The plastomes of heterotrophs went through varying degrees of degradation along with the transition from autotrophic to heterotrophic lifestyle. Here we examined the plastome of mycoheterotrophic species *Burmannia itoana* and compared it with those of its reported relatives including three autotrophs and one heterotroph (*Thismia tentaculata*) in Dioscoreales. *B. itoana* yields a rampantly degraded plastome reduced in size and gene numbers at the advanced stages of degradation. Its length is 44,463 bp with a quadripartite structure, about thirty percent of the total length of the autotrophic relatives and nearly three times over that of *T. tentaculata*. The *B. itoana* plastome contains 39 unique genes (23 protein coding genes, 4 rRNAs and 12 tRNAs), with 33 putatively functional genes and six tentative pseudogenes. Among four inversions (Inv1/Inv2/Inv3/Inv4) and four insertions (Ins1, Ins2, Ins3 and Ins4) detected in *B. itoana* plastome, Inv2 likely is consequence of the shift to heterotrophic lifestyle, and others may be associated with the mobile elements and recombination of distinct tRNA genes, respectively. Our results fill the gap of knowledge about the heterotroph plastomes in Burmanniaceae and provide a new evidence for the convergent degradation patterns of plastomes in plants en route to heterotrophic lifestyle.

Plastome of mycoheterotrophic *Burmannia itoana* Mak. (Burmanniaceae) exhibits extensive losses of photosynthesis genes along with unusual retention of genes and distinct rearrangements

Introduction

Plastids were derived from a common cyanobacterial ancestor that established a permanent endosymbiotic relationship with mitochondriate ancestor (Gould et al. 2008; Ku et al. 2015). One nature of plastome is that its genes could be transferred or pruned. For instance, the ancestor genes of the plastid have transferred to other two genomes (nuclear and mitochondria) or lost during evolution (Martin and Herrmann 1998; Cusimano and Wicke 2016). Most plastomes of land plants are canonical circular and quadripartite including two inverted repeats (IRs) separated by larger single copy region (LSC) and small single copy region (SSC), and its lengths usually ranges from 120 kbp to 170 kbp with about 113 unique genes including about 79 protein-coding genes, 4 rRNA genes, and 30 tRNA genes (Wicke et al. 2011). These genes are classified into 3 main classes depending on functions: (1) photosynthesis related genes (*ndh/atp/psa/psb/pet/ycf3/ycf4/rbcL*); (2) transcription, transcript maturation and translation related genes (*rpo/infA*, *matK* and *tRNAs/rRNAs/rps/rpl*), (3) other non-bioenergetic function genes (*accD/clpP/ycf1/ycf2/ccsA/cemA*) (Bock 2007; Wicke et al. 2011).

Parasitic and mycoheterotrophic plants, which establish a physiological relationship with either plants or fungi to obtain organic and mineral nutrients, are referred to have partially or fully lost the capacity of photosynthesis (Wicke and Naumann 2018). The transition of lifestyle from autotrophic to heterotrophic may have left measurable clues in genomes, such as adaptive and non-adaptive changes (Wicke et al. 2016). Studies about plastomes of heterotrophs revealed that plastomes of heterotrophic plants experienced convergent degradation syndromes including overall decreases in genome size along with functional and physical gene losses, decrease in GC-content, increased frequency of rearrangements, accumulation of indels and losses of introns, *etc.*, compared with plastomes of autotrophs (Wicke et al. 2013; Logacheva et al. 2014; Lam et al. 2015; Lim et al. 2016; Wicke et al. 2016; Petersen et al. 2018; Schneider et al. 2018).

Hitherto, several conceptual models of plastome degradation have been proposed to account for the order of the heterotrophs plastomes degradation in a simplified and idealized manner. In general, plastome degradation follows five major stages (Barrett and Davis 2012; Barrett et al. 2014; Naumann et al. 2016; Wicke et al. 2016; Graham et al. 2017): (1) *ndh* genes become dispensable once plants have the ability of obtaining nutrients using heterotrophic way; (2) when the lifestyle transfer to obligate heterotrophic, most of photosynthesis related genes and some housekeeping genes are lost; (3) *atp/rbcL* and nonessential housekeeping genes are lost or functionally replaced; (4) other nonbioenergetic genes (e. g. *accD*, *clpP*, *ycf1/2*) are lost or functionally replaced; (5) all plastid genes are lost.

