Meat, long hypothesized as an important food source in human evolution, is still a substantial component of the modern human diet, with some humans relying entirely on meat during certain times of the year. Understanding the socio-ecological context leading to the successful acquisition and consumption of meat by chimpanzees (*Pan troglodytes*), our closest living relative, can provide insight into the emergence of this trait because humans and chimpanzees are unusual among primates in that they both (i) frequently hunt mammalian prey, (ii) share meat with community members, and (iii) form complex social hierarchies within their communities. However, females in both human hunter-gatherer societies as well as chimpanzee groups rarely hunt, instead typically access meat via males that share the prey with conspecifics. In female chimpanzees, dominance rank affects feeding competition in general, but the effect on meat access found different results within and across study groups. Here we contribute to this debate on how rank influences meat access while controlling for a wider spectrum of socio-ecological control variables than has previously been considered. Multivariate analyses of 773 separate meat-eating events collected from more than 25 years from two Taï chimpanzee communities were used to test the importance of female dominance rank for being present, and for acquiring meat during meat-eating events. We found that high-ranking females were more likely to be present during a meat-eating event and, in addition, they were more likely to eat meat compared to the subordinates. These findings of the importance of female social rank were robust to large demographic changes (decrease of community size) and as well as seasonal ecological changes (fruit abundance dynamics).

## 22 Abstract

23 Meat, long hypothesized as an important food source in human evolution, is still a  
24 substantial component of the modern human diet, with some humans relying entirely on meat  
25 during certain times of the year. Understanding the socio-ecological context leading to the  
26 successful acquisition and consumption of meat by chimpanzees (*Pan troglodytes*), our closest  
27 living relative, can provide insight into the emergence of this trait because humans and  
28 chimpanzees are unusual among primates in that they both (i) frequently hunt mammalian prey,  
29 (ii) share meat with community members, and (iii) form complex social hierarchies within their  
30 communities. However, females in both human hunter-gatherer societies as well as chimpanzee  
31 groups rarely hunt, instead typically access meat via males that share the prey with conspecifics.  
32 In female chimpanzees, dominance rank affects feeding competition in general, but the effect on  
33 meat access found different results within and across study groups.

34 Here we contribute to this debate on how rank influences meat access while controlling for  
35 a wider spectrum of socio-ecological control variables than has previously been considered.  
36 Multivariate analyses of 773 separate meat-eating events collected from more than 25 years from  
37 two Tai chimpanzee communities were used to test the importance of female dominance rank for  
38 being present, and for acquiring meat during meat-eating events. We found that high-ranking  
39 females were more likely to be present during a meat-eating event and, in addition, they were more  
40 likely to eat meat compared to the subordinates. These findings of the importance of female social  
41 rank were robust to large demographic changes (decrease of community size) and as well as  
42 seasonal ecological changes (fruit abundance dynamics).

43 In addition to social rank, we found that other female properties had a positive influence  
44 on meat access and presence at meat-eating events, including oestrus status, nursing of a small

45 infant, and age. Similar to findings in other chimpanzee populations, our results suggest that  
46 females reliably acquire meat over their lifetime even if they are rarely active hunters. We discuss  
47 our findings and offer implications of this study for chimpanzee understanding.

48

## 49 **Introduction**

50           Hunting and meat eating are considered important behaviors shaping early hominid  
51 evolution and are proposed to be key innovations in the evolution of Australopithecines to *Homo*  
52 *erectus* (Isaac, 1978; Washburn, 1978; Leakey, 1981; Hill, 1982). In particular, meat consumption  
53 has for at least several decades been suggested as the food that powered brain expansion in human  
54 evolution (Washburn & Lancaster, 1968; Milton, 1999). Meat has become a substantial component  
55 in many modern human diets, recently averaging 42 kg of meat per capita per year (Faostat, 2014).

56           Placed within the context of human evolution, observations of hunting and meat eating  
57 in our closest living relatives, chimpanzees (*Pan troglodytes*), are critical in helping to reconstruct  
58 early human behaviors (Wrangham, 1987; Boesch-Acherman & Boesch, 1994). Since early-  
59 published records of chimpanzee hunting and meat eating by Jane Goodall (1963), numerous other  
60 field studies have reported these as common chimpanzee behaviors (Boesch & Boesch, 1989;  
61 Uehara et al., 1992; Boesch & Boesch-Achermann, 2000; Mitani & Watts, 1999). Although  
62 chimpanzee diets are composed primarily of fruits (Goodall, 1968; Sugiyama & Koman, 1992;  
63 Morgan & Sanz, 2006), meat is considered an important food source year round, making up to 9%  
64 of their activity budget, with males and females eating an average of 186 g and 25 g of meat per  
65 day, respectively (Boesch & Boesch-Achermann, 2000). Because of its high quality calorific  
66 package of protein, fat and micronutrients that are difficult to find in plant foods (Milton, 2003;

67 Tennie et al., 2009); the nutritional value of meat is not easily to substitute (Goodall, 1986; Boesch  
68 & Boesch-Achermann, 2000).

