Hastisetae are a specific group of detachable setae characterizing the larvae of Megatominae (Coleoptera: Dermestidae), commonly known as carpet and khapra beetles. These setae are located on both thoracic and abdominal tergites and they are the primary defense of the larva against invertebrate predators. According to previous studies, the main purpose of hastisetae is to work as a mechanical obstacle, but they are also capable to block and kill a predator. Hastisetae, single or aggregate, function as an extremely efficient mechanical trap, based on an entangling mechanism of cuticular structures (spines and hairs) and body appendages (antennae, legs and mouthparts). It is believed that this defensive system evolved primarily to contrast predation by invertebrates, however it has been observed that hastisetae may affect vertebrates as well. Although information on the impacts of vertebrate predators of the beetles is lacking, hastisetae have been shown to be a possible threat for human health as an important contaminant of stored products (food and fabric), work and living environment. Review of old and recent literature on dermestid larvae has revealed that despite these structures indicated as one of the distinctive characters in species identification, very little is known about their ultrastructure, evolution and mechanism of action. In the present work, we will provide the state of the art knowledge on hastisetae in Dermestidae and we will present and discuss future research perspectives intended to bridge the existing knowledge gaps.

18 Abstract

19 Hastisetæ are a specific group of detachable setæ characterizing the larvae of Megatominae
20 (Coleoptera: Dermestidae), commonly known as carpet and khapra beetles. These setæ are
21 located on both thoracic and abdominal tergites and they are the primary defense of the larva
22 against invertebrate predators. According to previous studies, the main purpose of hastisetæ is to
23 work as a mechanical obstacle, but they are also capable to block and kill a predator. Hastisetæ,
24 single or aggregate, function as an extremely efficient mechanical trap, based on an entangling
25 mechanism of cuticular structures (spines and hairs) and body appendages (antennae, legs and
26 mouthparts). It is believed that this defensive system evolved primarily to contrast predation by
27 invertebrates, however it has been observed that hastisetæ may affect vertebrates as well.
28 Although information on the impacts of vertebrate predators of the beetles is lacking, hastisetæ
29 have been shown to be a possible threat for human health as an important contaminant of stored
30 products (food and fabric), work and living environment. Review of past and recent literature on
31 dermestid larvae has revealed that despite these structures indicated as one of the distinctive
32 characters in species identification, very little is known about their ultrastructure, evolution and
33 mechanism of action. In the present work, we will provide the state of knowledge on hastisetæ
34 in Dermestidae and we will present and discuss future research perspectives intended to bridge
35 the existing knowledge gaps.

40

41 Introduction

42 The cuticle plays a pivotal role in several aspects of arthropod biology, representing the interface
43 between the living tissue and the external environment (Bereiter-Hahn *et al.*, 1984). Thus, the
44 cuticle displays structural specializations such as denticles, setae, setulae and spines, all with
45 specific functions (Winterton, 2003). Correlations between structure and function are well
46 studied especially in insects (Neville, 1975) and crustaceans (Garm, 2004a, b; Garm and
47 Watling, 2013). Setae are multicellular protuberances on the cuticle, used primarily for
48 mechanoreception (Steinbrecht, 1984; Keil and Steinbrecht, 1984; Keil, 1997; Winterton, 2003;
49 Barth, 2004). In all groups of arthropods, the role of setae has evolved from simple
50 mechanoreception to various other functions, including defense (Battisti *et al.*, 2011),
51 locomotion (Lebarque *et al.*, 2017), prey capture (Felgenhauer *et al.*, 1989), pheromone dispersal
52 (Steinbrecht, 1984), sexual display (Perez-Miles *et al.*, 2005), preening (Felgenhauer *et al.*,
53 1989), and camouflage (Zeledon *et al.*, 1973; Hultgren and Stachowicz, 2008; Stevens and
54 Merilaita, 2009). Detachable setae are true setae characterized by the loss of the neural
55 connection and the detachment of the base of the hair from the integument (Battisti *et al.*, 2011).
56 The proximal end of each seta is attached to an integument stalk or inserted into a socket and can
57 be easily removed with any kind of mechanical stimulation. This class of hairs has evolved as a
58 defensive structure against predation at least four times in Arthropoda. The class is subdivided in
59 two main morpho-ecological groups: urticating hairs and anchor-like setae. Urticating hairs are
60 characterized in some Lepidoptera families such as the Nodotontidae (subfamily
61 Thaumetopoeinae), Erebidae, Saturniidae and Zygenidae and the spider family Theraphosidae
62 (sub. fam. Theraphosinae) (Battisti *et al.*, 2011) and are described to protect from vertebrate
63 predators (Battisti *et al.*, 2011; Bertani and Guadanucci, 2013). Anchor-like setae are
64 characterized in some larvae of Dermestidae (Insecta: Coleoptera) and Polyxenidae (Myriapoda:
65 Polyxenida) where they work as entangling mechanism against invertebrates (Nutting and
66 Spangler, 1969; Eisner *et al.*, 1996). Dermestid detachable setae (hastisetae) are used by the
67 larvae as an active trapping system against arthropod predators (Nutting and Spangler, 1969).
68 These specialized setae are almost exclusively prerogative of Megatominae, the most species
69 rich group in the entire family (Hava, 2015). The mechanism of action of hastisetae and their
70 microstructure remains largely obscure and restricted to few case studies (Nutting and Spangler
71 1969; Mills and Partida, 1976); furthermore, how the evolution of hastisetae is related to the