Burmania contains about 60 species spanning from autotrophic, hemi-mycoheterotrophic to mycoheterotrophic (Jonker 1938; Zhang 1999; Wu et al. 2010), providing an excellent model system for understanding the evolution of plastome responding to the lifestyle shift from autotrophic to heterotrophic. Although the plastome of autotrophic *Burmanna disticha* (Ma et al. 2018) has been described, the plastome of mycoheterotrophic species in *Burmanna* has never been reported, hindering our efforts in elucidation of plastid evolution in the genus. Aiming to provide new evidence in our understanding of the mechanism of plastid evolution in mycoheterotrophic angiosperms, here we focus on *Burmanna itoana*, a mycoheterotrophic perennial herb distributed in the coastal provinces of southern China and Ryukyu Islands of Japan (Jonker 1938; Zhang 1999; Wu et al. 2010). We sequenced the *B. itoana* plastome and examined its content and structure. We furthermore compared the plastome of *B. itoana* with those of its documented relatives (e. g. *B. disticha*, *T. tentaculata*) in Dioscoreales.

Materials and methods

DNA extraction and sequencing

Samples of *B. itoana* were collected from the Longmen Park, Guangdong Province, China. The voucher specimens (LXJLM07) are deposited in the IBSC (Herbarium of South China Botanical Garden). Total DNA was extracted using a DNeasy Plant Mini Kit (Qiagen, Hilden, Germany). The total DNA was used to generate libraries with average insert size of 500 bp and sequenced using Illumina HiSeq 2000 with 150 bp paired-end read lengths.

Plastome *de novo* assembly and annotation

The plastome was assembled using CLC Genomics Workbench v9.0 (CLC BIO, Aarhus, Denmark) with parameters as follows: wordsize 63, bubble size 50, minimal contig length 1000 bp. Three plastome-like contigs were picked out through mapping all assembled contigs to the sequence of *B. disticha* plastome, and then these contigs were merged using Geneious (version 11.1.5) (Kearse et al. 2012) to build draft plastomes. Specific primers were designed to confirm the overlap of the aligned contigs and identify the borders of the LSC, SSC, and IRs regions using through PCR and Sanger sequencing method. Validated complete plastome was annotated using GeSeq (Tillich et al. 2017) with default sets. tRNAs were predicted using tRNAscan-SE (Schattner et al. 2005). Finally, the plastome map was visualized using OGDRAW v. 1.2 (Lohse et al. 2007). The annotation of plastome is summarized in Additional file 1.

Data collection and Comparative analysis of plastomes

Four reported plastomes of *B. itoana* relatives including *B. disticha* (Burmanniaceae), *T. tentaculata* (Thismiaceae), *Tacca chantrieri* (Taccaceae), and *D. zingiberensis* (Dioscoreaceae) were downloaded from GenBank, and the Genbank accession is MG792012, KX171421, KX171420 and NC_027090M, respectively.

The GC-content of plastome and the four junctions of LSC/IRB, LSC/IRA, SSC/IRB and SSC/IRA were identified using Geneious version 11.1.5 (Kearse et al. 2012). Gene contents of plastomes were compared between *B. itoana* and four reported species in Dioscoreales. Gene orders excluding copies in IRs were explored using Mauve (Darling et al. 2004) plugged in Geneious.

Results

General characteristics of *B. itoana* plastome

The *B. itoana* plastome represents a quadripartite circular molecule with 44,636 bp in length. It contains two larger inverted repeat regions (IRA/IRB: 12,174 bp), separated by a large single-copy region (LSC: 18,441 bp) and a small single-copy region (SSC: 1674 bp) (**Fig. 1**). The *B. itoana* plastome contains 39 genes (**Fig. 1**, **Fig. 2**). 33 genes are putatively functional and 6 genes are putative pseudogenes. The presumably functional genes include 4 rRNA genes, 8 tRNA genes and 21 protein genes. The *petG*, *rpl36*, *trnH_GUG*, *trnD_GUC*, *trnG_GCC* and *trmS_UGA* are putative pseudogenes. The *rpl16*, *rpl2* and *rps12* genes contains one intron (the 3-end intron of *rps12* is absent), respectively, and the *clpP* gene harbors two introns. The overall GC-content of *B. itoana* plastome is 32%, which is lower than those of its autotrophic relatives but is higher than that of *T. tentaculata*. The GC-content of IR, LSC and SSC in *B. itoana* is 37.8%, 24.5% and 32.4% (Table 1), respectively. The circular plastome was deposited in GenBank under the Accession Number MK318822.

Comparison of gene contents and order between Dioscoreales plastomes

The plastomes of the *B. disticha*, *T. chantrieri* and *D. zingiberensis* contain 112 genes (**Fig. 2**). In *B. itoana* plastome, rps16 is also lost, and the second intron of rps12 is lost while it is retained in autotrophs' plastomes. Like in *T. tentaculata*, the *B. itoana* plastome is not just downsizing but also lost most photosynthesis related genes and some housekeeping genes. However, in *B. itoana* plastome, one photosynthesis related genes, pseudogenized petG is retained. *B. itoana* plastome shares the whole 12 genes retained in *T. tentaculata* plastome. In comparing with the *B. itoana* plastome, degradation of *T. tentaculata* plastome goes further.

