Abstract

The uptake of dissolved organic compounds, i.e. osmotrophy, has been shown to be an efficient nutritional strategy for algae. However, this mode of nutrition may affect the biochemical composition, e.g. the fatty acid contents, of algal cells. This study focused on the osmotrophic assimilation of glucose and leucine by selected seven algal strains belonging to chlorophytes, chrysophytes, cryptophytes, dinoflagellates and euglenoids. Our laboratory experiments with stable isotope labeling showed that osmotrophy occurred in four of the selected seven strains. However, only three of these produced long chain omega-3 fatty acids eicosapentaenoic acid (EPA; 20:5ω3) and docosahexaenoic acid (DHA; 22:6ω3). High glucose content (5 mg L^{-1}) affected negatively on the total fatty acids of *Mallomonas kalinae* and the total omega-3 fatty acids of *Cryptomonas* sp. Further, glucose assimilation explained 35% (negative effect) and leucine assimilation 48% (positive effect) of the variation of EPA, DHA and the fatty acids related to their synthesis in *Cryptomonas* sp. Moderate glucose concentration (2 mg L^{-1}) was found to enhance the growth of *Cryptomonas ozolinii*, whereas low leucine (20 μg L^{-1}) enhanced the growth of *Mallomonas kalinae*. However, no systematic effect of osmotrophy on growth rates was detected. Our study shows that osmotrophic assimilation of algae is species and compound specific, and that the effects of the assimilated compounds on algal metabolism also varies depending on the species.

Introduction

Mixotrophy, i.e. the ability of an organism to combine autotrophy and heterotrophy and thus get sustenance simultaneously from inorganic and organic sources, is gaining increasing attention in studies of aquatic as well as terrestrial ecosystems. In aquatic habitats, mixotrophy is common in unicellular organisms such as algae, cyanobacteria and protists (Flynn et al. 2013; Schmidt et al. 2013). The heterotrophic nutrition in mixotrophy is via phagotrophy (particle or cell uptake) or osmotrophy (uptake of dissolved organic compounds), both of which may occur in tandem with photosynthesis or during dark periods, e.g. nights.

The detection of mixotrophic behavior can be challenging both in laboratory and field conditions, and thus, for example, radioactive isotope labelling has been applied to study the osmotrophic nutrient uptake (Kamjunke & Tittel 2008; Tittel et al. 2009; Beamud et al. 2014). These studies have shown that many algae have the ability to assimilate carbohydrates (e.g. glucose), amino acids (e.g. glutamine, leucine, thymidine, aspartic acid) and other organic compounds (e.g. acetic acid, coumaric acid, glycerol), which they use as carbon and nitrogen sources, and which are commonly released by the algae themselves or by bacteria (Hellebust 1965; Kamjunke& Tittel 2008; Tittel et al. 2009; Beamud et al. 2014; Dąbrowska et al. 2014). Osmotrophy has been shown to be an efficient nutrition strategy for algae in nature: osmotrophic assimilation of amino acids prevent nitrogen limitation, which favors biomass growth in oligotrophic lakes (Kamjunke & Tittel 2008). Similarly, osmotrophic uptake of fulvic acids enhances biomass growth and boost bloom forming in humic lakes (Rengefors et al. 2008).

Osmotrophic nutrition may affect the biochemical composition of algal cells. Biosynthesis of various molecules is determined by phylogeny-based traits and there is a significantly different composition of, for example, fatty acids (FAs) in different algal taxa (Kohli et al. 2016). It is reported that growth conditions account for relatively low variation in algal FAs compared to phylogeny (Galloway & Winder 2015), however, studies with *Ochromonas* sp. (Boechat et al. 2007) showed decreased polyunsaturated fatty acid (PUFA) concentration by feeding mode. Thus, even though the FA profiles and the quality of synthetized FAs may not change, the quantity of different FAs might be affected by the growth mode. For example, nitrogen limitation favors FA synthesis and lipid accumulation in algal cells, and thus if algae can assimilate leucine

68 and use it as their nitrogen source, they should not start to accumulate lipids but carry on cell

69 division as long as the other essential nutrients are available. In turn, osmotrophically assimilated

70 glucose is channeled directly into lipid synthesis, i.e. to palmitic acid (16:0), which results in