72 biological success of the Megatominæ remains unresolved. Although information on the impacts
73 of hastisetæ on vertebrate predators is lacking, dermestid larvae and Megatominæ in particular
74 have been documented as possible source of allergens in human (Mullen and Durden, 2009).
75 Hastisetæ and integument fragments carrying them can be contaminants of stored commodities
76 and are present in working and living environments (Hinton, 1945). Hastisetæ seem to be
77 involved in allergic reactions through skin contact, ingestion or inhalation; symptoms can vary
78 accordingly to exposition and consist of skin rushes, asthma, conjunctivitis and digestive system
79 inflammation (Gorgojo *et al.*, 2015; MacArthur *et al.* 2016). Correlation between the presence of
80 hastisetæ and the incidence of allergies in humans exists but the scarce and incomplete
81 information available do not allow to consider hastisetæ as a major hazard in living and working
82 places. The aim of this review is to synthesize the knowledge on the hastisetæ of dermestid
83 beetles, to evaluate their occurrence in the group and their ecological importance, and to assess
84 their possible implications in the human health. Finally, future perspectives on the study of the
85 hastisetæ with special emphasis on Megatominæ are envisaged.

86

87 **Survey methodology**

88 In order to compile and then review the most exhaustive literature on hastisetæ we performed a
89 careful and reiterated research in Google Scholar and Scopus through the use of keywords such
90 as “hastisetæ”, “Dermestidae”, “defense”, “larva”, integrated by the usage the Boolean operators
91 AND, OR, NOT and the use of " " for specific word combinations. The literature not available
92 online has been recovered thanks to Network Inter-Library Document Exchange (NILDE), a
93 web-based software for the service of Document Supply and Inter-Library Loan, managed by the
94 Italian National Research Council. Our research has enabled the collection of more than a
95 hundred publications, of which ninety were considered in the realization of this review. The
96 library created was comprehensive of literature in English, German and French.

97

98 **Results**

99 **Hastisetæ, structure and function**

100 Hastisetæ (or hastate setæ) have been cited in several papers dealing with Dermestidae
101 systematics (Rees, 1943; Kiselyova and McHugh, 2006), species identification (Booth *et al.*
102 1990; Peacock, 1993), and product contamination (Bousquet, 1990). However, the amount of