The alignment using Mauve showed the autotrophs' plastomes are general syntenic with the exceptions that the inversion of the SSC in *B. disticha*, and extremely modified plastome of *T. tentaculata* (**Fig. 3**). Here, we mainly focus on the comparison between the plastome structure of the *B. itoana* and *B. disticha* represented in **Fig. 1** and **Fig. 3**. The results showed that the gene order of *B. itoana* plastome exhibits eight rearrangements including four inversions (Inv1, Inv2, Inv3, Inv4) and four insertions (Ins1, Ins2, Ins3 and Ins4) versus the *B. disticha* plastome. Inv1 contains the cluster of trnS_GUA - trnG_GCC - trnM_CAU - rps14 (ca. 1282 bp), and Inv2 just contains accD (ca. 2725 bp), and both are located in LSC. Inv3 contains the cluster of rps7 - rps12 - rrn16 - rrn23 - rrn4.5 - rrn5 (ca. 6678 bp) stretching across the IRs and SSC, and Inv4 contains the cluster of rrn16 - rrn23 - rrn4.5 - rrn5 (ca. 5007 bp) located in IRs. Ins1 and Ins2 contain the cluster of partial truncate ndhD - rpl32 (ca. 720 bp), and both Ins3 and Ins4 contain rps15 - truncate ycf1 - trnN (ca. 1900 bp). The cluster in Ins1/Ins2 is located in the SSC of all autotrophic plastomes, and the cluster in Ins3/Ins4 is located in IRs and SSC of *B. disticha* plastomes and IRs of *T. chantrieri* plastomes.

Boundaries of SC/IRs of Dioscoreales plastomes

The boundary of LSC/IR in *B. itoana* plastome slightly expands to rps3, which is different from that in its autotrophic relatives. For example, the boundary of LSC/IR *B. disticha* is located in rpl22, and those of *T. chantrieri* and *D. zingiberensis* are located in the intergenic space of rps19 and trnH_GUG. The boundaries of SSC/IR in *B. itoana* plastome reside in rps7. In contrasting to that, the boundaries of SSC/IR are located in the intergenic of rps15 and ycf1, the ycf1 in *B. disticha* and *D. zingiberensis*, respectively. In *T. chantrieri*, one boundary of SSC/IR is expanded to the intron of ndhA plastome. In summary, the IRs are expanded in both plastomes of *B. itoana* and *B. disticha* relative to others. The boundaries of SC/IRs of Dioscoreales plastomes are showed in **Fig. 1**.

Discussion

Convergent evolution of plastomes in heterotrophs

Accompanying with forfeiting of photosynthetic capabilities, the plastomes of heterotrophic plants undergo varying degrees of degradation of size and gene contents (Wicke et al. 2013; Wicke et al. 2016). For instance, the largest is that of heterotrophic chlamydomonadalean alga *Polytoma uvella* with about 230 kb in length (Figueroa-Martinez et al. 2017), while the smallest sequenced plastome is 11, 348 bp in endoparasitic *Pilostyles aethiopica* (Bellot and Renner 2015). Moreover, other studies reported that plastome has been possibly lost in green algal genus *Polytomella* (Smith and Lee 2014) and land flowering plant *Rafflesia lagascae* (Molina et al. 2014). Our results showed that *B. itoana* plastome displays a typical quadripartite architecture with LSC and SSC separated by IRs consistent with that of canonical land plant plastomes. The length of *B. itoana* platome is only one-third of its autotrophic relative *B. disticha* and is nearly three times that of *T. tentaculata*. As previously mentioned, gene losses in plastomes of heterotrophs follow five stages (Barrett and Davis 2012; Barrett et al. 2014; Naumann et al. 2016;

Graham et al. 2017; Wicke and Naumann 2018). Our results showed that the *B. itoana* plastome is likely at the fourth stage with nonbioenergetic and housekeeping genes (e. g. *ycf1/2*, *rps23*/tRNAs) being physically or functionally lost. Losses of *ycf1* and *ycf2* in *B. itoana* plastome support that a general core set of genes (*ycf1*, *ycf2*, *accD*, *clpP*, *infA* and *trnE*) varies among heterotrophs (Bellot and Renner 2015; Schelkunov et al. 2015; Lim et al. 2016; Naumann et al. 2016; Roquet et al. 2016).