71 building up of triacylglycerols and e.g. long chain polyunsaturated fatty acids (LC-PUFAs;

72 Ratledge 2004). Some LC-PUFAs belong to omega-3 FAs (e.g. eicosapentaenoic acid [EPA;

73 20:5ω3] and docosahexaenoic acid [DHA; 22:6ω3]), and for their part are of utmost importance

74 for the growth and reproduction of consumers in aquatic food webs (Peltomaa et al. 2017;

75 Taipale et al. 2018). Since algae are practically the only primary source of EPA and DHA in

76 aquatic food webs (Colombo et al. 2017), osmotrophic nutrient uptake may affect the whole food

77 web by influencing the availability of these nutritionally essential compounds, and thus the

78 growth and reproduction of upper trophic levels (Jonasdottir 1994; Brett et al. 2006; Peltomaa et

79 al. 2017; Taipale et al. 2018).

80

81 In this study we focused on the osmotrophic uptake of glucose and leucine by selected seven

82 algal strains belonging to chlorophytes, chrysophytes, cryptophytes, dinoflagellates and

83 euglenoids. We conducted short-term stabile isotope labelling experiments with these algae to

84 determine if they are able to assimilate glucose and/or leucine. Since we were especially

85 interested in the effects of osmotrophy on EPA and DHA production, we analyzed the fatty acids

86 of these strains. For studying the impact of osmotrophy on fatty acid synthesis, we selected the

87 EPA and DHA synthesizing osmotrophic strains and cultured them with glucose, leucine and

88 mix of these two in a long-term experiment for 14 days, i.e. until the cultures reached the

89 stationary or late exponential phase, during which the LC-PUFAs are mobilized from the

90 membranes into storage lipids (Roessler 1990; Boelen et al. 2017). We hypothesized that (1) all

91 of the strains are osmotrophic, i.e. assimilate glucose and leucine, (2) osmotrophy has positive

92 effect on their growth, and that (3) the osmotrophic uptake of glucose increases the EPA and

93 DHA concentrations in algae capable of synthesizing these fatty acids, whereas (4) the uptake of

94 leucine does not affect specifically their EPA and DHA concentrations, but may actually lower

95 their total FA content.

96

Materials & Methods

98 *The algal strains and growth conditions*

99 The studied algal strains were from freshwater origin, and included chlorophytes

100 *Chlamydomonas reinhardtii* (from the collection of the University of Washington, UWCC) and

101 *Selenastum* sp. (SCCAP K-1877), chrysophyte *Mallomonas kalinae* (SCCAP K-1759),

102 cryptophytes *Cryptomonas* sp. (CPCC 336) and *C. ozolinii* (UTEX LB 2782), dinoflagellate

103 *Peridinium* sp. (author's collection, isolated from Lake Valkea-Kotinen, Finland, 61.14°N,

104 25.04°E in 2015) and euglenoid *Euglena gracilis* (CCAP 1224/5Z). The stock cultures of the

105 strains were grown autotrophically in AF6 medium (*E. gracilis*; Watanabe 2000) or MWC

106 medium (all the other strains; Guillard & Lorenzen 1972) at 20 °C under light:dark cycle of 16:8

107 h with light intensity of 70-100 µmol m^{-2} s^{-1}. The cultures were not axenic, but the initial

108 numbers of bacteria were low due to the growth media consisting of inorganic nutrients. The

109 bacterial numbers were not determined, but bacterial FA biomarkers were included in the FA

110 analysis (see below). The algal cultures were grown to late exponential phase before they were

111 used in the experiments.

112

113 *Short-term stable isotope labelling experiments*

114 For the short-term stable isotope experiment, the autotrophically grown seven algal strains were

115 grown to stationary phase, collected with centrifugation into pellets (200 mL, 5 min, 2000 rpm,

116 which was pre-examined as safe for the fragile flagellates), and further resuspended into 50 mL

117 of fresh AF6 (*E. gracilis*) or MWC media (all the other strains) enriched with glucose 5 mg L^{-1}

118 (containing 4.9 mg L^{-1} non-labeled D-(+)-Glucose [Sigma-Aldrich Co., St Louis, MO, USA] and

