# **Abstract**

## **Background.**

A wealth of data on the networks of ecological interactions present in the modern biota can be readily obtained, due to the ease of unlimited access to the living organisms. In contrast, understanding of such interactions in ecosystems of the geologic past is incomplete. Specifically, in past terrestrial ecosystems we know comparatively little about plant biotic interactions besides saprotrophy, herbivory, mycorrhizal associations, and oviposition. Due to taphonomic biases, epiphyte communities are particularly rare in the fossil record, despite their prominence in modern ecosystems. Accordingly, little is known about how epiphyte communities have changed across geologic time. Here, we describe a tiny in situ fossil epiphyte community that sheds light on plant-animal and plant-plant interactions more than 50 million years ago.

## **Methods.**

A single silicified *Todea* rhizome from a new locality of the early Eocene (ca. 52 Ma) Tufolitas Laguna del Hunco (Patagonia, Argentina) was studied in serial thin sections using light microscopy. The community of organisms colonizing the tissues of the rhizome was characterized by identifying the organisms, as well as mapping and quantifying their distribution. A 200 x 200  $\mu\text{m}$  grid was superimposed onto the rhizome cross section, and the colonizers present at each node of the grid were tallied.

## **Results.**

Preserved in situ, this community offers a rare window onto aspects of ancient ecosystems usually lost to time and taphonomic processes. The community is surprisingly diverse and includes the first fossilized leafy liverworts in South America, also marking the only fossil record of leafy bryophyte epiphytes outside of amber deposits; several types of fungal hyphae and spores; microsclerotia with possible affinities in several ascomycete families; and oribatid mite coprolites.

## **Discussion.**

The community associated with the Patagonian rhizome enriches our understanding of epiphyte communities in the distant past and adds to a growing body of literature on osmundaceous rhizomes as important hosts for component communities in ancient ecosystems, just as they are today. Because osmundaceous rhizomes represent an ecological niche that has remained

virtually unchanged over time and space and are abundant in the fossil record, they provide a paleoecological model system that could be used for exploring epiphyte community structure through time.

## Introduction

In the modern biota, direct access to organisms has revealed significant parts of their networks of ecological interactions. In contrast, understanding of such interactions is incomplete in ecosystems of the geologic past. Specifically, in past terrestrial ecosystems we know comparatively little about plant biotic interactions besides saprotrophy, herbivory, mycorrhizal associations, and oviposition (DiMichele et al., 1992; Labandeira & Currano, 2013; Taylor et al., 2015). Here, we investigate a complex community of organisms that lived in association with an osmundaceous fern, preserved in Eocene rocks (ca. 52 Ma) of La Huitrera Formation, Argentinean Patagonia. La Huitrera Formation hosts one of the most diverse Eocene floras characterized to date (Wilf et al., 2003, 2005a), yet the interactions of plants in this flora with other organisms are just beginning to be characterized (Wilf et al., 2005b). The fossil community associated with the osmundaceous fern is surprisingly diverse and includes the first fossil epiphytic liverworts known outside of amber deposits. Preserved in situ, this community offers a rare window onto aspects of ancient ecosystems usually lost to time and taphonomic processes. Such ecologically relevant aspects of community dynamics (abundance and diversity of epiphytes and incidence of herbivory), typically unavailable for fossil associations, are described here. Rather than describing in detail the biotic interactions between members of this community, here we aim to provide an assessment of epiphyte community structure. We also use a broad definition of epiphyte, which encompasses all organisms that live on a host plant. Together, the fossils represent a tiny epiphyte community centered around a single host plant.

## Materials and Methods

### Geologic setting

The fossils described here come from a new site ca. 2.1 km south of the Chubut River and 9.8 km due west of Piedra Parada in northwestern Chubut Province, Patagonian Argentina, S 42°39'20.60", W 70°13'22.20". The source strata belong to the Tufolitas Laguna del Hunco, an early Eocene, volcanoclastic, caldera-fill lacustrine deposit of La Huitrera Formation that is