It is a well-accepted tenet that *matK* encodes one kind of protein required for group IIA intron splicing of seven plastid genes *trnV_UAC*, *trnI_GAU*, *trnK_UUU*, *trnA_UGC*, *rpl2*, *rps12* (3-end intron) and *atpF* (Liere and Link 1995; Zoschke et al. 2010). Normally, the group IIA intron will not be spliced out from the transcripts without *matK*. Parallel losses of *matK* and group IIA intron-containing genes have occurred in *Cuscuta* (McNeal et al. 2009). In *B. itoana* plastome, *matK* is physically lost accompanying with the loss of other 6 genes, however, the *rpl2* and *rps12* are retained. Similarly, in the plastomes of *Cynomorium coccineum*, *Rhizanthella gardneri* and *Epipogium aphyllum*, the absence of *matK* or truncated *matK* is also along with *rps12* lost the second intron and intact *rpl2* (Delannoy et al. 2011; Bellot and Renner 2015; Schelkunov et al. 2015). The introns of both *rpl2* and *rps12* are still sustained while the *matK* are absent in *Hydnora visseri* plastome, and all *rps12* and *rpl2* are transcribed properly, however, both the *rps12* and *rpl2* appear to be pseudogenes in *Hydnora longicollis* (Naumann et al. 2016). A large proportion of the *matK* genes in some species of orchids are pseudogenes while all seven genes with group II introns are retained (Kim et al. 2014; Feng et al. 2016). These instances of *matK* loss or pseudogenization with retention of group IIA introns may be because that the function of *matK* are recovered by that of genes from nucleus (Mohr and Lambowitz 2003), or some group IIA introns may be able to self-splice (Kim et al. 2014).

Like others at the advanced stage of degradation, the *B. itoana* plastome lost most of plastid encoded tRNAs and only holds 12 tRNAs (eight functional and four pseudogenized). Two tRNAs (*trnE_UUC* and *trnfM_CAU*) are shared within most heterotrophs. It was a plausible explanation that the two tRNAs are essential for haem biosynthesis and mitochondrial protein synthesis, respectively, and cannot be replaced with their cytosolic orthologues (Barbrook et al. 2006). However, the subset of tRNAs remained in *B. itoana* plastome has not been detected in others. For instance, it shares only eight tRNAs with *R. gardneri* (containing 10 tRNAs) (Delannoy et al. 2011), seven with *E. roseum* (containing eight tRNAs) (Schelkunov et al. 2015) and six with *Sciaphila densiflora* (containing six tRNAs) (Lam et al. 2015). Moreover, only two were found in *T. tentaculata* (Merckx et al. 2017) and *Sciaphila thaidanica* (Petersen et al. 2018), and no functional tRNAs was found in two endoparasitic species of *Pilostyles* (Bellot and Renner 2015). These suggest that the tRNAs loss is likely unique and undergoes varying degrees within heterotrophs.

Unusual retention of genes in *B. itoana* plastome

Generally, plastomes of heterotrophs which at the fourth stage of degradation begin to shed all coding regions for photosynthetic pathway (Barrett et al. 2014; Graham et al. 2017; Wicke and Naumann 2018). Attractively, the frame of *petG*, which encodes a subunit protein of the cytochrome *b6/f* complex for the connection of PSI and PSII (Bock 2007; Wicke et al. 2011), is idiosyncratically retained in *B. itoana* plastome but is not detected in other heterotrophs at the advanced stage of degradation. In *B. itoana*, *petG* is proximate to *trnW_CCA* and *accD*. However, the *petG* is lost while *trnW_CCA* and *accD* are intact in the plastomes of *R. gardneri* and *S. densiflora* (Delannoy et al. 2011; Lam et al. 2015). Otherwise, functional loss of *petG* indicates that it is nonessential in *B. itoana* plastome. Therefore, it could not been explained using the proposal that proximity to the essential gene or essential function

can help genes escaping from being lost (Lohan and Wolfe 1998). One study suggested that holding pseudogenes illustrates that the plastome is undergoing the further degradation (Naumann et al. 2016).

In heterotrophs, the ribosomal genes begin to be absent from plastomes with varying degrees at the advanced stages (Barrett and Davis 2012; Barrett et al. 2014; Naumann et al. 2016; Wicke et al. 2016; Graham et al. 2017). So far, no study reported functional or physical loss of rpl36 while rpl32, rpl20, rpl22, rpl23 and rpl33 are retained. Interestingly, rpl36 become a pseudogene in *B. itoana*. Some factors, such as short length, location in conserved operon or difficulty to be replaced by plastid compartments, may contribute to the retention of genes (Lohan and Wolfe 1998; Wicke et al. 2013; Wicke et al. 2016). Commonly, rpl36 is located in the intergenic space of rps11 and infA in the most conservative operon including almost all of ribosomal protein-coding genes. Therefore, residing in essential operon and adjacent essential genes could not prevent rpl36 from being pseudogenized in *B. itoana* plastome. It's plausible to speculate that the function of rpl36 is not essential, or its loss can be compensated by other intracellular genomes in *B. itoana* plastome (Schelkunov et al. 2015; Cusimano and Wicke 2016; Naumann et al. 2016; Petersen et al. 2018).