69           Yet how meat is acquired, and the value of meat across individuals is not uniform within  
70 and across gender. A stable isotope study of hair and bones confirmed sex differences in meat  
71 consumption, with higher levels of meat eating among Tai chimpanzee males compared to females  
72 (Fahy et al., 2013).

73           Social rank can also play an important role in the access and consumption of meat  
74 (O'Malley et al., 2016, but see Samuni et al., 2018b). A study of Gombe chimpanzees showed that  
75 females use their dominance rank position to maximize their access to meat, with high-ranking  
76 females consuming more meat than subordinates (O'Malley et al., 2016). Further, it has been  
77 shown that meat is an important food source for female chimpanzees during periods of pregnancy  
78 and nursing (O'Malley et al., 2016), a nutritionally and energetically costly body state for females  
79 (Clutton-Brock & Harvey, 1978; Thompson et al., 2012). The Gombe study found an interaction  
80 between reproductive state and rank, and revealed that high-ranking females do not differ in meat  
81 consumption between different reproductive states, but low-ranking females do, with low-ranking  
82 females consuming more meat during pregnancy than during lactation and baseline (not pregnant/  
83 not lactating females) (O'Malley et al., 2016). In Sonso chimpanzees of the Budongo forest in  
84 Uganda, high-ranking individuals monopolize meat irrespective of their own hunting role, whereas  
85 in the neighbouring Waibira community no rank effect on meat access was found (Hobaiter et al.,  
86 2017). Dominance rank has been shown to affect sociality, ranging, and feeding competition in  
87 female chimpanzees at Gombe (Pusey et al., 1997; 2005; Williams et al., 2002a;b; Murray et al.,  
88 2006; 2007) and Kibale (Thompson et al., 2007; 2010; Kahlenberg et al., 2008).

89           In the Taï National Park in Côte d'Ivoire, male chimpanzees are primarily the hunters; they  
90 capture the prey in most cases, and subsequently share it with their community members (Boesch  
91 & Boesch-Achermann, 2000; Samuni et al., 2018b). Females participate in hunts much less than  
92 males, with their involvement in hunting being approximately 13%-15% (Boesch & Boesch, 1989;  
93 Samuni et al., 2018b). The majority of meat (98%) in these groups is accessed via sharing (Samuni  
94 et al., 2018b). Because hunting participation can largely determine meat access (Boesch & Boesch-  
95 Achermann, 2000; Samuni et al., 2018b), the consumption of meat is not evenly distributed  
96 between community members, resulting in some individuals frequently not receiving meat while  
97 others obtain it regularly (Boesch & Boesch, 1989; Boesch, 1994; Boesch & Boesch-Achermann,  
98 2000).

99           In the absence of hunting participation, “cheating”, defined as consuming meat from a  
100 successful hunt that an individual did not participate in, can occur. By cheating, females are able  
101 to increase their caloric intake without suffering the energetic costs related to hunting. Females are  
102 more successful at cheating than males because male hunters tolerate female cheaters much more  
103 than male cheaters (Boesch & Boesch-Achermann, 2000). Female cheaters also receive more meat  
104 than male cheaters, accessing meat in 15% versus 48% by males of the all prey captures (Boesch  
105 & Boesch-Achermann, 2000).

106           Male hunters share meat unevenly with females, and males might share with cheating  
107 females because females copulated more with males who shared meat with them than with males  
108 who did not share meat with them, irrespective of e.g. male rank, female rank, or age (Gomes &  
109 Boesch, 2009). Despite the low frequency in which females participate in hunting, some high-  
110 ranking females in the Taï North group can reach a very high status in the meat access order  
111 although they did not participate in the hunt, occasionally even surpassing low and middle ranking

112 males (Boesch & Boesch-Acher mann, 2000). Because females can benefit from sharing by males,  
113 it is of interest whether social rank can increase cheating opportunities. In the Taï North group,  
114 high-ranking females monopolize and possess the food after a dyadic female/female food conflict  
115 (Wittig & Boesch, 2003). Recent results investigating all food sharing events in Taï South and East  
116 groups found a three-way interaction between rank of the beggar and the possessor with sex on  
117 food access through sharing (Samuni et al., 2018a), indicating that rank neighbours were sharing  
118 more than dyads with a larger rank asymmetry. When investigating access to meat only, however,  
119 another study on the same chimpanzee groups found an impact of hunt participation, age, prey size  
120 and fruit availability on meat consumption, but none by sex or dominance rank (Samuni et al.,  
121 2018b).