119 0.1 mg L^{-1} ^{13}C-labeled D-Glucose [Sigma-Aldrich Co.]) or with leucine 400 µg L^{-1} (containing

120 392 µg non-labeled L-Leucine [Sigma-Aldrich Co.] and 8 µg ^{15}N-labeled L-Leucine [Sigma-

121 Aldrich Co.]) or with both. Three independent replicates were used for each algae and treatment,

122 and non-labeled autotrophic controls were run in parallel. The incubation took place at 20 °C

123 under a constant light intensity of 70-100 µmol m^{-2} s^{-1}, i.e. the possible dark-time heterotrophic

124 assimilation of glucose and leucine was excluded from this short-term experiment. The

125 incubation time was only 30 minutes to preventing respiration loss of the labels, but it was still

126 long enough to acquiring detectable changes in cellular δ^{13}C and δ^{15}N concentrations. After the

127 incubation, the samples were centrifuged (2000 rpm, 5 min), the supernatants were discarded,

128 and the pellets were flushed by diluting them into 30 mL of fresh AF6 (*E. gracilis*) or MWC

129 media (all the other strains) and centrifuging them again. After discarding the supernatants, the

130   pellets were frozen in -80 °C, and freeze-dried within two days. The $\delta^{13}C$ and $\delta^{15}N$ as well as

131   fatty acid profiles were analyzed from these samples.

132

133   *The $\delta^{13}C$ and $\delta^{15}N$ analyses*

134   For the $\delta^{13}C$ and $\delta^{15}N$ analyses, approximately 2 mg of the freeze-dried algal biomass was

135   weighed into tin capsules. The analyses were carried out on a Carlo-Erba Flash 1112 series

136   Element Analyzer connected to a Thermo Finnigan Delta Plus Advantage IRMS (Thermo Fisher

137   Scientific, USA). Four replicates were run from each sample. The samples were compared to the

138   NBS-22 standard using birch leaf powder as a laboratory-working standard. The precision of the

139    $\delta^{13}C$ and the $\delta^{15}N$ analyses were 0.2% and 0.3%, respectively, for all samples.

140

141   *Fatty acid analysis*

142   Two replicates of each freeze-dried sample were weighed (1-2 mg/sample) into tin capsules and

143   the lipids were extracted using chloroform:methanol (2:1) NaCl -method (Parrish 1999). Toluene

144   and sulfuric acid were used for the transesterification of fatty acid methyl esters (FAMEs) at 90

145   °C for 1 h. The FAMEs were analyzed with a gas chromatograph (Shimadzu Ultra, Japan)

146   equipped with a mass detector (GC-MS; Shimadzu Ultra, Kyoto, Japan) and using helium as a

147   carrier gas and an Agilent® (Santa Clara, CA, USA) DB-23 column (30 m × 0.25 mm × 0.15

148   μm). Fatty acid concentrations were calculated using calibration curves based on known standard

149   solutions of a FAME standard mixture (GLC standard mixture 566c, Nu-ChekPrep, Elysian,

150   MN, USA) (see Taipale et al. 2016 for further details). The 16:0, alpha-linolenic acid (ALA;

151   18:3ω3), stearidonic acid (SDA, 18:4ω-3), EPA and DHA concentrations, and the total sum of

152   monounsaturated fatty acids with 16 carbons (16 MUFAs) and 18 carbons (18 MUFAs) were in

153   the focus of this study and thus reported here. The fatty acid biomarkers for bacteria (i-14:0, i-

154   15:0, a-15:0, i-16:0, i-17:0 and a-17:0; Brennan 1989; Taipale et al. 2015) were also detected in

155   order to ensure that the numbers of bacteria were low, i.e. the glucose and leucine were

156   assimilated by the algae, not by bacteria.