Among the ribosomal genes, rps15 and rpl32 are the first batch of genes to be absent from the reported plastomes at the advanced stage of degradation. However, the rps15 and rpl32 are still retained and putatively functional in *B. itoana* plastome. Previous study suggested that there is a strong positive correlation between the number of putatively functional genes and plastome length among heterotrophic angiosperms (Barrett and Kennedy 2018). To date, the two genes rps15 and rpl32 are only preserved in reported plastomes whose length are longer than 80 kb only except the *Monotropa hypopitys* plastome with ca. 40 kbp in length (Ravin et al. 2016). In *B. itoana* plastome, rps15 and rpl32 are resided in IRs, typically located in SSC. Previous studies proved that two copies of genes in IR offer more opportunities to correct the aberrant mutations (Zhu et al. 2016; Choi et al. 2018). Thus, we could reasonably speculate that IRs may shelter these genes from being deleted in *B. itoana* plastome.

Different origination of rearrangements in *B. itoana* plastome

It has been showed that some rearrangements are correlated with intermolecular recombination between distinct tRNA (Hiratsuka et al. 1989; Haberle et al. 2008; Barrett and Kennedy 2018). In typical autotrophs' plastomes, the cluster in Inv1 is part of the cluster of trnS_UGA – psbZ -trnG_GCC-trnfM_CAU - rps14 - psaB - psaA - ycf3 - trnS_GGA in *B. disticha* plastome. We postulate that the recombination of trnS_UGA and trnS_GGA may resulted in the Inv1 of *B. itoana* plastome. The Inv2 containing accD is also present in the plastomes of heterotrophic plants *Petrosavia stellaris* and *S. densiflora* (Logacheva et al. 2014; Lam et al. 2015). This inversion is in a block mainly consisting of the photosynthesis related genes, most of which were lost in *B. itoana* plastome. Thus, it is a plausible explanation that gene losses may trigger the inversion along with the shift from autotroph to heterotroph. Few rearrangements are located in the middle IR in land plants plastomes with exceptions in plastomes of some ferns, Geraniaceae and Campanulaceae (Knox 2014; Weng et al. 2014; Robison et al. 2018). It was hypothesized that MORFFO (mobile open reading frames) elements are regularly associated with inversions and changes to the inverted repeats (Robison et al. 2018). Interestingly, the six rearrangements (Inv3/Inv4/Ins1/Ins2/Ins3/ins4) occur in IRs-SSC, IRs, IRs and IRs of *B. itoana* plastome, respectively. The patterns of these rearrangements are analogous to those of rearrangements in several plastomes of ferns (Robison et al. 2018). Therefore, we suppose that these insertions may be MORFFOs in the *B. itoana* plastome.

Conclusion

Consistent with convergent evolution of plants plastomes en route to heterotroph, *B. itoana* plastome exhibits rampant degradation and distinct rearrangements. Based on models of plastome evolution, the *B. itoana* plastome is at the advanced stages of degradation, and the occurrence of six putative pseudogenes suggests that it could undergo further degradation. Unusual retention of genes indicates that complex constraints affect the fate of the plastomes in heterotrophs. Although, heterotrophs share a universal pattern of plastome degradation, each species holds a unique plastome, accurately. In general, our study fills the gap of knowledge about the plastome of heterotrophs in Burmanniaceae, and it would be attractive to investigate dense intraspecific or interspecific plastomes to characterize the trajectories of plastomes evolution.

Figure 1(on next page)

Fig. 1 Plastome structure of five species in Dioscoreales.

All genes are colored according to functional complexes. Genes shown left the line are transcribed counterclockwise, those right the line are transcribed clockwise. The light red blocks show inversions and light blue blocks show insertions. Genes containing intron(s) are marked with the symbol *. Pseudogenes and truncated genes are marked with “&” and “#”, respectively. The inverted repeats (IRs) are shown with bold lines.

