**Objective:** To analyze the clinical manifestations, diagnosis, and treatment outcomes in a series of patients with epididymal tuberculosis.

**Methods:** This study is a retrospective data analysis of 47 cases of histologically-confirmed epididymal tuberculosis in patients treated at our hospital from November 2014 to December 2018.

**Results:** The average age of the patients was approximately 41.98 years. The epididymal lesion location was left-sided in 15 patients (31.9%), right-sided in 22 patients (46.8%), and bilateral in 10 patients (21.3%). The main symptoms were painless swelling of the scrotum in 21 cases (44.7%) and scrotal drop pain in 21 cases (44.7%). Scrotal physical examination revealed epididymal beaded enlargement in 12 patients (25.5%), testicular mass in 1 patient (2.1%), scrotal tenderness alone in 7 patients (14.9%), ill-defined epididymal-testicular border in 21 patients (44.7%), and sinus formation in 6 patients (12.8%). After 2 to 4 weeks of anti-tuberculosis chemotherapy, the patients underwent a surgical resection procedure. We found that 10 (83.3%) of the 12 patients whose main symptom was epididymal beaded enlargement underwent simple epididymal resection. Of the 21 patients whose main clinical manifestation was ill-defined testis-epididymis demarcation, 16 (72.2%) underwent epididymis-testicular resection. All patients underwent postoperative chemotherapy for 3 to 6 months. Postoperative follow-up showed good response to treatment.

**Conclusion:** It is difficult to diagnose early-stage epididymal tuberculosis. Epididymal tuberculosis is likely to have invaded surrounding tissues when signs such as epididymal beaded changes and ill-defined epididymis-testis border are present. Surgical resection combined with preoperative and postoperative chemotherapy is an effective approach to treating this condition.

9 **Abstract:**

10 **Objective:** To analyze the clinical manifestations, diagnosis, and treatment outcomes in a series of  
11 patients with epididymal tuberculosis.

12 **Methods:** This study is a retrospective data analysis of 47 cases of histologically-confirmed  
13 epididymal tuberculosis in patients treated at our hospital from November 2014 to December 2018.

14 **Results:** The average age of the patients was approximately 41.98 years. The epididymal lesion  
15 location was left-sided in 15 patients (31.9%), right-sided in 22 patients (46.8%), and bilateral in 10  
16 patients (21.3%). The main symptoms were painless swelling of the scrotum in 21 cases (44.7%)  
17 and scrotal drop pain in 21 cases (44.7%). Scrotal physical examination revealed epididymal  
18 beaded enlargement in 12 patients (25.5%), testicular mass in 1 patient (2.1%), scrotal tenderness  
19 alone in 7 patients (14.9%), ill-defined epididymal-testicular border in 21 patients (44.7%), and  
20 sinus formation in 6 patients (12.8%). After 2 to 4 weeks of anti-tuberculosis chemotherapy, the  
21 patients underwent a surgical resection procedure. We found that 10 (83.3%) of the 12 patients  
22 whose main symptom was epididymal beaded enlargement underwent simple epididymal resection  
23 . Of the 21 patients whose main clinical manifestation was ill-defined testis-epididymis  
24 demarcation, 16 (72.2%) underwent epididymis-testicular resection. All patients underwent  
25 postoperative chemotherapy for 3 to 6 months. Postoperative follow-up showed good response to  
26 treatment.

27 **Conclusion:** It is difficult to diagnose early-stage epididymal tuberculosis. Epididymal  
28 tuberculosis is likely to have invaded surrounding tissues when signs such as epididymal beaded  
29 changes and ill-defined epididymis-testis border are present. Surgical resection combined with  
30 preoperative and postoperative chemotherapy is an effective approach to treating this condition.