embedded in the Middle Chubut River Volcanic-Pyroclastic Complex (Aragón and Mazzoni, 1997). The new fossil site sits in the southern exposure area of the Tufolitas Laguna del Hunco, ca. 24 km SSW of the well-known Laguna del Hunco fossil locality (Berry, 1925; Petersen, 1946; Wilf et al., 2003), which lies in the northeastern exposures of the same extensive, highly fossiliferous unit. This is the first report of fossil plants from the southern exposures, although the nearby Laguna Fría mammal assemblage potentially correlates to these strata (Tejedor et al., 2009). In this southern area, an ignimbrite that caps the fossil lake bed exposures ca. 5 km east of the new fossil site yielded an  $^{40}\text{Ar}$ - $^{39}\text{Ar}$  age on plagioclase of  $49.26 \pm 0.56$  Ma (early Eocene, Ypresian) in an unpublished thesis (Gosses, 2006; Gosses et al., 2006), directly providing a minimum age for the osmundaceous rhizome. We note that this age has not been subsequently vetted or revised for updated decay constants (Kuiper et al., 2008), but it is likely to be broadly accurate because it lies in correct stratigraphic order relative to other dated samples from the Eocene caldera system (Gosses, 2006; Gosses et al., 2006; Kuiper et al., 2008; Tejedor et al., 2009).

At Laguna del Hunco (northeastern exposures), three  $^{40}\text{Ar}$ - $^{39}\text{Ar}$  ages from volcanic ashes and two recorded paleomagnetic reversals, all from strata located within the main fossiliferous section of the Tufolitas Laguna del Hunco, constrain the time of fossil deposition there to the early Eocene as well (Wilf et al., 2003, 2005a). The most reliable radiometric age at Laguna del Hunco, on sanidines from an ash taken from the middle of the most densely sampled fossiliferous interval and analyzed in two different labs, is  $52.22 \pm 0.22$  Ma (early Eocene, Ypresian) following recalibration for modern decay constants (Wilf et al., 2003; Wilf et al., 2005; Kuiper et al., 2008; Wilf, 2012; Wilf et al., 2017). Thus, the osmundaceous rhizome can safely be considered Ypresian and in the age range of ca. 49.3 to perhaps 52.5 Ma. We prefer the older end of this range because the dates from Laguna del Hunco, despite their ca. 24 km geographic distance from the new fossil site, come from tuffs located within the Tufolitas Laguna del Hunco, the same unit that holds the osmundaceous rhizome fossil. The dated ignimbrite in the southern area (Gosses, 2006; Gosses et al., 2006) lies above that unit.

At Laguna del Hunco itself, the Tufolitas Laguna del Hunco host one of the most diverse Eocene compression floras known (Wilf et al., 2003, 2005a). The flora has a robust Gondwanic component displayed among its gymnosperm and angiosperm species, as described extensively elsewhere; among the most striking occurrences are the well-preserved and abundant fossils of

*Agathis* (Araucariaceae) and *Eucalyptus* (Myrtaceae) (Wilf et al., 2013; Gondolfo et al., 2011; Wilf et al., 2014).

# The host fern

The host plant is a permineralized osmundaceous fern rhizome ca. 8 cm in diameter and 20 cm tall. This rhizome and associated sterile foliage collected from the same locality were recently described as *Todea* cf. *amissa* M. Carvalho, a species initially described based on compressions of sterile and fertile foliage from the northeastern exposures of Laguna del Hunco (Carvalho et al., 2013; Bomfleur and Escapa, 2019). The two records of *Todea* in the Tufolitas Laguna del Hunco comprise the only South American fossil or extant record of the genus (extant in Australia, New Guinea, and southern Africa) (Carvalho et al., 2013).

# Methods

The *Todea amissa* rhizome was studied in serial thin sections using light microscopy. Photographs of whole thin sections were taken using a light box and a Canon EOS 70D Camera fitted with a Canon 60mm macro lens, and were stitched together using Photoshop CC (Adobe, San Jose, California, USA). All other micrographs were taken using a Nikon Coolpix E8800 digital camera mounted on a Nikon Eclipse E400 microscope and processed using Photoshop CC. All specimens and preparations are housed in the collections of the Museo Paleontologico Egidio Feruglio (MPEF), Trelew, Argentina. The distribution of colonizing organisms in fern tissue was quantified by superimposing a 200  $\mu$ m x 200  $\mu$ m grid onto the cross section of the rhizome (Fig. 1). At each intersection of the grid, we recorded the type of fern tissue and the presence and type of colonizers. This yielded 3,820 data points for the entire rhizome cross section. Of these, 252 data points included colonizing organisms (see Table 1).