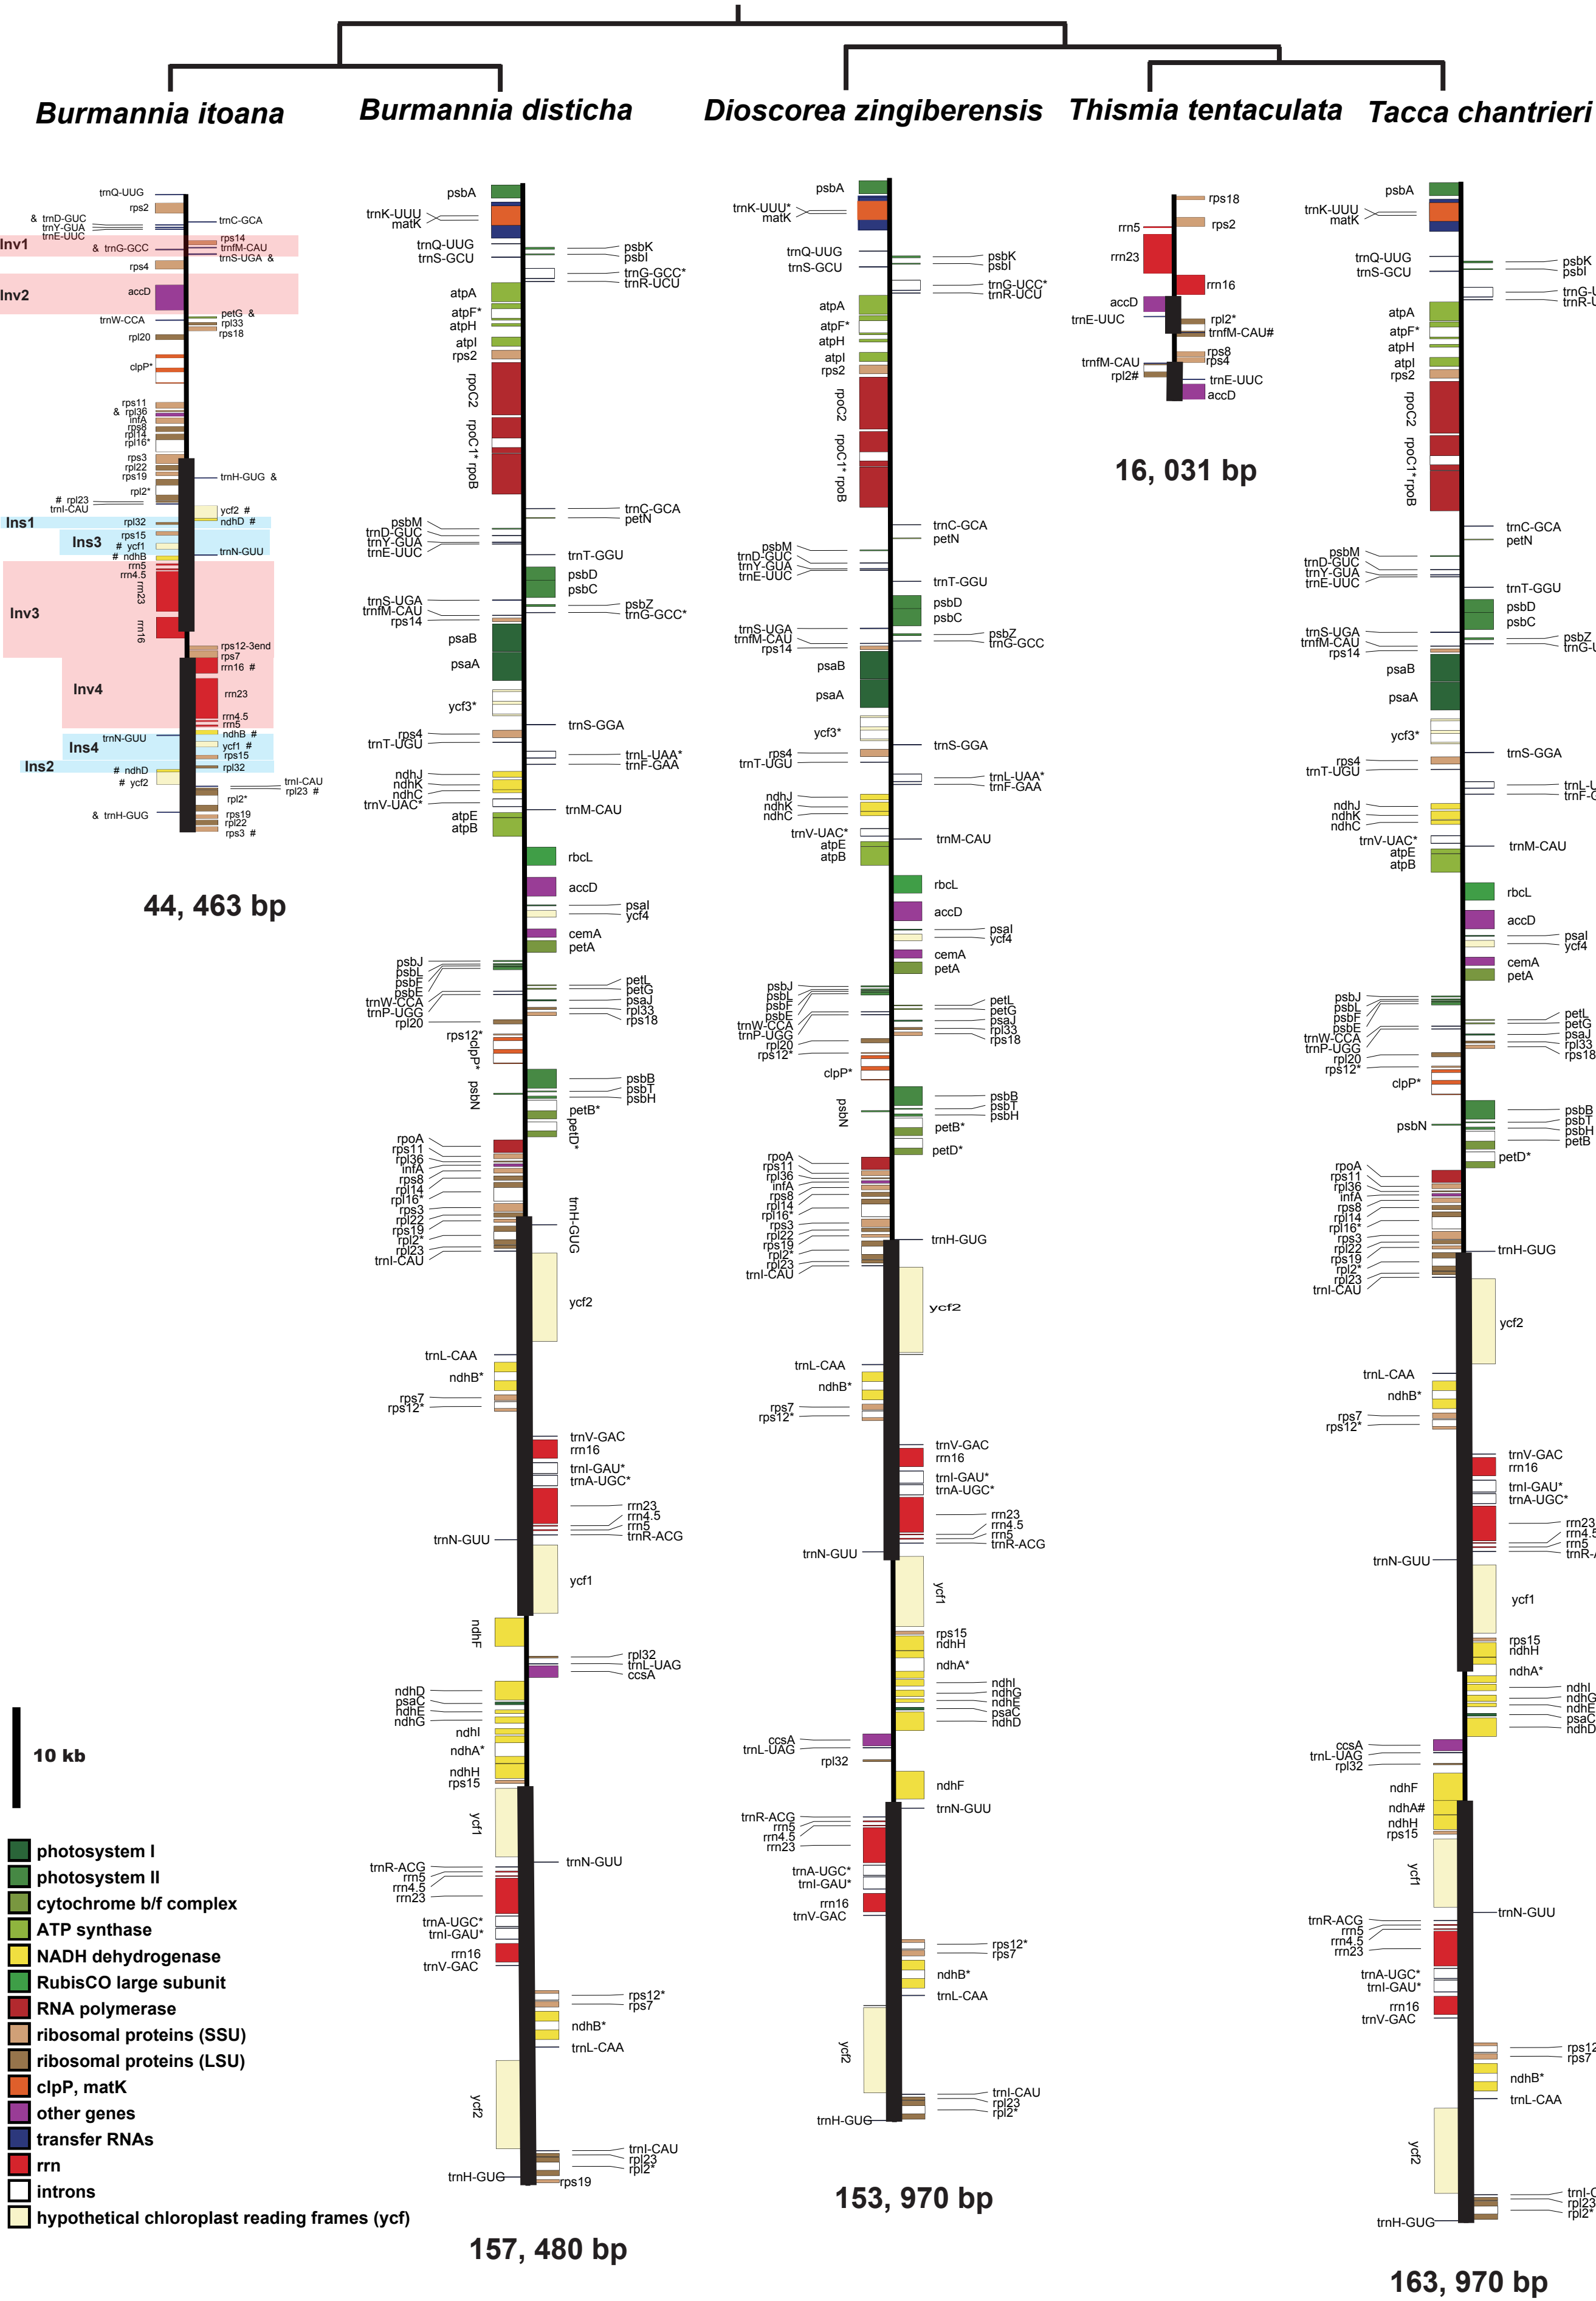

Figure 2 (on next page)

Fig. 2 Heat map showing gene contents in five species in Dioscoreales.

Genes in blue are retained and presumed fully functional; those in red are absent and those in yellow are putative pseudogenes. Gene names of photosynthesis related genes, genetic apparatus genes and other genes are in green, black, and red, respectively.