157

158   *The long-term osmotrophy experiments*

159   The long-term experiments were done only for those three strains that were detected to be

160   osmotrophic (i.e. assimilated either glucose or leucine or both in the short-term experiment) and,

161   based on the results from the short-term study, were detected to synthetize either EPA or DHA or

162   both. These strains were: *M. kalinae*, *Cryptomonas* sp. and *C. ozolinii*. The long-term

163   experiments were run in independent triplicates, and using three different glucose (0.5, 2 and 5

164   mg L^{-1}) and leucine (20, 100 and 400 µg L^{-1}) concentrations selected based on literature

165   (Kamjunke et al. 2008, Kamjunke & Tittel 2008). There were no mixed treatments of glucose

166   and leucine, but autotrophic controls were run in parallel. The algal cells were collected into

167   pellets from the stock cultures similarly to short-term experiments before transferring them into

168   the experimental flasks of 250 mL. The strains were grown for 15-16 days in similar conditions

169   as the algal stock cultures and the growth was followed through microscopic counts every third

170   day using Sedgewick Rafter –counting cells and preservation with acid Lugol's solution (Willén

171   1962). The specific growth rates (µ; d^{-1}) for all strains were calculated using the equation 1. The

172   cells were grown into the stationary or late exponential phase (Fig. S1), harvested during the

173   light-period of the light:dark-cycle, and pelleted, frozen (-80 °C) and freeze-dried. The fatty acid

174   profiles were analyzed similarly to the short-term samples (see above), but only from two

175   replicates of each treatment and from one control.

176

177                                     $$\mu = \ln(cellsT_x/cellsT_0)/(T_x-T_0) \qquad (1)$$

178

179   where:

180   µ is the specific growth rate

181                             $cellsT_0$ is the cell number at time 0 (T_0)

182                             $cellsT_x$ is the cell number at time x (T_x)

183

184   *Statistical analyses*

185   The results of the short-term isotope labelling experiments were statistically tested with t-test by

186   comparing the non-labeled autotrophic control samples with the labeled samples. The effects of

187   osmotrophy on growth and FA contents were in the long-term experiment tested with the

188   analysis of variance (ANOVA) and Tukey's honestly significant difference (HSD) post hoc test.

189   Levene's test was used for testing the homogeneity of variances. Principal component analysis

190   (PCA), permutational multivariate analysis of variance (PERMANOVA) and similarity

191   percentages (SIMPER) were used for a more detailed study of the similarity of the FA profiles

192   between the treatments in the long-term experiment. In PCA the 16:0, alpha-linolenic acid

193   (ALA; 18:3ω3), stearidonic acid (SDA, 18:4ω-3), EPA and DHA concentrations, and the total

194   sum of monounsaturated fatty acids with 16 carbons (16 MUFAs) were included in the analysis.

195   In PERMANOVA and SIMPER the analysis included the above mentioned FAs and also

196   MUFAs with 18 carbons (18 MUFAs). All glucose treatments and all leucine treatments were

197   pooled for the analysis in PERMANOVA and SIMPER. PERMANOVA was run with

198   unrestricted permutation of raw data and type III sums of squares. Monte Carlo adjustment was

199   used in PERMANOVA due to low numbers of replicates. In the statistical testing, p-values <

200   0.05 were considered as significant. ANOVA and Tukey's and Levene's tests were conducted

201   with IBM SPSS Statistics for Windows, Version 22.0 (IBM Corp., Armonk, NY, USA). PCA,

202   PERMANOVA and SIMPER were done using Primer 7 (version 7.0.13, Quest Research

203   Limited, Auckland, New Zealand).

204

Results

206   *The osmotrophic glucose and leucine uptake*

207   The studied strains showed different responses to glucose and leucine additions in the short-term

208   experiment (Fig. 1, Table S1). The chlorophyte *C. reinhardtii,* the dinoflagellate *Peridinium* sp.

209   and the euglenoid *E. gracilis* did not show glucose or leucine assimilation at all. Whereas, the

210   chlorophyte *Selenastrum* sp. assimilated both compounds (glucose t-test p < 0.001, leucine t-test

211   p = 0.04), as did also the cryptophytes *Cryptomonas* sp. (glucose t-test p < 0.01, leucine t-test p =

212   0.02) and *C. ozolinii* (glucose t-test p < 0.01, leucine t-test p < 0.001). The chrysophyte *M.*

213   *kalinae* did not assimilate glucose, but assimilated leucine (t-test p < 0.01).