# **Results**

## Epiphytic plants

More than 25 small leafy shoots are found, primarily along the outer perimeter on one side of the rhizome, but also between leaf bases elsewhere along the rhizome (Fig. 1). The leafy shoots are up to 3.75 mm long and 230-410  $\mu$ m in diameter. They exhibit pinnate branching, with branches > 200  $\mu$ m long, diverging at 450-850  $\mu$ m intervals (Fig. 2B-C). Stems are 30-180

µm in diameter, comprised entirely of isodiametric to oval parenchyma cells 10-22 µm across and 55-78 µm long (Fig. 2B). Leaves are two-ranked and attached at 10-45 µm intervals (Fig. 2A). Incompletely preserved, they are at least 490 µm long, lack a midrib, and are inserted at 30-40° angles (Fig. 2A-B). Their thickness (7.5-12.5 µm) indicates that they are probably unistratose.

Additionally, a small root was found in the detritus at the periphery of the rhizome (Fig. 1). The root is 0.7 mm in diameter and has a diarch protostele ca. 100 µm wide (Fig. 2D). Secondary xylem with narrow (10-21 µm) tracheids (Fig. 2D) comprise ca. 75 % of the root; some bark is also preserved (Fig. 2D).

## Fungi

Fungal hyphae are abundant in highly degraded parts of the rhizome and in surrounding plant detritus (Fig. 1, 2L). They fall into two types: (1) smaller, apparently aseptate hyphae 1.5-2.0 µm in diameter; and (2) larger, septate hyphae 3.0-5.0 µm in diameter (Fig. 2L). The latter have septa spaced at 21-22 µm; clamp connections were not observed.

Darkly pigmented, round to oval cerebriform microsclerotia are also abundant in highly degraded parts of the rhizome and in the associated plant detritus (Fig. 1). The microsclerotia are 42-50 µm in diameter and composed of isodiametric to oval cells 4-12 µm in size (Fig. 2F).

Five other types of dispersed fungal reproductive structures are present in detritus associated with the rhizome (Fig. 1, 2G-K). These reproductive structures are multicellular (three to eight celled), uniseriate, more-or-less linear spores lacking obvious pores (Fig. 2G-K); four of the five types are preserved with narrow stalks (Fig. 2G, 2H-K). Type one consists of stalked, three-celled spores (Fig. 2G) ca. 15 µm long x 6 µm wide. The apical cell is rounded, 4 µm long x 6 µm wide. The middle cell is smaller, rectangular, 3 µm long x 6 µm wide. The basal cell is >10 µm long and 6 µm wide, tapering basally into a stalk 4 µm wide. Type two includes three celled, stalked spores roughly elliptical in shape, ca. 40 µm long and up to 16 µm wide (Fig. 2K). The apical cell is shaped like a truncated ellipse, 18 µm long and 16 µm wide. The subapical cell is rectangular, 11 µm long x 16 µm wide. The basal cell is trapezoidal, 6 µm long and 13 µm wide apically, tapering to 6 µm basally. The stalk tapers to 4 µm. Type three consists of elongate, stalked, 7- or 8-celled spores ca. 35 µm long and 6 µm wide (Fig. 2H). Cells, except for the basal and apical ones, are rectangular, 3-5 µm long x 6 µm wide. The apical