103 information available concerning their microstructure (Elbert, 1976; 1978), function (Nutting and
104 Spangler, 1969; Mills and Partida, 1976) and evolution (Zhantiev, 2000; Kiselyova and McHugh,
105 2006) is quite scarce. These hairs, located on the dorso-lateral surface of the tergites of larvae
106 and pupae (Fig. 1) (Rees, 1943; Beal, 1960; Kiselyova and McHugh, 2006; Kadej, 2012a, Kadej,
107 2012b; Kadej and Jaroszewicz 2013, Kadej, *et al.* 2013; Kadej and Guziak 2017; Kadej 2017;
108 2018a, b), are generally quite small with an estimated length, according to the literature, between
109 150 and 900 μm . Density and distribution of the hastisetae vary substantially not only among
110 genera and species but also among tergites of the same species. The hastisetae of the thoracic
111 segments are generally scattered and in low numbers in respect to the other parts of the body.
112 While the abdominal tergites present a wider distribution pattern, from hastisetae covering the
113 major part the tergal disc up to proper setae fields located at the posterior corners of tergites (i.e.
114 *Reesa*, *Trogoderma*). In some larvae, the hastisetae give origin to real tufts of hairs located on
115 the posterior corners of the terga IV-VII (i.e. *Ctesias*) or V-VII (i.e. *Anthrenus*) (Mroczkowski,
116 1975; Kadej *et al.* 2013; Kadej 2017; 2018a, b). The hastisetae are inserted in setal sockets on the
117 integument and are connected to the tormogen cell through the pedicel (Elbert, 1978). The pedicel
118 is the breaking point of the shaft which allows the detachment of the hastiseta (Elbert, 1978).
119 Hastisetae microstructure consists of two main parts: the shaft and the apical head (Fig. 1). The
120 shaft is long and filiform, subcylindrical in section. It is made by repeated modules, from 5 to 77,
121 each of them constituted by one cylindrical segment provided with one wreath of spines/scales in
122 the distal part (Elbert, 1978). These spines/scales are postero-laterally oriented and can vary in
123 number from five to seven (Elbert, 1978). The last module of the shaft is generally bigger and
124 thicker than the previous and can slightly vary in general shape to the others; this structure,
125 however, has not been characterized yet. The head of the seta is a subconical anchor-like, spear-
126 shaped structure subdivided longitudinally in sections; the apex of the head is blunt (Elbert,
127 1976; 1978) (Fig. 1). The head consists of five to seven longitudinal, circularly arranged,
128 elements separated from each other by one deep groove, connected to the stem in the upper half
129 by cross-bracing and free in the lower part. The “anchor-like head”, set against the thorns of the
130 last shaft module, is involved in entangling invertebrate body parts (Nutting and Spangler, 1969),
131 functioning as trap for antennae, legs, mouthparts, setae and spines (Mills and Partida, 1976).
132 This structure is apparently species specific, varying in shape and length between taxa (Elbert,
133 1976; Kiselyova and McHugh, 2006; Kadej *et al.* 2013; Kadej 2017; 2018a). The shaft allows

134 setae to cluster together amplifying the “trapping” effect and the spines increases friction and
135 entangling among hastisetae and between setae and body parts. The combined action of several
136 hastisetae affects small predators (Nutting and Spangler, 1969) and possibly food competitors
137 (Kokubu and Mills, 1980). These setae are hollow (Elbert, 1976; 1978) and could potentially
138 contain proteins or other chemicals involved in the defense, as it has been shown in Lepidoptera
139 (Battisti *et al.*, 2011). Hastisetae morphology and distribution, combined together with other
140 characters, constitute a useful tool for species identification (Rees, 1943; Beal, 1960; Peacock,
141 1993, Kadej, 2012a, b; Kadej and Jaroszewicz 2013, Kadej, *et al.*, 2013; Kadej and Guziak 2017;
142 Kadej 2017; 2018a, b).

143

144 **Hastisetae in the systematic and ecology of Dermestidae**

145 Dermestidae is a cosmopolitan, comparatively small family of Coleoptera, regarded as ‘a well-
146 defined, monophyletic group’ (Lawrence and Newton, 1982), consisting of six subfamilies:
147 Orphilinae, Thorictinae, Dermestinae, Attageninae, Trinodinae and Megatominae (Hava, 2015)
148 (Fig. 2). Dermestids are homogeneous only in general appearance, hiding a complex and rich
149 diversity in term of morphological, ecological and ethological aspects. Specific traits and
150 evolutionary tendencies could be observed in several lineages, associated to ecological groups
151 and niches (Zhantiev, 2009); these traits can be observed at adult (Zhantiev, 2000) and larval
152 stage (Kiselyova and McHugh, 2006). Orphilinae are mycetophagous, with sclerotized
153 burrowing larvae (Lenoir *et al.*, 2013). Thorictinae are myrmecophilous and larvae protection is
154 provided by the associated ant species (Lenoir *et al.*, 2013). Dermestinae, the basal group of the
155 “necrophagous clade” (*sensu* Zhantiev, 2009), have larvae feeding on fresh or relatively humid
156 animal remains (over 15% in water content) (Zhantiev, 2009). Since Dermestinae food resource
157 is highly perishable, the larvae develop rapidly and persist only for short periods. The oblong,
158 sub-cylindrical and sclerotized larvae of this subfamily can dig through the feeding substrate and
159 live in butyric fermentation condition, under animal remains. It’s is plausible that the absence of
160 hastisetae on larval tergites is directly attributable to their burrowing lifestyle. Anchor-like
161 detachable setae could be disadvantageous to move within the substrate. Hastisetae would in fact
162 create friction and would be systematically lost, requiring an important energy expenditure
163 necessary for their replacement. The defensive strategy in Dermestinae is based on the fast
164 escape behavior and the sclerotized integuments of the body. The larvae specifically require the