122         Here we utilize a large, long-term (greater than 25 years) dataset that enables a wider  
123 spectrum of socio-ecological control variables, such as community size and fruit abundance, to  
124 detect the long-term importance of different social factors on female success to access meat. The  
125 central two hypotheses tested here are that in comparison to lower ranking females, high-ranking  
126 females are more likely to (1) be present during a meat eating event, and to (2) have increased  
127 access to meat given both are at a meat eating event. The primary predictor variable of interest  
128 here is female dominance rank, while controlling for age, oestrous status and the nursing of a small  
129 infant, important factors in determining feeding competition more broadly (Riedel et al., 2011;  
130 O'Malley et al., 2016) and hence important control variables to include when testing for the  
131 importance of rank. We added socio-ecological control variables such as community size and fruit  
132 abundance to test for the robustness of rank effects besides seasonal ecological changes and large  
133 demographic changes (decrease of community size).

134

## 135 **Materials & Methods**

### 136 *Study site and data collection*

137 We analysed meat-eating data from two habituated chimpanzee communities in Tai  
138 National Park, henceforth labelled North and South due to the relative geographic locations of  
139 their territories. Habituation of the North and South groups started in 1979 and 1989, respectively.  
140 Researchers and local field assistants have since continuously observed both communities. During  
141 the study period, the North group decreased from 76 to 19 individuals and the South group from  
142 56 to 39 chimpanzees (Figure 1), largely related to disease outbreaks, poaching and not to food  
143 availability.

144 Human observers carried out daily focal animal follows (Altmann, 1974) using  
145 standardised check-sheets and shifted to *ad libitum* data recording for hunting and meat eating  
146 events. Inter-observer reliability among Tai assistants is very good (Deschner et al., 2004; Riedel  
147 et al., 2011). During the daily focal animal follows, the observers make continuous records of  
148 social interactions, party composition, and number and identity of females in oestrous encountered  
149 by the focal chimpanzee throughout the observation day. From these focal data, we were able to  
150 identify female dominance rank and the oestrous status. At hunting and meat eating events, the  
151 assistants changed the focus from the focal animal to the whole hunting and meat-eating situation  
152 and recorded as much information as possible about all visible individuals and interactions  
153 between them. At meat eating events, observers noted which chimpanzees were present, who held  
154 the prey, dyadic membership in meat sharing events, who was begging, who ate meat, who was  
155 aggressive and received aggression, as well as consumption time and prey details such as species  
156 and age-class. From the *ad libitum* data, we obtained information on whether a female was present  
157 or not within the meat-eating party, and whether the female got meat or not. The dataset covers a

158 27-year period for the North group (1987 - 2014) with 451 meat-eating events, and a 15-year period  
159 for the South group (1999 - 2014) with 376 meat-eating events. Due to logistical constraints, not  
160 all meat-eating events during this period were recorded.

161 Our meat eating analyses focused on adult females, defined to be 13 years or more (Boesch  
162 & Boesch-Achermann, 2000), with 39 adult females from the North group and 33 females from  
163 the South group. Females in Taï give birth to their first infant when they are approximately 13  
164 years old, at this age they are also fully grown and defined to be adult (Boesch & Boesch-  
165 Achermann, 2000).

166 From the 827 observed meat-eating events, 773 had at least one adult female present and  
167 these were used for analysis. Analysis of data for which at least one female from each rank category  
168 was present (N=464) did not differ from the results using the full dataset; thus we present results  
169 based on the entire 773 events dataset. The meat eating events were almost entirely on separate  
170 days (to 94%) with a mean interval of 17 days (range of 1-254) for South and 25 days (range 1-  
171 289) for North group.

172 Assistants trained in botanical monitoring censused fruit tree phenology every month using  
173 established routes in both chimpanzee territories. They also noted the presence of ripe fruits of tree  
174 species whose fruits were chimpanzee foods (Anderson et al., 2002; 2005; Polansky & Boesch,  
175 2013).

176 All field protocols, data collection procedures, and data analyses were conducted in  
177 accordance with wildlife research protocols and ethical standards of the Max Planck Society in  
178 Germany, “Ministère de l'Enseignement supérieur et de la Recherche scientifique”, “Ministère des  
179 Eaux et Forêts”, and “Office Ivoirien des Parcs et Réserves” in Côte d’Ivoire.