cell is rectangular-trapezoidal and slightly smaller, 2  $\mu\text{m}$  long x 5  $\mu\text{m}$  wide. The basal cell is also smaller, rectangular-trapezoidal, 3.5  $\mu\text{m}$  long x 4  $\mu\text{m}$  wide. The stalk tapers to 2  $\mu\text{m}$ . Type four is the most abundant fungal spore, three-celled, stalked and spatulate, ca. 25-30  $\mu\text{m}$  long and 15  $\mu\text{m}$  wide (Fig. 2J). The apical cell is round, 13-17  $\mu\text{m}$  in diameter. The middle cell is small and rectangular, 5-7  $\mu\text{m}$  long x 7-8  $\mu\text{m}$  wide. The basal cell is rectangular-trapezoidal, 8  $\mu\text{m}$  long and 7  $\mu\text{m}$  wide apically, tapering to 5  $\mu\text{m}$  basally. The stalk tapers to 3-4  $\mu\text{m}$ . Type five consists of slightly curved chains of five cells, ca. 38  $\mu\text{m}$  long and 9  $\mu\text{m}$  wide (Fig. 2I). The apical cell is rounded, 8  $\mu\text{m}$  long and 6  $\mu\text{m}$  wide. The sub-apical cell is inflated, 7  $\mu\text{m}$  long x 9  $\mu\text{m}$  wide. The third cell is rectangular-trapezoidal, 7  $\mu\text{m}$  long x 5  $\mu\text{m}$  wide, tapering to 4  $\mu\text{m}$ . The fourth cell is rectangular, 6  $\mu\text{m}$  long x 4  $\mu\text{m}$  wide. The basal cell is square, 4  $\mu\text{m}$  across.

### Coprolites

Small, round to ovoid coprolites occur towards the periphery of the rhizome, in excavations of the parenchymatous mesophyll, fiber band, and vascular tissue (Fig. 1, 2E). Coprolites also occur externally to fern tissues, around highly degraded portions of the rhizome (Fig. 1). They have smooth surfaces and are 23-260  $\mu\text{m}$  in diameter, composed of angular cell-wall fragments and opaque bodies (Fig. 2E).

### Minute spherical structures

The degraded portions of the rhizome have groups of cells that are filled with small, spherical structures 2-6  $\mu\text{m}$  in diameter (Fig. 2M). These structures occur in cells of all tissue types (parenchymatous leaf base mesophyll, fiber band, and vascular tissue) (Table 1).

## **Discussion**

### Taxonomic affinities of epiphytes

#### *Small epiphytic plants*

The small size of these plants and their lack of conducting tissues indicate that they are bryophytes. The only bryophyte group that combines pinnately branched gametophytes with two-ranked leaves that are unistratose, lack a midrib, and are inserted at wide angles to the stem are leafy liverworts (Schofield, 1985). The incomplete preservation of the leaves, which

typically provide taxonomically informative characters among liverworts, precludes a narrower systematic placement of these plants.

# *Root*

The diarch primary xylem and high proportion of secondary xylem, lacking vessels, are features typical of gymnosperms (Esau, 1965).

# *Fungi*

The microsclerotia documented here are similar in size and morphology to the cerebriform microsclerotia described in the roots of *Eorhiza arnoldii* Robison et Person from the Eocene of Canada, which were attributed to dark septate endophytes belonging to a lineage of dematiaceous ascomycetes (Klymiuk, Taylor & Taylor, 2013b).

Type one spores compare in overall morphology to smaller members of the dispersed fossil spore genus *Diporicellaesporites* Elsik, especially *D. minisculus* Sheffy et Dilcher, but the pores diagnostic of this genus (Kalgutkar & Jansonius, 2000) are not observable in the Argentinean material. Type two and four spores are comparable to species of the dispersed spore genus *Brachysporites* Lange et Smith, whose multicellular, usually spatulate spores resemble conidia of the extant dematiaceous ascomycete genus *Brachysporium* Saccardo (Kalgutkar & Jansonius, 2000; Taylor, Krings & Taylor, 2015). Within *Brachysporites*, type two spores are most similar to *B. atratus* Kalgutkar, while type four spores are most similar to *B. pyriformis* Lange et Smith (Kalgutkar & Jansonius, 2000). Type three spores are comparable to conidia of the extant magnaporthaceous ascomycete *Clasterosporium* Schwein. (Kalgutkar & Jansonius, 2000); the extinct *C. eocenicum* Fritel et Viguiet is especially similar to our type three spores, although the latter are slightly smaller. Type five spores are comparable to the conidia of the extant pleosporaceous ascomycete *Curvularia* Boedijn based on their size, curved shape, and inflated subapical cell (Elsik, 1993).