165 pupation chamber to molt and they are capable to dig into soil and/or substrate in case of lacking
166 suitable places where to hide. The pupae of this subfamily present gin-traps on the integuments,
167 as a defensive system against predators (Hinton, 1946; Kiselyova and McHugh, 2006) (Fig. 2).
168 Attageninae have burrowing larvae associated to wood dust, fissures of rocks and sandy
169 environments and feed off of insects and other arthropods remains; the larvae are oblong-
170 fusiform with integuments covered of three different kind of hairs (Zhantiev, 2000; Kiselyova
171 and McHugh, 2006). The larvae show a fast escape behavior, similar to Dermestinae.
172 Attageninae prefer to pupate in hidden niches and the pupae bear gin-traps in most of the cases
173 (Zhantiev, 2000). Trinodinae are inquiline of animals' nests: rodent borrows with larvae phoretic
174 on mammal (Zhantiev, 2009) or larvae associated to spider nests (Beal, 1959; Kadej, 2011). The
175 hastisetae, with the single exception of the genus *Trinodes* (Trinodinae), in which modified
176 hastisetae are described (Kiselyova and McHugh, 2006), are prerogative of the Megatomininae
177 larvae and they are strictly associated to larval and pupal morphology and behavior (Kiselyova
178 and McHugh, 2006; Zhantiev, 2009) (Fig. 2). Megatomininae is the richest in species subfamily
179 within Dermestidae and its biological success is most probably attributable to the hastisetae
180 occurrence. Amber fossils indicate that hastisetae morphology is highly conserved and remained
181 virtually unchanged since late Cretaceous (Poinar and Poinar, 2016). This group shows a
182 remarked investment on hastisetae as a defensive tool (Nutting and Spangler 1969; Mills and
183 Partida, 1976), exploiting their resistance and durability over time to protect both larvae and
184 pupae (Kiselyova and McHugh, 2006; Zhantiev, 2009). Megatomininae is the clade within the
185 xerophilous necrophagous dermestids (*sensu* Zhantiev, 2009), which can survive on low-water
186 food resources, especially chitinous and keratinous remains (Armes, 1990; Beal, 1998; Zhantiev,
187 2009). These substrates are capable to stand in the environment for a long time but the poor
188 nutrients prolong the duration of larval development, with major implications on morphology,
189 ethology and defensive behavior. Lengthening of the larval phase and its persistence in the
190 environment for a long time has promoted the evolution of morphological and ethological
191 features in Megatomininae that otherwise would have been disadvantageous in a different lifestyle.
192 The inability of the larvae to delve into the living substrate (Zhantiev, 2009) favored the
193 evolution of defensive structures (hastisetae) with low energy investment for their synthesis and
194 to remain functional even after being dispersed in the environment. Over time, energetic
195 investment in cuticularized integuments in larvae and gin-traps in pupae shifted to the