214

215   *Fatty acid profiling of the short-term experiment*

216   The fatty acid profiling of the short-term experiments showed that the strains capable of EPA

217   and/or DHA synthesis were *M. kalinae* (average EPA 0.3 % of all FAs, sd 0.0; average DHA 3.2

218   % of all FAs, sd 0.1), *Cryptomonas* sp. (EPA 17.6 %, sd 0.0; DHA 2.3 %, sd 0.0), *C. ozolinii*

219   (EPA 13.9 %, sd 1.3; DHA 2.1 %, sd 0.2), *Peridinium* sp. (EPA 13.4, sd 0.0; DHA 25.1, sd 0.6)

220   and *E. gracilis* (EPA 14.3 %, sd 0.8; DHA 8.4 %, sd 0.2). However, because only *M. kalinae,*

221   *Cryptomonas* sp. and *C. ozolinii* were showing osmotrophic uptake of glucose and/or leucine,

222   these three strains were selected for the long-term experiment. Fatty acid biomarkers for bacteria

223   (i-14:0, i-15:0, a-15:0, i-16:0, i-17:0 and a-17:0) were not found in the analysis.

224

225   *The effect of osmotrophy on growth, total FAs and EPA and DHA production*

226   In general, *C. ozolinii* had higher specific growth rates than the two other studied strains in the

227   long-term experiment. The highest growth rate in *C. ozolinii* ($\mu = 0.88$ d^{-1}; ANOVA p < 0.01)

228   was detected with moderate glucose concentration of 2 mg L^{-1}, and in *M. kalinae* ($\mu = 0.47$ d^{-1},

229   ANOVA p < 0.01) with low leucine concentration of 20 µg L^{-1}, but otherwise there were no

230   signs that the osmotrophic nutrition would have had increased or decreased the growth rates of

231   the studied three strains (Table 1).

232

233   The highest total FA concentration (i.e. 88.8 µg FA in mg DW) was found in the autotrophic *M.*

234   *kalinae*, and the total fatty acids of *M. kalinae* were also detected to vary according to the

235   treatment that was lowest (33.8 µg FA in mg DW) in the 5 mg L^{-1} glucose treatment (Table 2).

236   However, it could not be firmly stated that either glucose or leucine addition would have had

237   certain effects on the total FA content in *M. kalinae*. There were no treatment-based variation in

238   the total FAs of the two cryptophytes either, but there was species specific variation: the total FA

239   concentrations in *Cryptomonas* sp. (52.8-73.6 µg FA in mg DW) were substantially higher in all

240   treatments than in *C. ozolinii* (range 32.9-45.1 µg FA in mg DW; Table 2). Fatty acid biomarkers

241   for bacteria (i-14:0, i-15:0, a-15:0, i-16:0, i-17:0 and a-17:0) were not found in the FA analysis.

242

243   The proportion of omega-3 FAs (i.e. ALA, SDA, EPA and DHA) out of total FAs varied

244   between the strains being lowest in *M. kalinae* (range 21.3-40.3%), and was substantially higher

245   in *Cryptomonas* sp. (range 76.8-89.9%) and in *C. ozolinii* (69.9-94.8%; Fig. 2). The PCA plot of

246   the omega-3 FAs clustered the strains into their own groups in spite of the growth conditions

247   (Fig. 3) indicating strong genetic control of FA profiles and synthesis. When EPA and DHA

248   were studied more in detail, no clear evidence of the effects of osmotrophy on the contents of

249   these FAs were found with ANOVA: in *M. kalinae* EPA and its precursor ALA varied between

250   the treatments, in *Cryptomonas* sp. variations were found in 16:0, ALA and EPA, and in *C.*

251   *ozolinii* in EPA and DHA, but either glucose or leucine could not be stated to have specific effect

252   on these omega-3 FAs (Tables 2, S2). However, when the 16:0, ALA, SDA, EPA, DHA, 16

253 MUFA and 18 MUFA concentrations were studied with PERMANOVA, the glucose

254 assimilation were found to explain 35% (PERMANOVA, $F_{(3,6)} = 2.74$, $p = 0.025$) and the leucine

255 assimilation 48% (PERMANOVA, $F_{(3,6)} = 3.78$, $p = 0.021$) of the variation in these FAs in

256 *Cryptomonas* sp. (Table 3). Statistically significant results were not found with PERMANOVA

257 for *M. kalinae* or *C. ozolinii* (Table 3). These observations are in line with the results of the PCA

258 (Fig. 3), indicating that *Cryptomonas* sp. differ from *M. kalinae*, but also from *C. ozolinii*.