Overall, the fungal reproductive structures documented on the *Todea* rhizome are comparable with those of several ascomycete lineages, including Dematiaceae (microsclerotia and two of the spore types), Magnaporthaceae, and Pleosporaceae (Elsik, 1993; Kalgutkar & Jansonius, 2000; Klymiuk, Taylor & Taylor, 2013b). Septate hyphae lacking clamp connections frequently found in the vicinity of these reproductive structures are consistent with ascomycete

affinities. Given that all this fungal material was found in detritus or very degraded plant material (Fig. 1), these fungi, which were a component of the epiphyte community, were probably saprotrophs, rather than parasites or endophytes.

### *Coprolites*

Based on their size, shape and texture, the excavations and coprolites were probably produced by oribatid mites (Labandeira, 1998; Kellogg & Taylor, 2004; McLoughlin and Bomfleur, 2016).

### *Small spherical structures*

Their perfectly circular shape, tendency to completely fill cells, and variable size indicate that these structures are not microorganisms and are probably not of cellular nature. Instead, they probably represent a type of cell content degradation and aggregation due to the fossilization processes, also seen in the Early Devonian Rhynie chert plants (Michael Krings, personal comm., 2017).

### Distribution patterns

The distribution of colonizing organisms and differential preservation of central vs. peripheral tissues in the *Todea* rhizome indicate that parts of this rhizome were probably alive prior to fossilization. Consistent with this interpretation, vascular tissues near the center of the rhizome are well-preserved and are neither populated by colonizers (Fig. 1) nor degraded (Figure 3A). However, some of the peripheral leaf bases are highly degraded, surrounded by organic detritus (Figure 3A), and richly populated with colonizers (Fig. 1). The leaf bases on one side of the rhizome are particularly degraded, and this region is most densely colonized by epiphytic organisms (Fig. 1). Some leaf bases in this region contain coprolite-filled galleries large enough to adversely affect the physiological functions and structural integrity of these leaves (Figure 3B). Together, these observations indicate that the most degraded and heavily colonized peripheral leaf bases were probably dead at the time of fossilization, whereas the stem and more centrally-located, less degraded leaf bases were probably alive. This distribution of degraded and living tissues is not surprising, since the rhizomes of living Osmundaceae are often surrounded by a mantle of degraded and richly colonized dead leaf bases (Fig. 3C).

The fossil *Todea* rhizome exhibits dense colonization by a diverse community of epiphytes, which cover it in several kinds of life (Fig. 1), just like extant osmundaceous rhizomes (Fig. 3C). The distribution and frequency of each kind of organism associated with the rhizome by tissue type (Fig. 2N-O; Table 1) show that most associated organisms are much more abundant in the more degraded region of the rhizome (Fig. 1). Liverworts and fungi in detritus are found primarily external to the fern tissues, and secondarily within some of the most degraded tissues near the periphery of the rhizome (Fig. 1, 2N-O). Coprolites also occur in all types of tissue, as well as externally to some of the most degraded leaf bases, indicating that the arthropods that produced them did not have strong preference for lignified or parenchymatous tissues (Fig. 1, 2N-O).

#### Comparison with the Jurassic community associated with *Osmunda pulchella*

A community of organisms similar to that of the *Todea* rhizome has been described associated with an exceptionally well preserved *Osmunda pulchella* Bomfleur, G. Grimm et McLoughlin rhizome from the Jurassic of Sweden (Bomfleur, McLoughlin & Vajda, 2014; McLoughlin & Bomfleur, 2016). Like the Patagonian community, this Jurassic community included fungi, oribatid mites (coprolites) and epiphytic plants. However, in the case of the *Osmunda pulchella* community, the epiphytic plants are exclusively vascular (lycopsids and ferns), which may indicate that bryophytes had not yet evolved the epiphytic habit during the Jurassic. Additionally, fungal material is more abundant and diverse in the Patagonian rhizome, probably correlated with higher proportions of decomposed tissues. The richness of the communities associated with both of these osmundaceous rhizomes suggests that other permineralized fern rhizomes are likely to yield diverse communities of associated organisms.

#### Significance of the leafy liverwort fossils

Given the sparse fossil record of liverworts (Oostendorp, 1987; Tomescu, 2016; Heinrichs et al., 2018; Tomescu et al., 2018), it is not surprising that these tiny epiphytes represent the first report of fossil leafy liverworts from South America. *Marchantites hallei* Lundblad (Lundblad, 1955), a thalloid liverwort from the Early Cretaceous of Argentina, is the only other unequivocal fossil liverwort known from South America (Oostendorp, 1987; Tomescu et al., 2018). However, three additional compression fossils from Bolivia and Argentina that

lack cellular detail have also been compared with thalloid liverworts (Jain and Delevoryas, 1967; Cardozo and Iannuzzi, 2004; Coturel and Savoretti, 2018; Tomescu et al., 2018).