180

181 *Data analysis, model predictors and motivations*

182 We constructed and analysed two models for the response variables of (i) whether a female  
183 was present or absent in the meat eating party (hypothesis 1) and (ii) whether the female did or did  
184 not receive meat (hypothesis 2). Both models therefore have a bivariate response variable. We  
185 considered four ‘individual female’ properties and ‘socio-ecological’ properties as predictor  
186 variables, with interactions between some of these predictors, which we describe next.

187 Dominance rank

188 According to Wittig and Boesch (2003), we expected linear dominance hierarchies for the  
189 adult females in Tai. Using the software package MatMan (De Vries 1995), we determined annual  
190 linear dominance hierarchies following the direction of greeting behaviour: pant-grunts (PG),  
191 greeting-hoos (GH) and greeting-pants (GP) (Wittig & Boesch, 2003). Only 6 out of 44 annual  
192 dominance hierarchies reached significance. The reasons why we rarely detected linear female  
193 hierarchies are a high percentage of unknown dyadic dominance relationships between females  
194 and years with just four adult females in the North group. Due to this, we implemented three rank  
195 categories (high, middle and low) following the method used in Gombe by Pusey and colleagues  
196 (1997). We determined rank categories as follows. High-ranking females either gave no greetings  
197 to any females or gave occasional greetings to other high-ranking females and received greetings  
198 from middle- and low-ranking females. Middle-ranking females greet to high- and some middle-  
199 ranking females, and received greetings from low- and some middle-ranking females. Low-  
200 ranking females rarely, if ever, received greetings from any adult females but often gave them to  
201 middle- and high-ranking females. When there was no greeting behavior observed between a  
202 female dyad in a certain year, we considered the ranks and interactions between these females in  
203 the year before and after. Furthermore, we consulted other rank data published about the Tai

204 females (Boesch & Boesch-Achermann, 2000; Wittig & Boesch, 2003) and have always been able  
205 to assign females to one of the three categories. Female rank categories remained stable across  
206 years in both communities, with 58 of 80 females maintaining a single rank category over the study  
207 period. Twenty-two females moved to the adjacent category, mostly from low to middle (10  
208 females) and from middle to high (10 females). Only two females (one in each community)  
209 dropped in rank from high to middle during the last years before death, as their physical condition  
210 deteriorated. A recent study from Taï also found that female dominance hierarchies of both the  
211 North and South group were largely stable over time and only few rank changes were described  
212 (Mielke et al., in press).

### 213 Nursing a small infant

214 We controlled whether the female was nursing a small infant ( $\leq 2$  years old) at the day of  
215 the meat-eating event because several studies have shown that chimpanzee mothers are less  
216 gregarious (Goodall, 1986; Takahata, 1990; Sakura, 1994; Wrangham, 2000; Williams et al.,  
217 2002b; Otali & Gilchrist, 2006; Murray et al., 2007; but also see Riedel et al., 2011). This suggests  
218 that mothers with small infants avoid meat-eating events for the protection of their infants because  
219 of the large party sizes and competitive interactions to access meat at these events (Boesch &  
220 Boesch-Achermann, 2000). Alternatively, nursing females may disproportionately benefit from  
221 the nutritive value of meat, so it is also plausible to predict that they would try to join meat-eating  
222 events at higher frequencies. Males might prefer to share meat with mothers and their infants  
223 (potentially their own offspring) as a provisioning strategy. In Gombe chimpanzees, the  
224 reproductive state of females influenced meat consumption, with pregnant females consuming  
225 more meat than lactating and not pregnant/ not lactating females (O'Malley et al., 2016).

### 226 Oestrous status

227 We controlled for oestrous state as females with a maximal sexual swelling are more  
228 gregarious (Boesch & Boesch-Achermann, 2000) and adult males tend to share more meat with  
229 oestrous than with anoestrous females in Taï National Park given their proportional representation  
230 in hunting parties (Gomes & Boesch, 2009). Assistants recorded the oestrous status, which coded  
231 sexual skin swellings after visual inspection following Furuichi (1987). Three stages of  
232 tumescence were coded: (1) no swelling: minimal size and maximal degree of wrinkling; (2) partial  
233 swelling: relative increase/decrease in size and loss/appearance of wrinkles compared with stage  
234 1 or 3; (3) maximum swelling: maximum size with no wrinkles and tight appearance. For the  
235 analysis we used whether the female had a maximal swelling at the meat-eating event.

#### 236 Age

237 We controlled for the age of the adult female although Wittig and Boesch (2003) found  
238 that female linear hierarchy in Taï was related to the outcome of the contest, while it was  
239 independent of age. Other studies in Gombe and Mahale found that females increased their rank  
240 as they aged (Nishida, 1989; Pusey et al., 1997). Older Taï chimpanzees gained more access to  
241 meat (Samuni et al., 2018b).