259

260 **Discussion**

261 In this study, we focused on the osmotrophic nutrition and omega-3 FA production of seven algal

262 strains representing chlorophytes, chrysophytes, cryptophytes, dinoflagellates and euglenoids.

263 We expected that all of the studied strains would assimilate glucose and leucine (Hypothesis 1),

264 but this was not the case. The chlorophyte *C. reinhardtii*, the dinoflagellate *Peridinium* sp. and

265 the euglenoid *E. gracilis* did not assimilate either glucose or leucine during the 30 minutes

266 incubation period of our short-time experiment. Furthermore, the chrysophyte *M. kalinae*

267 assimilated only leucine. The uptake velocities of different algae may vary for different

268 compounds (North and Stephens 1972) and depending on the growth mode (Wheeler et al.

269 1974), and thus it is possible that even though our cultures were on stationary phase and

270 assumingly depleted by nutrients, our 30 min incubation time was not sufficient enough for

271 assimilation for some of the algae used in this study. We did the incubations in light, which also

272 could have affected the results, since in some cases algae have shown higher osmotrophic

273 assimilation in dark than in light for glucose (Beamud et al. 2014) and leucine (Ruiz-González et

274 al. 2012). However, many algal species are reported to enhance their osmotrophic uptake in light

275 (Tittel et al. 2009; Beamud et al. 2014). Additionally, our experiments were done in nutrient-rich

276 AF6 or MWC medium, but inorganic nutrient limitation could have triggered rapid osmotrophic

277 uptake (Kamjunke & Tittel 2008). However, it has also been shown by Beamud et al. (2014) that

278 osmotrophic feeding mode is not triggered only by nutrient deficiency: in their study the

279 chlorophytes *Keratococcus rhaphidioides* and *Watanabea* sp. assimilated leucine, thymidine,

280 aspartic acid and acetate also under high levels of inorganic nitrogen and phosphorus, and not

281 only during nutrient limitation. Altogether, our study and the previous observations show that

282 osmotrophic assimilation of algae is both species and compound specific, and that

283 generalizations on the occurrence of osmotrophy within certain taxa cannot be done.

284

285   For studying the effects on osmotrophy on algal fatty acids, especially the LC-PUFAs, the FA

286   profiles of the strains were screened in the short-term study. It is already known that most EPA

287   and DHA producing algae belong to the kingdom Chromista, i.e. to cryptophytes, haptophytes

288   and heterokonts (Cavalier-Smith 2010; Mühlroth et al. 2013). This was the case also with our

289   algae: EPA and DHA was found in all strains excluding the chlorophytes *C. reinhardtii* and

290   *Selenastrum* sp. However, since we specifically focused on the effects of osmotrophic nutrition

291   on EPA and DHA production, only *M. kalinae* and the two cryptophyte strains showing

292   osmotrophic assimilation were studied in our long-term experiment. In this experiment, we

293   expected that (Hypothesis 2) the growth rates would have been enhanced by the osmotrophic

294   growth mode, as has earlier been reported for the raphidophyte *Gonyostomum semen* (Rengefors

295   et al. 2008) and for the chlorophytes *K. rhaphidioides* and *Watanabea* sp. (Beamud et al. 2014).

296   This however was not the case, and excluding some statistically significant differences in the

297   growth rates of *M. kalinae* and *C. ozolinii*, the growth rates could not be directly related to

298   glucose or leucine assimilation. We cannot fully explain the reason behind these two

299   observations on higher growth rates, but are aware that for example mixotrophic phagotrophy on

300   bacteria may increase algal growth (Yoo et al. 2017). We did not observe high amounts of

301   bacteria in the samples during the algal cell counts or detect bacterial FA biomarkers in the FA

302   analysis. However, we did not calculate the bacterial numbers nor study the possible assimilation

303   of bacteria by the algal strains, and thus cannot explicitly state that phagotrophic mixotrophy did

304   not occur during the long-term experiment.