196 morphology of hastisetae and its defense mechanisms. Hastisetae provide protection in both
197 larvae and pupae, favoring a positive energy trade-off in larval development. All the larvae of
198 this subfamily are stout, feebly sclerotized, slow moving and present an aggressive, non-escaping
199 defensive behavior (Kiselyova and MchHugh, 2006). In a disturbance, the larva stops moving,
200 arches its body and spread the hastisetae, frequently from the posterior part of the body where it
201 is densely packed with hastisetae towards the stimulus (Kiselyova and MchHugh, 2006). In
202 general, Megatominiae do not make pupation chambers or hide, but simply pupate where they
203 have been feeding. Pupae completely lack gin-traps and remain protected inside the last larval
204 exuvia, completely covered in hastisetae (synapomorphy of Trinodinae + Megatominiae)
205 (Kiselyova and McHugh, 2006) (Fig. 2). Megatominiae have been able to adapt against
206 interspecific and intraspecific competition for food resources. A common trait associated with
207 the evolution of the hastisetae in the dermestids is, in the necrophagous clade, the transition from
208 scavenger habits of adults to anthophily or aphagy (Zhantiev, 2009) (Fig. 2).

209

210 **Hastisetae and human health**

211 The capability to feed on a wide range of food resources scarce in water content and to resist to
212 prolonged starvation makes Megatominiae larvae the perfect candidate to inhabit working and
213 living spaces. In addition, due to their slow movements and cryptic behavior these larvae result
214 difficult to detect and remove. For this reason, some species are now synanthropic and
215 cosmopolitan (Bouchet *et al.*, 1996; Gamarra *et al.*, 2009), having been spread all over the world
216 with trade. These species became serious pests, causing considerable loss and damage to stored
217 goods of both animal and plant origin (Hinton, 1945; Burges, 1959; Kantack and Staples, 1969;
218 Mroczkowski, 1975; Beal, 1991; Veer *et al.*, 1991a, b; Veer and Rao, 1995; Veer *et al.*, 1996;
219 Imura, 2003; Rajendran and Hajira Parveen, 2003; Lawrence and Slipinski, 2010) and to objects
220 of organic origin in museums of cultural and natural history (Jurecka, 1987; Zaitseva, 1987;
221 Armes, 1988; Bousquet, 1990; Pinniger and Harmon, 1999; Stengaard Hansen *et al.*, 2012;
222 Quarner, 2015). The hastisetae released by the larva throughout its entire development and
223 abandoned in the environment in association to the exuviae are an important contaminant in
224 dwelling, public spaces as well as food stuff (Gorham, 1979; 1989; Burgess, 1993) and can
225 contribute as allergens in humans (Wiseman *et al.*, 1959; Johansson *et al.*, 1985; Baldo and
226 Panzani, 1988; Burgess, 1993; Gorgojo *et al.*, 2015; McArthur *et al.*, 2016): chitin, likely the

227 main constituent of the hastisetæ, is in fact a powerful and widely recognized allergen, and its
228 interaction with Th2 lymphocytes and human chitinases enhances the inflammation process
229 (Brinchmann *et al.*, 2011; Bucolo *et al.*, 2011; Mack *et al.*, 2015). However, it is still unclear
230 whether the inflammatory effect of the hastisetæ is attributable to the mechanical action of the
231 seta and its penetration through the epithelia or if it is associated to the presence of specific
232 molecules capable to start an immunological reaction. Hastisetæ have been directly linked to
233 occupational diseases in working environments (Loir and Legagneux 1922; Renaudin, 2010),
234 especially when processing organic materials such flour, wool, silk and other commodities (Veer
235 *et al.*, 1996; Brito *et al.*, 2002), or stored objects of organic origin in museums and art galleries
236 (Siegel *et al.* 1991). The exposure to and inhalation of hastisetæ, even in the form of dust, are
237 reported to cause rhinoconjunctivitis (Brito *et al.*, 2002) and asthma (Cuesta-Herranz *et al.*,
238 1997; Brito *et al.*, 2002; Bernstein *et al.*, 2009). Megatominæ are also one of the arthropod
239 groups most commonly recorded inside houses (Gamarra *et al.*, 2009; Bertone *et al.*, 2016;
240 Madden *et al.* 2016); the larvae persist in these environments for months, even for years, feeding
241 on food (Gorham, 1979; 1989; Hirao, 2000), pet food (Rudolph *et al.*, 1981), dust, insect
242 remains and clothes, especially wool fabric (Bouchet *et al.*, 1996). This prolonged presence
243 inside houses together with the persistence of the hastisetæ in the environment greatly increase
244 the possibility for the humans to come into contact and develop a sensitization to these
245 detachable hairs (Wiseman *et al.*, 1959; Kaufman *et al.*, 1986; Burgess, 1993; Jakubas-Zawalska
246 *et al.*, 2016). The direct exposure of hastisetæ to the skin, maybe due to contaminated bed or
247 clothes, causes severe dermatitis (Sheldon and Johnston, 1941; Cormia *et al.*, 1945; Okamura,
248 1967; Ahmed *et al.*, 1981; Alexander, 1984; Johansson *et al.*, 1985; Southcott, 1989; Horster *et*
249 *al.*, 2002; Zanca *et al.*, 2012; Hoverson *et al.*, 2015; McArthur *et al.*, 2016), while the repeated
250 inhalation over a longer period may cause asthma (Cuesta-Herranz *et al.*, 1997; Brito *et al.*,
251 2002; Bernstein *et al.*, 2009). Food contamination and hastisetæ ingestion has been proved to
252 cause the inflammation of the digestive system, manifesting through nausea, fever, diarrhea
253 (Hirao, 2000), proctitis and perianal itching (Krause *et al.*, 1998). Unusual, and apparently
254 asymptomatic findings of hastisetæ have been done on sputum (Johnson and Batchelor, 1989)
255 and cervical specimens (Bechtold *et al.*, 1985; Bryant and Maslan, 1994; Williamson *et al.*,
256 2005). The incidence of pathologies associated with Dermestidae and Megatominæ in particular,
257 seems to be considerably reduced in recent decades probably due to the increased degree of