Figure 3(on next page)

Fig. 3 Synteny of plastomes from five species .

The dashed lines and olidlines illustrate rearranged gene blocks and collinear between the two plastomes, respectively.

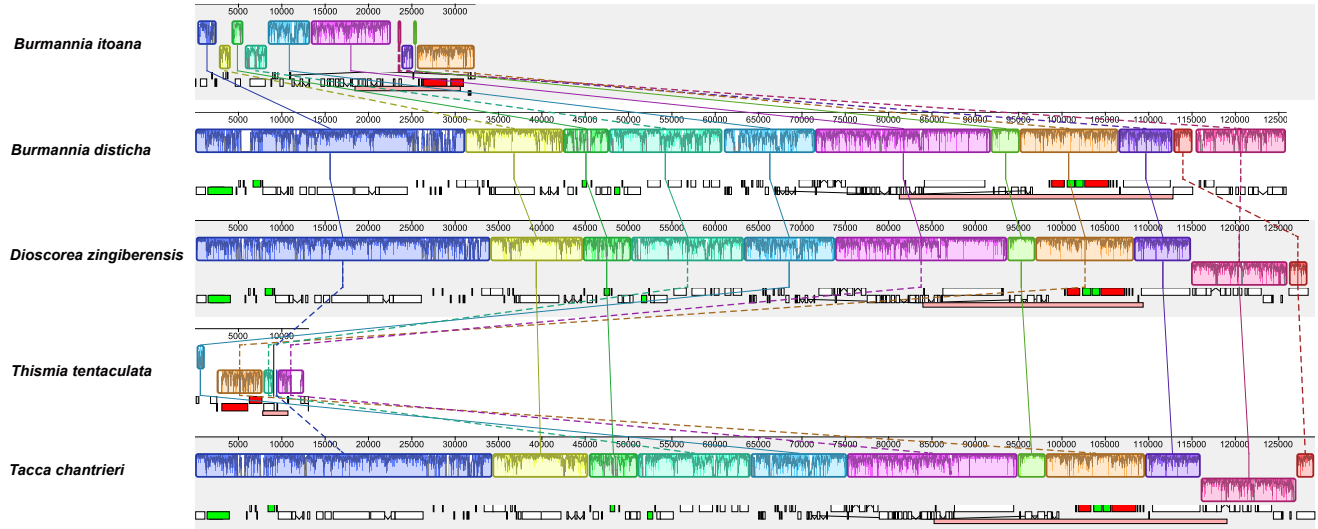

Table 1 (on next page)

Table 1. General information of plastomes from five species in Dioscoreales.

Taxon	Length (bp) /GC-content (%)				Gene number		
	Total	IR	LSC	SSC	rRNAs	tRNAs	Protein coding
<i>Burmannia itoana</i>	44463/32.0	12174/37.8	18441/24.5	1674/32.3	4	12	23
<i>Burmannia disticha</i>	157480/34.9	31616/39.5	81231/32.3	13017/28.8	4	30	78
<i>Dioscorea zingiberensis</i>	153970/37.2	25491/43.0	83950/35.1	19038/31.2	4	30	78
<i>Tacca chantrieri</i>	163007/36.7	33837/40.3	85241/34.7	10092/30.6	4	30	78
<i>Thismia tentaculata</i>	16031/27.2	2948/30.0	7799/29.1	2336/13.7	3	2	7