#### 242 Number of females and males

243 We controlled for the number of adult females and males present at the meat-eating event  
244 because an increase in competitors also increases the within-group contest competition over food  
245 (Wittig & Boesch, 2003), although sub-group size previously had no effect on meat consumption  
246 in Taï East and South group (Samuni et al., 2018b).

#### 247 Community ID

248 We controlled for potential differences across the two chimpanzee communities (Luncz et  
249 al., 2012) and included to which community the female belonged (either North or South group).

275 Interactions between some predictors

276 Rank effects might be different in North and South group, so we included an interaction of  
277 female dominance rank and community ID into both models. Because intra-annual dynamics of  
278 FAI are substantial (Anderson et al., 2005, Polansky & Boesch, 2013), we included an interaction  
279 between FAI and female dominance rank into both models. In the presence model, community  
280 size and number of adult females were highly correlated (Pearson coefficient = 0.97), so we choose  
281 between the two variables and excluded community size from the analysis to test for the effect of  
282 number of adult females. We included the interaction of number of females with rank into both  
283 models. Female dominance rank might have less of an influence for presence at meat eating events  
284 if the number of adult females is low and therefore there is less competition. The same might be  
285 true for the access to meat, when there are many other female competitors at the meat-eating event,  
286 high rank might have a strong influence on the chances of accessing meat. Whereas when there is  
287 only a small number of other females present all of them independently of their rank might receive  
288 parts of the males share.

289 In addition, we included the interaction between female dominance rank and oestrous status  
290 into both models, because females in oestrous are very social and interesting for the males  
291 (Deschner et al., 2004), and independent of their rank they might be present and access meat. So  
292 not only high-ranking females in oestrus might get meat, but also low ranking females in oestrus.

293

294 *Statistical Analyses*

295 Generalized linear mixed models (GLMM) with a logit link function were built to analyze  
296 the significance of the factors described above. The GLMM framework accommodates the  
297 bivariate data (indicating either female presence or absence or whether or not she received meat,

298 given presence at a meat eating event), while the mixed structure (both fixed and random effects)  
299 allows proper treatment of repeated measurements on individual females and meat eating events  
300 due to unobserved variables (e.g. total amount of meat available). Fixed effect predictor variables  
301 were adult female dominance rank, age, oestrous status, whether the individual was nursing an  
302 infant, community ID, FAI, the number of adult males present, and number of adult females  
303 present (community size was highly correlated with number of adult females in the presence  
304 model). Random effects grouping variables were the individual female ID and the meat-eating  
305 event ID. As discussed previously, for both models we included the interactions of dominance  
306 rank and FAI, dominance rank and community ID, dominance rank and number of adult females  
307 present, and dominance rank and oestrus status.

308         We fit models in the R version 3.5.2 environment (R Development Core Team, 2018) using  
309 the lme4 package (Bates et al., 2015) and following the general guidelines described by Bolker  
310 and colleagues (2009). The general model building process proceeded by first fitting a model with  
311 only random effects to ensure estimated standard deviations were not close to zero. For the  
312 presence model, this revealed numerical issues when random slopes were allowed for categorical  
313 predictor variables (oestrus, nursing an infant, and dominance rank), so these were removed prior  
314 to estimating a null model with only an intercept and supported random effects. For the meat access  
315 model, no random slopes were included to avoid numerical issues. Given the null model consisting  
316 only of an intercept, random effects, and an overall variance estimate, the full model including  
317 main effects and interactions along with random effects was compared to the null model using a  
318 likelihood ratio test (LRT). Interaction terms were removed one at a time from the full model and  
319 their statistical support quantified using LRTs. Because the interactions were not statistically  
320 supported, reduced models that excluded all interaction terms was re-fit to facilitate direct

321 interpretation of the coefficient estimates, and the support for each of these main effects was  
322 evaluated using LRTs by removing each predictor variable one at a time.

323         Prior to fitting the full GLMMs, we standardized continuous predictor variables to have  
324 mean = 0 and standard deviation = 1 to increase model fitting stability. Furthermore,  
325 multicollinearity was checked by examining the generalized variance inflation factors (GVIF; Zuur  
326 et al., 2009) as implemented in the car package (Fox & Weisberg, 2011) in a full model without  
327 interactions or random effects. This indicated that community size and number of females were  
328 too correlated (GVIF = 21.094) to simultaneously include in the presence model. We checked  
329 residual temporal autocorrelation and correlation with time since last observation within  
330 individuals across events to ensure no systematic bias in predictions related to time. We remark  
331 that there was no strong evidence (GVIF values always less than 2) that female age and dominance  
332 rank were correlated.