The liverworts described here are also the first epiphytic leafy gametophytes documented in the fossil record outside of amber deposits [see Grolle and Meister (2004), Frahm (2010), and Heinrichs et al. (2018) for reviews of bryophytes preserved in amber]. All other non-amber fossils of epiphytic bryophytes are moss protonemata described on angiosperm leaves (Mägdefrau, 1956; Selkirk, 1974; Barclay et al., 2013).

# Importance of understanding epiphyte communities in fossil biotas

Today, rich epiphyte communities are found in several biomes, including boreal forests (McCune, 1993), tropical lowland rainforests (Cornelissen and Ter Steege, 1989), and tropical montane forests (Wolf, 1993a,b). In these ecosystems, epiphyte communities provide critical ecological services, including soil production within forest canopies (Enloe et al., 2006), increased nutrient input (Coxson and Nadkarni, 1995), and increased water storage (Pócs, 1980; Vaneklaas and van Ek, 1990; Pykper et al., 2005). Thus, epiphyte communities significantly influence the ecology of their host plants. The makeup of epiphyte communities is diverse in the modern biota and co-varies dramatically with forest composition. In boreal forests of Pacific Northwest North America, lichens and mosses may dominate epiphyte communities (McCune, 1993), whereas bromeliads and orchids may dominate such communities in a mid-elevation rainforest of central Mexico (Hietz and Hietz-Seifert, 1995). The evolution of the deeply divergent epiphyte communities in these biomes is critical in understanding the ecology and evolutionary history of the forests themselves. However, our understanding of epiphyte community composition in the distant past is poor and based on a small number of examples (e.g., Rothwell, 1991; Rössler, 2000; McLoughlin & Bomfleur, 2016).

Knowledge of complex epiphyte communities in fossil biotas, including detailed insight into component communities like those of this Patagonian rhizome, is needed to paint a more complete picture of life in the geologic past and contextualize the evolution of epiphyte communities. Past epiphyte communities probably provided the same kinds of ecosystem services as those of the modern biota because these functions are independent of epiphyte community structure. Thus, attempts to understand the ecology of these fossil biotas without epiphytes ignore a critical component of the ecosystem. If we wish to understand the ecology of

past terrestrial environments, an understanding of epiphyte community structure is necessary. Similarly, an understanding of ancient epiphyte communities is required to contextualize their modern counterparts in an evolutionary framework (Gerhold et al., 2018).

### Osmundaceous rhizomes as a model system for understanding epiphyte community structure

In principle, an appropriate host organism could provide a model system to track epiphytes through geologic time, and from this we could determine when certain groups evolved the epiphytic habit (e.g., modern leptosporangiate ferns, lycophytes, bryophytes, angiosperms) and how epiphyte community structure varied between different forest types in the distant past. A model system would also allow for rigorous testing of hypotheses on the evolution of epiphytic leafy liverworts (Feldberg et al., 2014), lycophytes, and filicalean ferns (Lovis, 1977; Schneider et al., 2004). Such a host organism would need to meet four requirements: (1) a morphology that facilitates colonization by epiphytes; (2) morphological stasis over a wide stratigraphic range; (3) widespread geographic distribution; and (4) abundance in the fossil record.

Permineralized osmundaceous rhizomes satisfy these requirements for a model system to track epiphyte community structure through time. (1) The leaf bases found at the periphery of osmundaceous rhizomes have a rich microtopography that facilitates colonization by epiphytes. Indeed, living osmundaceous fern rhizomes are often covered in epiphytes (Fig 3C). (2) Osmundaceous ferns have been in morphological stasis since the Permian (> 250 million years) (Miller, 1971; Bomfleur et al., 2017). (3) Osmundaceae were widespread geographically in the geologic past (Miller, 1971; Bomfleur et al., 2017). (4) Osmundaceous ferns arguably have the richest fossil record of any living fern lineage (Arnold, 1964; Miller, 1971; Tidwell and Ash, 1994; Bomfleur et al., 2017). Additionally, living osmundaceous ferns allow direct comparison of the fossil epiphyte communities to their extant counterparts.