31 **Keywords:** epididymal tuberculosis, clinical characteristics, chemotherapy

32

33 **Introduction:** Epididymal tuberculosis is a rare extrapulmonary form of tuberculosis that occurs  
34 in young adults(Surati et al. 2012).Patients with this disease may have no obvious clinical  
35 symptoms or only mild symptoms.The disease typically develops slowly and early diagnosis is  
36 difficult;delayed diagnosis and misdiagnosis are common.Recently,due to the emergence of multi-  
37 drug resistant bacteria (MDR), anti-tuberculosis drug resistance, and the widespread use of  
38 glucocorticoids, the incidence of male genitourinary tuberculosis, including epididymal  
39 tuberculosis, has been increasing worldwide. Epididymal tuberculosis remains an important health  
40 problem in many developing countries,including China(Kulchavenya et al. 2012).The pathological  
41 features of epididymal tuberculosis are extensive tissue destruction and fibrosis, eventually leading  
42 to destruction of the epididymis and surrounding genital tissues and organs and complications such  
43 as infertility and other serious effects on male reproductive system function.

44 At present, early diagnosis and regular chemotherapy are the keys to curing male reproductive  
45 system tuberculosis and to avoid surgical treatment.However, due to its late onset and nonspecific  
46 clinical signs and symptoms, and the lack of rapid, sensitive, and specific diagnostic methods,the  
47 disease is often misdiagnosed or the diagnosis is delayed. Therefore, surgical treatment combined  
48 with chemotherapy has been the preferred treatment approach to this disease. This study, a  
49 retrospective analysis of a series of cases of epididymal tuberculosis, is intended to more fully  
50 characterize the clinical features and outcomes of surgical treatment of this disease.

51 **Material and Methods:**We collected the medical records of 47 patients with histologically-  
52 diagnosed epididymal tuberculosis from November 2012 to October 2018 at the Second Hospital  
53 of Lanzhou University. Age, clinical signs and symptoms, diagnostic methods, and treatment  
54 effects were collected from the patients' electronic medical records, and the final results were  
55 compared and analyzed.The following information was supplied relating to ethical approvals (i.e.,  
56 approving body and any reference numbers):Ethics Committee of Lanzhou University Second  
57 Hospital Number:2019A-079.Written consent was obtained from all patients.

58 **Results:**The mean age of the patients was 41.98 years (range, 19-72 years); 15 patients (31.9%)  
59 had tuberculosis in the left epididymis, 22 patients (46.8%) had tuberculosis in the right  
60 epididymis, and 10 patients (21.3%) had bilateral epididymal tuberculosis. Of the 47 patients, 8  
61 (17.0%) had a history of tuberculosis, including 3 cases of pulmonary tuberculosis, 4 cases of renal  
62 tuberculosis, and 1 case of prostate tuberculosis( Table 1).

63 Main symptoms at the time of onset included: painless swelling of the scrotum in 21 patients  
64 (44.7%); scrotal drop pain in 21 patients (44.7%); urinary tract irritation such as urinary frequency,  
65 dysuria, and hematuria in 4 patients (8.5%); and scrotal skin ulceration in 1 patient (2.1%).  
66 Systemic symptoms such as low-grade fever, fatigue, and night sweats occurred in 6 patients  
67 (12.8%). All patients underwent scrotal physical examination, which revealed epididymal beaded

68 enlargement in 12 patients (25.5%), testicular mass in 1 patient (2.1%), scrotal tenderness alone in  
69 7 patients (14.9%), ill-defined epididymal testicular border in 21 patients (44.7%), and sinus  
70 formation in 6 patients (12.8%) (Table 1).

71 Urinalysis and chest imaging were performed in all patients. Twenty patients (42.6%) were  
72 positive for white blood cells in urine and 8 patients (17.0%) were positive for red blood cells in  
73 urine. Chest imaging was positive in 8 patients (17.0%). The preoperative diagnoses were  
74 epididymal tuberculosis in 41 patients (87.2%), epididymal tumor in 3 patients (6.4%), and  
75 epididymal mass in 3 patients (6.4%). All patients had evidence of surgical resection of the lesion.

76 Among the 47 cases, 41 (87.2%) were initially identified as epididymal tuberculosis and treated  
77 pre-operatively with rifampicin, isoniazid, pyrazinamide, and ethambutol for 2 to 4 weeks.  
78 Twenty-six patients (55.3%) had epididymectomy and 21 patients (44.7%) had epididymectomy  
79 combined with orchiectomy, and all recovered well after surgery.