333

## 334 **Results**

335         Seventy-two different adult females were observed, two of which never were present at  
336 any meat-eating event. Of the 773 events, at least one low, middle, and high-ranking adult female  
337 attended 530 (69%), 677 (88%), and 697 (90%) events. The number of events at least one female  
338 of a given rank received meat given that rank class was present was 329 (62%), 556 (82%), and  
339 619 (89%) for low, middle and high rank class, respectively.

340

### 341 *Probability of females being present at meat eating events*

342         The full model (including interactions) for the probability of being present at meat eating  
343 events was significantly better than a null model with only random effects and an overall intercept

368 community size and increased number of females statistically decreased the likelihood to obtain  
369 meat. The number of males, FAI, and community ID were not significant.

## 374 **Discussion**

375 We found support for our two principle hypotheses, that high-ranking females were more  
376 likely to be present during a meat-eating event and that they were more likely to eat meat when  
377 they were present compared to the subordinates. This research contributes to a growing body of  
378 literature on the topic, where high female rank has also been shown to provide priority of access  
379 to high quality foods in Kibale and Gombe chimpanzees (Murray et al., 2006; 2007; Kahlenberg  
380 et al., 2008; Williams et al., 2002a).

381 For chimpanzees at Tai National Park, our analyses further indicated that this positive  
382 effect of female dominance rank on acquiring meat was stable for the two chimpanzee  
383 communities (North and South) over a long period (more than 25 years). During this time, both  
384 communities experienced large declines in size with associated demographic changes that include  
385 different numbers of adult females and adult males and important changes in the communities'  
386 dominance hierarchies. In addition, the intra-annual fruit food fluctuations in Tai National Park  
387 are quite strong and have been increasing in the past decade (Anderson et al., 2005, Polansky &  
388 Boesch, 2013). Despite these changes in demographic and environmental conditions, no  
389 interactions between female social rank and the different socio-ecological variables was detected;  
390 the rank related behaviors of these female chimpanzees are both stable and robust across the two

391 communities. Further, the rank contribution to meat access remained constant across all these  
392 social changes.

393         In humans, sharing of food has been proposed to be the result of a collective action problem  
394 due to living in a risky foraging niche that produces a set of social norms of production and sharing  
395 (Jaeggi & Gurvgen, 2013). In other words, humans live in a niche where food sharing became a  
396 necessity. Considering that meat brings along a number of important micronutrients (Milton, 2003;  
397 Tennie et al., 2009), it seems that meat, acquired through the presence of sharing, is an important  
398 component of the diet in Tai chimpanzees.

399         Two recent studies in Tai, focusing on dyadic interactions or detailed hunting  
400 characteristics, have shown that social rank independent of sex has only a limited effect in the food  
401 sharing behaviour of the Tai chimpanzees or their ability to access meat after a hunt (Samuni et  
402 al., 2018a;b). In contrast, focusing on the characteristics of the females, here we found a clear  
403 effect of rank on meat access by females, with dominant females accessing more often meat than  
404 subordinates. At least three reasons may account for this difference: (1) since we used data over  
405 25 years the analysis had to fit the available long-term data, preventing us from analysing for  
406 example the effects of hunt participation or reciprocal relationships on meat access; (2) our  
407 research question was different and we did not include dyadic relationships; and (3) due to missing  
408 dyadic dominance relationships, we used three rank categories, which may provide a slightly  
409 different picture compared to linear dominance hierarchies. Our result, nonetheless, provides  
410 evidence that female dominance rank has an effect on the accessibility of valuable resources,  
411 indicating an advantage for dominant females as expected with contest competition over food  
412 similar to Wittig & Boesch (2003).

413 In Gombe and Kibale, high ranking females occupied higher-quality areas while  
414 subordinates had to settle elsewhere (Murray et al., 2006; 2007; Kahlenberg et al., 2008; Williams  
415 et al., 2002a) resulting in higher reproductive success for dominant females (Pusey et al., 1997;  
416 2005; Thompson et al., 2007). A better-fed female can invest more energy in reproduction and  
417 thereby produce more offspring, or she can supply more food to her offspring. In Gombe, the five  
418 most successful females at getting large amounts of meat had more surviving offspring than did  
419 the five least successful females (Mc Grew, 1992).