305

306   Because glucose is channeled directly to palmitic acid (16:0) and further into lipid synthesis

307   (Ratledge 2004), and the cellular neutral lipid content should be at highest during the light period

308   of the light:dark cycle (Roessler 1990), and because the LC-PUFA content should be at highest

309   during the stationary growth phase (Roessler 1990; Boelen et al. 2017), we expected (Hypothesis

310   3) that the osmotrophic uptake of glucose increases the FA content in algae. However, we did not

311   find any specific effect of glucose on the amount of total FAs or EPA or DHA. Our

312   PERMANOVA analysis for EPA and DHA, and the FAs related to the synthesis of these LC-

313   PUFAs (16:0, ALA, SDA, 16 MUFA, 18 MUFA), showed that the glucose assimilation

314   explained (35%) the concentrations of these FAs in *Cryptomonas* sp., but the effect was rather

315   negative than positive (Fig. 2). It has been shown earlier that too high glucose concentration may

316   inhibit growth and lipid synthesis and that the optimal glucose content is species specific (Liang

317   et al. 2009; Wan et al. 2011). This effect was seen besides in the omega-3 in *Cryptomonas* sp.

318   also in the total FA content in *M. kalinae*, which had lowest total FAs in the highest glucose

319   treatment (5 mg L^{-1}).

320

321   In contrast to glucose addition, we expected that (Hypothesis 4) the leucine addition would not

322   affect the EPA and DHA content of algae, but could boost their growth and thus simultaneously

323   actually reduce the amount of stored FAs. However, the growth rates were not affected by

324   leucine, and reduction in the total FAs compared to control was found only in *M. kalinae* in

325   leucine 100 μg L^{-1} treatment. For our surprise, in PERMANOVA, leucine assimilation explained

326   48% of the variation in the content of 16:0, ALA, SDA, EPA, DHA 16 MUFA and 18 MUFA of

327   *Cryptomonas* sp., and - unlike expected - the effect of leucine was positive. Again, these results

328   show that biochemical synthesis in algae is species specific, and that generalizations cannot be

329   made.

330

331   We selected the glucose and leucine concentrations based on literature (Kamjunke & Tittel 2008;

332   Kamjunke et al. 2008), and they are in line with the dissolved organic carbon (DOC) contents of

333   natural lakes; the DOC content in the clearwater lakes in Finland vary between 7-9 mg C L^{-1}

334   (Ojala et al. 2011; Brek-Laitinen et al. 2012), whereas in humic lakes the DOC values can be

335   even higher (10 to 45 mg C L^{-1}; Taipale et al. 2008; Ojala et al. 2011). However, in nature the

336   DOC consists of both recalcitrant compounds from mainly terrestrial origin and labile

337   compounds released by algae and bacteria. Further, the labile compounds constitute of different

338   carbohydrates, organic acids, dissolved and free amino acids, ketones and aldehydes with

339   variable concentrations (Hellebust 1965; Norrman et al. 1995; Peltomaa & Ojala 2010;

340   Dąbrowska et al. 2014), which makes the detection of osmotropic assimilation as well as the

341   evaluation of its effects on e.g. FA synthesis challenging. In this study, we found some positive

342   and some negative effects of osmotrophic assimilation on FA synthesis, but the effects were still

343   minor in general, which agrees with the study of Galloway and Winder (2015), who reported that

344   growth conditions account for relatively low variation in algal FAs. However, in extreme

345   conditions, e.g. during enhanced run-off (either due to climate change or seasonality) leading to

346   higher carbon or amino acids in the water, the magnitude of the effects on LC-PUFA availability
347   could be significant at food web level (from algae to fish; Jonasdottir 1994; Brett et al. 2006;
348   Peltomaa et al. 2017; Taipale et al. 2018) assuming that the LC-PUFA producers of the algal
349   community would consist of species capable on osmotrophic uptake of these compounds.
350

Conclusions

352   Our experiments show that osmotrophic nutrition can be found in different types of algae, but the
353   assimilation is species specific and may differ between different organic compounds, as shown
354   here with glucose and leucine. Furthermore, the effects of these two compounds on the algal
355   growth and metabolism was found to be species specific: moderate glucose concentration (2 mg
356   L^{-1}) enhanced the growth of *C. ozolinii*, whereas the growth of *M. kalinae* was enhanced by low
357   leucine (20 µg L^{-1}). Additionally, high glucose content (5 mg L^{-1}) affected negatively on the total
358   fatty acids of *M. kalinae* and the total omega-3 fatty acids of *Cryptomonas* sp. In general,
359   glucose assimilation explained 35% (negative effect) and leucine assimilation 48% (positive
360   effect) of the variation of EPA, DHA and the fatty acids related to their synthesis in
361   *Cryptomonas* sp. but not in the other algae studied. The broad spectrum of compounds and the
362   species-specific responses of algae makes the estimation of the importance of osmotrophy
363   challenging in planktonic food webs and natural waters in general.
364