80 We found that 10 (83.3%) of the 12 patients whose main symptom was epididymal beaded  
81 enlargement underwent simple epididymal resection and 2 (16.7%) underwent epididymis-  
82 testicular resection. Of the 21 patients whose main clinical manifestation was ill-defined testis-  
83 epididymis demarcation, 16 (72.2%) underwent epididymis-testicular resection and 5 epididymal  
84 resection (Table 2).

85 Macroscopically, all specimens contained solitary or confluent pale, grayish caseous necrotic  
86 nodules. Some lesions invaded the entire epididymis, some showed involvement of the testis with  
87 adherence to the scrotum to form a cold abscess, and some showed the formation of ulcerated sinus  
88 tracts in the skin. Microscopically, the centers of the specimens were red-stained with amorphous  
89 granular, irregularly sized foci of caseous necrosis surrounded by tuberculous granulation tissue  
90 (epithelioid cells, Langhans giant cells, and lymphocytes) (Figure 1,2).

91 All patients received anti-tuberculosis treatment with rifampicin, isoniazid, pyrazinamide, or  
92 ethambutol after surgery for 3 to 6 months. No recurrence was reported.

### 93 **Discussion:**

94 The number of TB patients in China accounted for 10%-12% of the total number of TB patients  
95 in the world, ranking second in the world (Glaziou et al. 2018; Zhang et al. 2016). People in Gansu  
96 Province of China have a high incidence of tuberculosis and are relatively delayed in seeking  
97 medical care (Zhang et al. 2016). The presentation of tuberculosis is increasingly  
98 atypical. Unfortunately, the prevalence of drug-resistant strains of TB is increasing (Lee et al.  
99 2015). The main treatment of epididymal tuberculosis is early anti-tuberculosis treatment.  
100 However, since most of the patients with epididymal tuberculosis in Gansu are in the terminal  
101 stage, surgical treatment combined with chemotherapy has been the best treatment modality for

102 this type of patients.

103 Reproductive system tuberculosis can occur in any age, mainly in men 30 to 50 years old. Due  
104 to the long incubation period, it is not common in children. The most commonly involved organ is  
105 the epididymis, followed by the seminal vesicle, prostate, testis, and vas deferens (Yadav et al.  
106 2017). Isolated epididymal tuberculosis is very rare (Gueye et al. 1998). One new study indicates  
107 that isolated epididymal tuberculosis may be the first or only manifestation of early genitourinary  
108 tuberculosis (Viswaroop et al. 2005). Similarly, in our patient cohort, there were 39 cases (82.9%)  
109 of isolated epididymal tuberculosis.

110 The pathogenesis of epididymal tuberculosis includes blood-borne transmission and  
111 transurethral reflux of *Mycobacterium tuberculosis* caused by factors such as trauma, alcohol  
112 abuse and excessive sexual activity (Tzvetkov & Tzvetkova 2006). Epididymal tuberculosis lesions  
113 first appear in the tail of the epididymis, owing to its rich blood supply and to retrograde infection  
114 from the vas deferens. The lesions of epididymal tuberculosis gradually invade the body to the  
115 head, finally affecting the entire epididymis. In severe cases, the testis can be involved (Chung et  
116 al. 1997). In this group, 21 patients (44.7%) with epididymal tuberculosis invading the testis  
117 underwent radical resection of the testicle. In our study, the main cause of the patient's visit was  
118 painless mass of the epididymis, which is consistent with previous studies (Kho & Chan 2012).  
119 However, the proportion of patient with scrotal pain is higher, mainly because the patients included  
120 in this study all had advanced epididymal tuberculosis or involvement of the testis or scrotum.

121 The gold standard for diagnosing tuberculosis is the isolation and culture of *Mycobacterium*  
122 *tuberculosis*. In cases of suspected genitourinary tuberculosis, we usually look for *M. tuberculosis*  
123 in the urine or tissue. Traditionally, the appearance of so-called sterile pyuria on microscopic  
124 urinalysis is considered to be a typical manifestation of urogenital involvement. In our patient  
125 cohort, leukocytes in urine were present microscopically (50%) or grossly in a majority of cases  
126 (50% and 10%, respectively). Hematuria and acidic urine have been associated with urinary  
127 tuberculosis, but they are nonspecific findings. Color Doppler ultrasound is the first choice for  
128 imaging analysis of epididymal tuberculosis (Viswaroop et al. 2005). CT and MR have little value  
129 in diagnosing epididymal tuberculosis; they are mainly used to diagnose tuberculosis in lung and  
130 kidney and provide support for the diagnosis of epididymal tuberculosis. Epididymal fine needle  
131 biopsy is a good method for the diagnosis of epididymal tuberculosis.