420 The effect of female dominance rank on feeding competition appears across chimpanzee  
421 populations besides differences in demography and female sociality (Wrangham, 2000; Fawcett,  
422 2000; Boesch & Boesch-Achermann, 2000; Williams et al., 2002a;b; Lehmann & Boesch, 2008).  
423 Tai females are more gregarious compared to those from Kibale and Gombe where females were  
424 relatively asocial (Wrangham & Smuts, 1980; Goodall, 1986; Wrangham et al., 1992; Pusey et al.,  
425 1997; Williams et al., 2002b). Females in Kibale and Gombe seem to disperse and to be less  
426 gregarious to reduce within-group contest competition. In contrast, the females in Tai remain  
427 highly gregarious and build a formal hierarchy to reduce contest competition (Wittig & Boesch,  
428 2003) also at meat-eating events. Higher gregariousness in Tai females may result from a  
429 combination of higher fruit abundance (Boesch, 2009) and higher predation pressure at Tai  
430 (Boesch, 1991; 2009) compared to the other study populations. Unequal access to monopolizable  
431 food, such as meat, might be an explanation for the development of the linear hierarchy in Tai  
432 females (Wittig & Boesch, 2003). Female dominance rank might help to reduce direct dyadic  
433 fighting by giving access to the dominant individual before even a conflict or fight have to evolve.

434 Samuni and colleges (2018b) found a positive effect of age on meat access in Tai  
435 chimpanzees, which we confirmed. It remains unclear why older chimpanzees are more likely to

436 access meat. It may be due to better begging and/or hunting skills. One hypothesis is that older  
437 females can have stronger friendships with chimpanzees in their community and can rely on long-  
438 term cooperative exchanges that gives them access to shared foods such as meat (Samuni et al.  
439 2018a). In addition, older females are also preferred mating partners by male chimpanzees (Muller  
440 et al. 2006).

441 Another female property proposed to play a role for presence and meat access was the  
442 oestrous status of the female. We found that oestrous females in Taï National Park were more  
443 likely to be present and to get meat than females with no oestrous. This agrees with the findings  
444 that oestrous females were more gregarious than anoestrous ones (Boesch & Boesch-Achermann,  
445 2000), and that adult males share more meat with oestrous than with anoestrous females, when  
446 controlled for their proportional representation in hunting parties (Gomes & Boesch, 2009).

447 Our results show that a nursing female with a small infant in Taï did not avoid meat eating  
448 events where elevated levels of intra-group aggression can occur. The increased need for high  
449 value food such as meat to support nursing an infant is a likely factor motivating these females to  
450 acquire meat. Chimpanzee mothers in Taï National Park remained as gregarious as non-mothers  
451 (Riedel et al., 2011), in contrast to other study populations, where mothers are less gregarious than  
452 non-mothers (Goodall, 1986; Murray et al., 2007; Williams et al., 2002b; Takahata, 1990; Sakura,  
453 1994; Wrangham, 2000; Otali & Gilchrist, 2006). Our results about lactating females accessing  
454 meat better than non-lactating females, confirms the findings from Gombe, where pregnant  
455 females consumed more meat than lactating and not pregnant/not lactating females (O'Malley et  
456 al., 2016). An interaction between reproductive state and rank in Gombe females, revealed that  
457 high-ranking females do not differ in meat consumption between different reproductive states, but

458 low-ranking females do, with low-ranking females consuming more meat during pregnancy than  
459 during lactation and not pregnant/ not lactating females (O'Malley et al., 2016).

460 For the ecological variable that we studied, we found that fruit abundance had no  
461 significant effect on female meat access, but plays a role on female presence at meat eating events,  
462 with more females being present during times of high fruit abundance. That those periods of high  
463 fruit abundance result in higher party sizes and sociality in Tai chimpanzees has been shown before  
464 (Doran, 1997; Riedel et al., 2011).

465 Females hunt much less than males, involvement in hunting was only 13%-15% (Boesch  
466 & Boesch, 1989; Samuni et al., 2018b). Nevertheless, we can report that adult females continued  
467 hunting and meat eating behaviors also during years when there were no or just one adult male in  
468 the North group. The North group had no adult males for four years and only one adult male for  
469 another six years, but a minimum of four adult females that continued to hunt and eat meat during  
470 this period. Although hunting frequencies seemed reduced, it is impressive that females engaged  
471 successfully in this behavior, further supporting the evidence that meat has a high nutritional value  
472 for chimpanzees. Impressively, low-ranking females and even nursing mothers joined these  
473 aggressive meat-eating events and were successful in accessing meat, which strengthens further  
474 the importance of meat in the female chimpanzee diet.

475

## 476 **Conclusion**

477 The benefits of female dominance rank for accessing meat are positive and robust to fruit  
478 abundance variations and large demographic changes (and hence some group level social changes  
479 such as in dominance hierarchies). Taken together this indicates that this female social property is  
480 persistent even when the competition for resources declines because of overall community size

481 declines or fruit abundance increases. Furthermore, other female properties such as age, oestrus  
482 status and the nursing of a small infant positively influenced meat access.

**Figure 1**(on next page)

Figure 1: Yearly maximal community size during the study period for North group (grey line) from 1987 until 2014 and for South group (black line) from 1999 until 2014.