258 attention regarding the presence of contaminants in food and the marked improvement in the
259 processes of conservation and storage of raw materials; the development of adequate plans for
260 monitoring and management of pests and the general improvement in the quality of life of people
261 associated with greater healthiness of the houses have contributed further to the imitation of the
262 impact (Athanassiou and Arthur, 2018). However, there is also the possibility that many
263 domestic cases of exposure to hastisetæ, especially in the case of skin rushes (erythemabullous
264 reactions) may be under-recognized and underdiagnosed, due to similar effects to attacks by
265 other arthropods (Burgess, 1993; McArthur *et al.*, 2016). Furthermore, almost all the cases
266 reported in the medical literature regard developed countries while the effect of hastisetæ on
267 human health in developing countries remains almost obscure and widely understudied.
268 Undoubtedly, a better knowledge of the inflammation caused by hastisetæ would allow the
269 recommendation of appropriated prevention measures and the formation of medical personnel
270 able to provide early diagnosis and administration of appropriate therapies. Moreover, a close
271 collaboration between occupational physicians, entomologists and immunologists could be of
272 great help for the development of new surveillance programs and new health and safety
273 guidelines for workers and people most at risk.

274

275 **Conclusions**

276 The scant information about the fine morphology and the ecological roles of hastisetæ, and their
277 implications in human health opens a whole horizon of research possibilities. Hastisetæ
278 morphology is undoubtedly the starting point for any future study. The characterization of
279 hastisetæ through electron microscopy and micro-CT is the basic and fundamental step to
280 understand their functional morphology. The identification of specific morphological traits in the
281 hastisetæ will help to solve Megatominæ systematics, highlighting the evolution of these
282 structures in relation to phylogeny and biology. A detailed knowledge of hastisetæ morphology
283 will allow us to understand the defensive mechanism and if it acts similarly in all Megatominæ.
284 Comparing reactions of different predators to hastisetæ will be useful to evaluate the different
285 effects and particularly if this defensive system is primarily directed towards invertebrates and/or
286 to vertebrates. Are humans or other vertebrates possible targets of hastisetæ, and if so what are
287 the causes of the unpleasant side-effects in humans? Is it the penetration of these setæ through
288 epithelia the main cause of inflammation and are there any particular substance inducing the

289 reaction, as it has been showed in Lepidoptera? Chemical analysis of secretions can identify and
290 characterize the compounds responsible of the inflammation in humans and clarify their possible
291 role as adjuvants in defense against the threats. Understanding the causes of allergic responses in
292 humans will allow the development of specific medical therapies. Hastisetae could become an
293 important addition in species identification, with relevant application in forensic entomology and
294 pest management on stored products. Furthermore, the creation of a molecular fingerprint based
295 on hastisetae content can aid in developing tools to detect insect fragments in contaminated
296 stored products, especially food.