365

Acknowledgements

367   The authors would like to thank the reviewers for all of their careful, constructive
368   and insightful comments in relation to this work, Miss Paula Ilut for helping with the algal
369   culturing and Mr. Roy Nyberg for editing the English of this manuscript.

3 DHA, 16 MUFA, 18 MUFA) between the treatments in the long-term experiment. For the

4 analysis, all glucose and all leucine treatments were pooled, thus replication n=9. SS sum of

5 squares, MS, mean squares, P(perm) significance, P(MC) significance after Montecarlo

6 correction. Statistically significant results are bolded.

Strain	Treatment	df	SS	MS	Pseudo-F	P(perm)	P(MC)
Mallomonas kalinae	glucose	3	1697.1	565.71	1.4768	0.253	0.271
	leucine	3	1564.9	521.63	1.3617	0.331	0.339
Cryptomonas sp.	glucose	3	375.57	125.19	2.7389	**0.025**	**0.047**
	leucine	3	518.04	172.68	3.7779	**0.021**	**0.03**
Cryptomonas ozolinii	glucose	3	117.55	39.184	0.20727	0.918	0.898
	leucine	3	339.31	113.1	0.59828	0.702	0.654

Figure 1

Osmotrophic glucose and leucine assimilation

Figure 1. The osmotrophic glucose and leucine assimilation in the studied algal strains was detected with stable isotope labelling. The figures show the isotopic difference in ^{13}C (panel A) and ^{15}N (panel B) between the treatments in *Cryptomonas* sp., *Cryptomonas ozolinii*, *Chlamydomonas reinhardtii*, *Euglena gracilis*, *Mallomonas kalinae*, *Peridinium* sp. and *Selenastrum* sp. in the short-term experiment. The cultures were inoculated with ^{13}C-labeled glucose, ^{15}N-labeled leucine and mixture of these two. The total concentration of glucose in the experiment was 5 mg L^{-1} and leucine 400 mg L^{-1}. Replication n=3. The bars show standard errors, statistically significant difference between the non-labeled and labeled treatments are marked with star symbols (ANOVA, * $p < 0.5$, ** $p < 0.1$ and *** $p < 0.01$).

A) ☐ 13C glucose   ☐ 15N leucine   ☐ 13C glucose + 15N leucine

B) ☐ 13C glucose   ☐ 15N leucine   ☐ 13C glucose + 15N leucine
Figure 2

Fatty acid contents

Figure 2. The proportions of omega-3 FAs (alpha-linolenic acid, ALA; 18:3ω3, stearidonic acid, SDA; 18:4ω3, eicosapentaenoic acid, EPA; 20:5ω3, docosahexaenoic acid, DHA; 22:6ω3) on total omega-3 FAs in (A) *M. kalinae,* (B) *Cryptomonas* sp. and (C) *C. ozolinii* in autotrophic controls and when grown osmotrophically with different glucose (i.e. 0.5 mg L^{-1}, 2 mg L^{-1}, 5 mg L^{-1}) and leucine (20 mg L^{-1},100 mg L^{-1},400 mg L^{-1}) concentrations in the long-term experiment. Replication n=3.

PCA plot

Figure 3. Principal component analysis (PCA) plot of the 16:0 fatty acid (FA), alpha-linolenic acid (ALA; 18:3ω3), stearidonic acid (SDA; 18:4ω3), eicosapentaenoic acid (EPA; 20:5ω3) and docosahexaenoic acid (DHA; 22:6ω3) of the long-term experiment showing that the studied three strains (*Mallomonas kalinae*, *Cryptomonas* sp. (CPCC 336) and *C. ozolinii*) differ from each other based on these FAs despite of the growth conditions (autotrophic, or osmotrophic with glucose or leucine; data shown in Table S2).