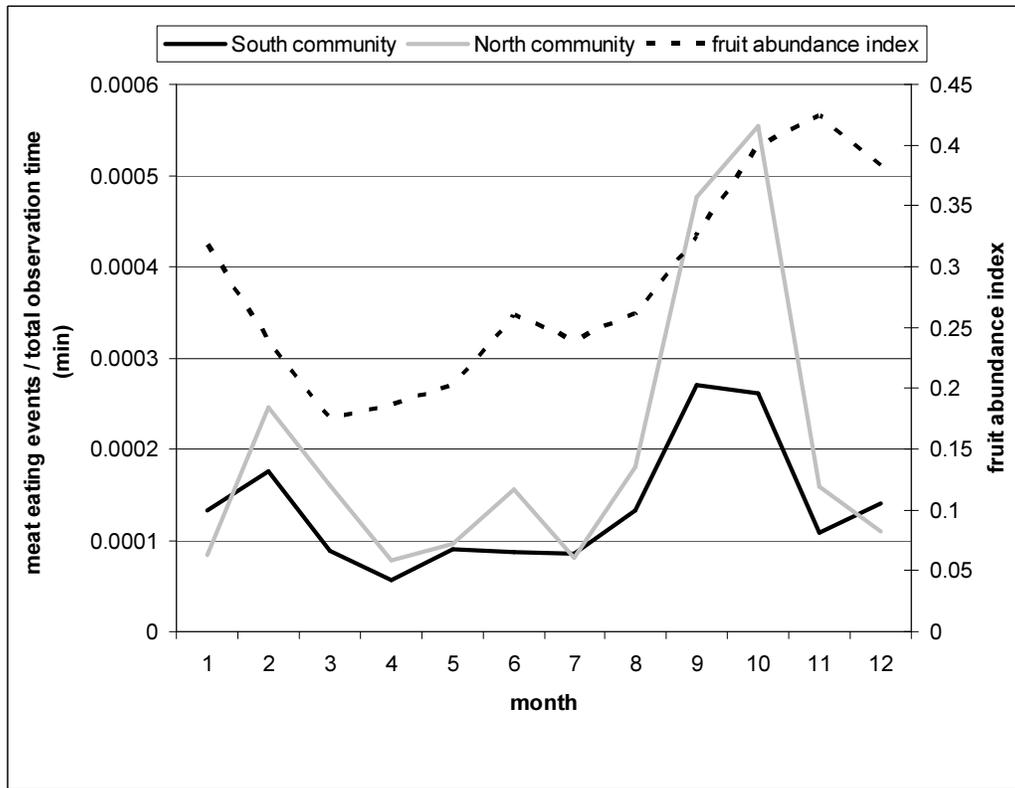

**Figure 1:** Yearly maximal community size during the study period for North group (grey line) from 1987 until 2014 and for South group (black line) from 1999 until 2014.

**Figure 2**(on next page)

Figure 2: Monthly variation in the meat eating frequency controlled for the total observation time and monthly fruit abundance index (FAI).

**Figure 2:** Monthly variation in the meat eating frequency controlled for the total observation time (min) for North and South group with a peak in September and October. Second Y-Axis shows the monthly fruit abundance index (FAI) with an increase in FAI during the two meat eating peak months.

**Table 1** (on next page)

Table 1: Summary of models for the probability of being present at meat eating events.

**Table 1:** Summary of models for the probability of being present at meat eating events. The term estimates columns show the estimate (Est), standard error (SE), and Z-value for model parameters, where the entries along the rows that do not include interactions (denoted by a colon) are based on the fitted reduced model with no interactions and the entries for rows with interactions are based on the fitted full model with all interactions and main effects. The term significance entries show results of likelihood ratio tests between either the full (when testing the importance of an interaction) or reduced model (when testing the importance of a predictor variable in isolation) and a model with the corresponding term removed;  $\chi^2$ - test statistic; df- degrees of freedom. Significant model parameters are marked bold.

1 **Table 1:** Summary of models for the probability of being present at meat eating events. The term  
 2 estimates columns show the estimate (Est), standard error (SE), and Z-value for model  
 3 parameters, where the entries along the rows that do not include interactions (denoted by a colon)  
 4 are based on the fitted reduced model with no interactions and the entries for rows with  
 5 interactions are based on the fitted full model with all interactions and main effects. The term  
 6 significance entries show results of likelihood ratio tests between either the full (when testing the  
 7 importance of an interaction) or reduced model (when testing the importance of a predictor  
 8 variable in isolation) and a model with the corresponding term removed;  $\chi^2$ - test statistic; df-  
 9 degrees of freedom. Significant model parameters are marked bold.
