)

P-values of two-way analysis of variance for the effects of stage (S) and nitrogen (N) on biomass, C content, and N content of different wheat components.

Table 1 *P*-values of two-way analysis of variance for the effects of stage (S) and nitrogen (N) on biomass, C content, and N content of different wheat components.

Treatment	Biomass				C content			N content		
	Root	Straw	Ear	Total plant	Root	Straw	Ear	Root	Straw	Ear
S	0.886	<0.001	<0.001	<0.001	0.598	0.003	<0.001	0.282	<0.001	<0.001
N	0.136	0.027	<0.001	<0.001	0.118	<0.001	0.947	0.282	<0.001	<0.001
S×N	0.393	0.331	<0.001	0.016	0.528	0.456	0.046	0.310	0.935	<0.001

Table 2 (on next page)

$\delta^{13}\text{C}$ value and ^{15}N excess in atom% (mean \pm SE, $n = 9$) of different wheat components.

Different lowercase letters in the same row denote significant differences (LSD, $p < 0.05$) in $\delta^{13}\text{C}$ or ^{15}N excess in atom% between components. Asterisks (*) in the same column denote either significant differences (t -test, $p < 0.05$) in $\delta^{13}\text{C}$ values between N treatments at the same stage or significant differences (t -test, $p < 0.05$) in ^{15}N excess in atom% between different stages under the same N treatment (^{15}N labeling). [†] -N = no N addition; ^{††} +N = N addition.

Table 2 $\delta^{13}\text{C}$ value and ^{15}N excess in atom% (mean \pm SE, $n = 9$) of different wheat components. Different lowercase letters in the same row denote significant differences (LSD, $p < 0.05$) in $\delta^{13}\text{C}$ or ^{15}N excess in atom% between components. Asterisks (*) in the same column denote either significant differences (t -test, $p < 0.05$) in $\delta^{13}\text{C}$ values between N treatments at the same stage or significant differences (t -test, $p < 0.05$) in ^{15}N excess in atom% between different stages under the same N treatment (^{15}N labeling). † -N = no N addition; †† +N = N addition.

			Ear	Leaves	Stem	Aboveground
$\delta^{13}\text{C}$ (‰)	Elongation	-N †	106.7 \pm 14.8c	594.9 \pm 29.9a*	226.9 \pm 15.4b	295.0 \pm 15.3*
		+N ††	107.2 \pm 18.5c	375.4 \pm 25.0a	198.8 \pm 20.1b	212.0 \pm 16.8
	Grain filling	-N	249.1 \pm 12.1a	105.7 \pm 4.6b	62.4 \pm 1.0c	81.2 \pm 3.1
		+N	285.3 \pm 11.4a	103.7 \pm 6.2b	68.5 \pm 4.1c	85.9 \pm 5.8
^{15}N excess in atom%	Elongation		3.8 \pm 0.2a	3.71 \pm 0.2 a	3.6 \pm 0.2a	3.6 \pm 0.1
	Grain filling		5.4 \pm 0.3a*	4.8 \pm 0.1b*	4.9 \pm 0.1b*	4.9 \pm 0.1*

Table 3(on next page)

P-values of two-way analysis of variance for the effects of stage (S) and nitrogen (N) on $\delta^{13}\text{C}$ value and $\delta^{15}\text{N}$ excess in atom% in different wheat components.

Table 3 *P*-values of two-way analysis of variance for the effects of stage (S) and nitrogen (N) on $\delta^{13}\text{C}$ value and $\delta^{15}\text{N}$ excess in atom% in different wheat components.

		Ear	Leaves				Stem			
			Upper	Middle	Lower	Whole	Upper	Middle	Lower	Whole
$\delta^{13}\text{C}$	N	0.214	0.929	<0.001	0.025	<0.001	0.116	0.595	0.076	0.398
	S	<0.001	<0.001	<0.001	0.006	<0.001	0.058	<0.001	<0.001	<0.001
	N×S	0.225	0.635	0.000	0.077	<0.001	0.545	0.952	0.199	0.192
^{15}N excess in atom%	S	0.000	<0.001	<0.001	0.278	<0.001	<0.001	<0.001	0.001	<0.001

Table 4(on next page)

Isotope values (mean \pm SE, $n = 9$) of upper, middle, and lower portions of shoot in wheat.

Different lowercase letters in the same row denote significant differences in $\delta^{13}\text{C}$ or ^{15}N excess in atom% (LSD, $p < 0.05$) between the three portions. Asterisks (*) in the same column denote either significant differences (t -test, $p < 0.05$) in $\delta^{13}\text{C}$ between N treatments at the same stage or significant differences (t -test, $p < 0.05$) in ^{15}N excess in atom% between different stages under the same N treatment (^{15}N labeling). [†] -N = no N fertilization; ^{††} +N = N fertilization.

Table 4 Isotope values (mean \pm SE, $n = 9$) of upper, middle, and lower portions of shoot in wheat.

Different lowercase letters in the same row denote significant differences in $\delta^{13}\text{C}$ or ^{15}N excess in atom% (LSD, $p < 0.05$) between the three portions. Asterisks (*) in the same column denote either significant differences (t -test, $p < 0.05$) in $\delta^{13}\text{C}$ between N treatments at the same stage or significant differences (t -test, $p < 0.05$) in ^{15}N excess in atom% between different stages under the same N treatment (^{15}N labeling). † -N = no N fertilization; †† +N = N fertilization.

			Upper portion	Middle portion	Lower portion
$\delta^{13}\text{C}$ (‰)	Elongation	-N †	383.0 \pm 44.6ab	510.6 \pm 48.2a*	339.1 \pm 37.9b*
		+N ††	371.2 \pm 48.6a	270.0 \pm 38.4ab	220.1 \pm 18.9a
	Grain filling	-N	110.4 \pm 7.5a	77.4 \pm 3.5b	64.3 \pm 1.5b