Figure 1

Hastisetae structure and distribution on Megatominae larvae (general scheme):

(a). Example of Megatominae larva (Megatoma undata (Linnaeus, 1758)), dorsal view. T1-T3: thoracic segments; A1-A8: abdominal segments. (b). Tuft of hastisetae on abdominal segments. (c). Hastisetae, lateral view. (d). Head of the hastiseta (subconical anchor-like, spear-shaped head). Image credit: Paolo Paolucci, Michał Kukla.

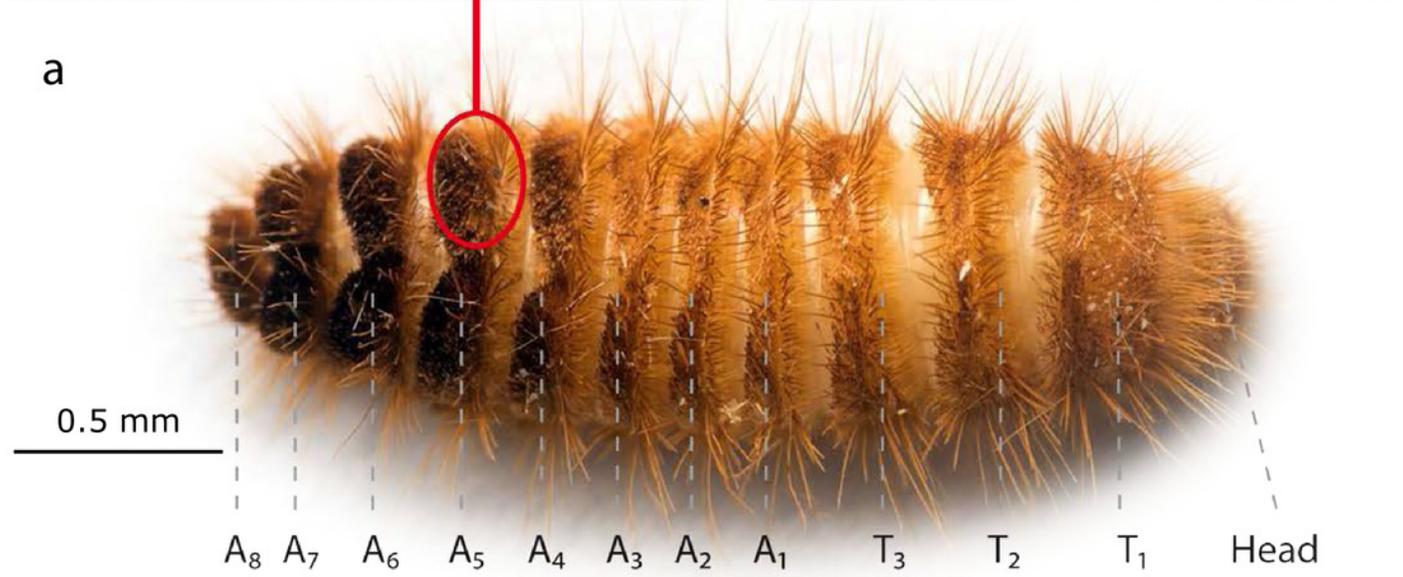

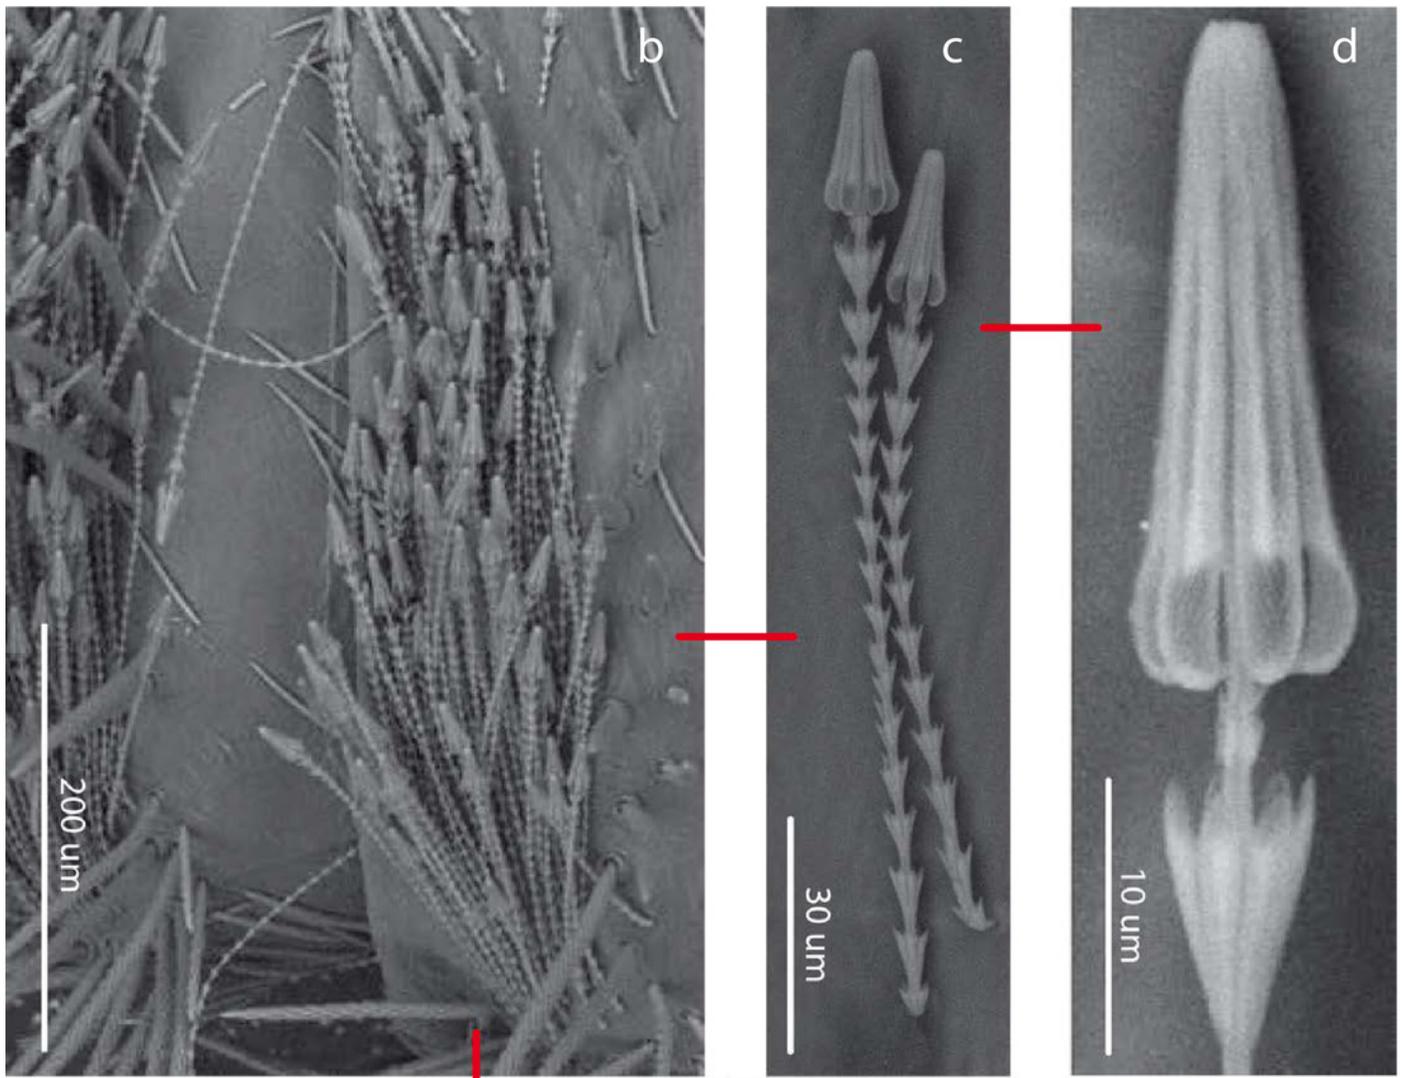

Figure 2

Schematic representation of Dermestidae phylogeny (based on Kiselyova and McHugh, 2006), with an indication of feeding habits of the adult beetles, duration of larval lifespan, and larval-pupal defensive structures.

The size of the colored bands in each subfamily is an approximated representation of the number of species. Image credit: Paolo Paolucci.