132 Tuberculous epididymitis can be the only manifestation of genitourinary tuberculosis.  
133 Therefore, even in the absence of clinical and laboratory markers of renal and urologic  
134 tuberculosis, all men with identified epididymal lesions should undergo a fine needle aspiration  
135 biopsy. Kim (Kim et al. 1993) suggests that epididymal tuberculosis can often be diagnosed by B-

136 ultrasound biopsy, which supports the above conclusions. Polymerase chain reaction has been an  
137 important method for diagnosis. Combined with pathological biopsy, it can improve the diagnosis  
138 rating epididymal tuberculosis in recent years (Chawla et al. 2012). It has the characteristics of high  
139 sensitivity, high specificity, and short turnaround time. However, at present, the diagnosis of simple  
140 epididymal tuberculosis is difficult, and there is no preoperative diagnostic method with high  
141 sensitivity and specificity. The clinical diagnosis of scrotal abscess and ulceration is not difficult.  
142 It is often possible to make a clear diagnosis by examining for acid-fast bacilli in samples of the  
143 ruptured tissue through pus or secretion smears.

144 The differential diagnosis of epididymal tuberculosis includes bacterial epididymitis,  
145 epididymal sperm granuloma, epididymal tumor, and other diseases. Patients with bacterial  
146 epididymitis often have testicular-epididymis pain, and scrotal swelling and heat. Features include  
147 a shorter course of illness, and symptoms are generally relieved after antibiotic treatment.  
148 Carl (Carl & Stark 1997) reported that epididymal tuberculosis should be highly suspected when  
149 patients have persistent or repeated epididymitis episodes and symptoms cannot be controlled after  
150 adequate antibiotic treatment.

151 Epididymal sperm granuloma mainly occurs in the head of the epididymis, characterized by a  
152 smooth solid mass, and antibiotics and anti-tuberculosis treatment are ineffective. Epididymal  
153 tumors are rare, accounting for about 0.9% of male reproductive system tumors. Most tumors occur  
154 during periods of sexual activity in men between 20 and 40 years of age. The disease is  
155 characterized by slow growth, large volume, and no tenderness. CT helps to confirm the diagnosis.

156 Epididymal tuberculosis, like other tuberculosis diseases, requires early, regular, full-course,  
157 moderate, combined anti-tuberculosis treatment. The drug treatment method uses 3 to 4 anti-  
158 tuberculosis drugs for 6 to 9 months (Peloquin 2014). Surgical treatment is necessary if there is no  
159 response to drug treatment or in cases of cold abscess formation. Because the early symptoms of  
160 epididymal tuberculosis are not obvious, abscesses or involvement of surrounding tissues such as  
161 the testicles have often developed at the time of treatment, so most patients need surgery. In 28  
162 cases in our patient cohort (59.6%) presenting as a testicular painless mass, the epididymal-testis  
163 border was unclear, or sinus formation was found, suggesting that the surrounding tissues were  
164 invaded. Although surgical resection is effective, patients still need regular anti-tuberculosis  
165 chemotherapy for 3 to 6 months after surgery and close follow-up.

166 **Conclusion:** epididymal tuberculosis is easy to diagnose in patients with a history of tuberculosis.  
167 However, in isolated epididymal tuberculosis, early symptoms are not obvious and cases are  
168 typically advanced at the time of diagnosis. There are obvious symptoms and signs such as  
169 epididymal enlargement, falling pain and bead-like changes. Epididymal tuberculosis has invaded

170 surrounding tissue by the time it is discovered. Surgical resection combined with preoperative and  
171 postoperative chemotherapy is an effective treatment approach. When epididymal tuberculosis  
172 manifests bead-like changes, testicular involvement, or sinus formation, good results can be  
173 achieved with definitive epididymal-testicular resection. This experiment involved a relatively  
174 small number of cases, and the patients did not undergo needle biopsy. Therefore, further research  
175 is needed to further characterize this disease and refine the treatment.