To date, permineralized osmundaceous rhizomes have yielded evidence for plant interactions with invertebrates (Schopf, 1978; Tidwell & Clifford, 1995; Bomfleur, McLoughlin & Vajda, 2014) and fungi (Kidston & Gwyne-Vaughan, 1907; Gould, 1970; Bomfleur, McLoughlin & Vajda, 2014). These occurrences confirm that osmundaceous rhizomes were important hosts for epiphyte communities in ancient ecosystems, just as they are today. Because permineralized osmundaceous rhizomes represent a well-populated epiphyte niche that has

remained unchanged over time and space, and have a rich fossil record reaching into the Permian, they provide a paleoecological model system for exploring epiphyte community structure and evolution.

## Conclusions

The complex community of organisms associated with an early Eocene osmundaceous fern rhizome from Patagonia allows a glimpse of a tiny, ancient epiphyte community centered around a single host plant. This community is surprisingly diverse and includes the first fossilized leafy liverworts in South America, also marking the only fossil record of leafy bryophyte epiphytes known outside of amber deposits; several types of fungal hyphae and spores; microsclerotia with possible affinities in several ascomycete families; and oribatid coprolites.

Understanding of complex epiphyte communities in fossil biotas, including detailed insight into epiphyte communities like those of this Patagonian rhizome, is needed to paint a more complete picture of life in the geologic past and to contextualize our understanding of modern epiphyte communities. In the fossil record, complex epiphyte communities have only been characterized in uncommon instances (e.g., the petrified forest of Chemnitz, Germany; Rössler, 2000). In contrast to these rare occurrences, fossil osmundaceous ferns and the communities they may harbor are widespread geographically and stratigraphically (Stewart & Rothwell, 1993; Taylor, Taylor & Krings, 2009). Osmundaceous ferns can be traced back into the Paleozoic (Miller, 1967, 1971; Stewart & Rothwell, 1993; Taylor, Taylor & Krings, 2009; Bomfleur et al., 2017), a time when terrestrial ecological networks were becoming canalized (DiMichele et al., 1992). Furthermore, osmundaceous morphology has been in stasis since the Paleozoic (Eames, 1936; Stewart & Rothwell, 1993; Bomfleur et al., 2017). As such, osmundaceous rhizomes represent a distinctive ecological niche, unchanged since the Permian, and act as hosts for epiphyte communities comprised of plants, animals, and fungi. These communities can also be studied in the modern biota and can be sampled systematically and consistently across all occurrences, fossil and extant. Because of the scale of the organisms (centimeter to decimeter), entire *in situ* tiny epiphyte communities can be studied directly in fossil specimens. Thus, osmundaceous rhizomes represent an ecological niche that has remained unchanged over time and provide a paleoecological model system for exploring epiphyte

community structure across geologic time and space. Given the diversity of epiphytes associated with osmundaceous rhizomes from the La Huitrera Formation and the Jurassic of Sweden (McLoughlin & Bomfleur, 2016), as well as the abundance of osmundaceous rhizomes in the fossil record (Miller, 1967; Miller 1971; Taylor, Taylor & Krings, 2009; Bomfleur et al., 2017), we predict that continued exploration will reveal additional aspects of the biotic networks centered around these important repositories of ecological data from the geologic past.

## Acknowledgements

The authors thank Carla J. Harper, (University of Kansas, Lawrence, Kansas) and Terry Henkel (Humboldt State University, Arcata, California) for help identifying fungal material associated with the fern rhizome, Michael Krings (Ludwig-Maximilians-Universität München, Germany) for help determining the origin of the degraded cell contents, Benjamin Bomfleur (Universität Münster, Germany) for identifying the host fern, Eduardo Ruigomez (Museo Paleontologico Egidio Feruglio, Trelew, Argentina) for facilitating work in the MPEF collections, and Russell Bryan for assistance rendering Figure 2N. This study was initiated during ACB's and AMFT's visit to Museo Paleontologico Egidio Feruglio as part of a collaboration funded by US National Science Foundation grant IIA-1322504 (to AMFT).
