Background: Diabetes and dyslipidemia are significantly associated with stroke recurrence, yet the evidence for this relationship is conflicting. Consequently, the parameters in the glucose and lipid profiles may inform us regarding their relationship with stroke recurrence, thus enhancing the physicians' clinical decision-making.

Aim: This study sought to investigate whether glucose and lipid profiles could prognosticate stroke recurrence in Malaysia.

Methods: We conducted a retrospective hospital-based study where we analyzed the first-ever stroke cases regarding about which the Malaysia National Stroke Registry was informed between 2009 and 2017, that fulfilled this study's criteria, and that were followed for stroke recurrence. Using the Cox proportional hazard regression analysis, we estimated the adjusted hazard ratios (HRs), which reflected the prognostic effect of the primary variables (i.e., glucose and lipid profiles on the first-stroke admission) on stroke recurrence.

Results: Among the 8,576 first-ever stroke patients, 394 (4.6%) experienced a subsequent first stroke recurrence event. The prognostic effect measured by univariable Cox regression showed that, when unadjusted, ten variables have prognostic value with regards to stroke recurrence. A multivariable regression analysis revealed that glucose was not a significant prognostic factor (adjusted HR 1.28; 95% CI: 1.00, 1.65), while triglyceride level was the only parameter in the lipid profile found to have an independent prognostication concerning stroke recurrence (adjusted HR: 1.28 to 1.36).

Conclusions: Triglyceride could independently prognosticate stroke recurrence, which suggests the role of physicians in intervening hypertriglyceridemia. In line with previous recommendations, we call for further investigations in first-ever stroke patients with impaired glucose and lipid profiles and suggest a need for interventions in these patients.

Abstract

Background: Diabetes and dyslipidemia are significantly associated with stroke recurrence, yet the evidence for this relationship is conflicting. Consequently, the parameters in the glucose and lipid profiles may inform us regarding their relationship with stroke recurrence, thus enhancing the physicians' clinical decision-making.

Aim: This study sought to investigate whether glucose and lipid profiles could prognosticate stroke recurrence in Malaysia.

Methods: We conducted a retrospective hospital-based study where we analyzed the first-ever stroke cases regarding about which the Malaysia National Stroke Registry was informed between 2009 and 2017, that fulfilled this study's criteria, and that were followed for stroke recurrence. Using the Cox proportional hazard regression analysis, we estimated the adjusted hazard ratios (HRs), which reflected the prognostic effect of the primary variables (i.e., glucose and lipid profiles on the first-stroke admission) on stroke recurrence.

Results: Among the 8,576 first-ever stroke patients, 394 (4.6%) experienced a subsequent first stroke recurrence event. The prognostic effect measured by univariable Cox regression showed that, when unadjusted, ten variables have prognostic value with regards to stroke recurrence. A multivariable regression analysis revealed that glucose was not a significant prognostic factor (adjusted HR 1.28; 95% CI: 1.00, 1.65), while triglyceride level was the only parameter in the lipid profile found to have an independent prognostication concerning stroke recurrence (adjusted HR: 1.28 to 1.36).

Conclusions: Triglyceride could independently prognosticate stroke recurrence, which suggests the role of physicians in intervening hypertriglyceridemia. In line with previous recommendations, we call for further investigations in first-ever stroke patients with impaired glucose and lipid profiles and suggest a need for interventions in these patients.

Keywords: survival analysis, glucose, triglycerides, stroke, recurrence.

Introduction

Stroke recurrence refers to "a new neurologic deficit, including ischemic (or transient ischemic attack) or hemorrhagic stroke [that is] associated with rehospitalization" (Mi et al. 2012). Dyslipidemia and diabetes are widely established risk factors for stroke development and stroke recurrence, but the evidence for this association is inconsistent.

In Malaysia, total cholesterol has shifted its ranking as one of the leading risk factors for the attributable burden of disease from 12th to the 7th position between 1990 and 2015, respectively (GBD 2015 Risk Factors Collaborators 2016). Furthermore, the various metabolic and cardiovascular risks, such as high fasting plasma glucose and high body mass index, have led to increased deaths and reduced disability-adjusted longevity from 2005 to 2015 (GBD 2015 Risk Factors Collaborators 2016; Ministry of Health Malaysia 2017). Hence, the role of impaired glucose and lipid metabolism in prognosticating stroke recurrence is worth exploring to enhance secondary stroke prevention (Awada 2011).

Previous studies have reported a significant relationship of impaired glucose metabolism (Chandratheva et al. 2011; Ghandehari et al. 2013; Jia et al. 2011; Mi et al. 2012) and lipid metabolism (Callaly et al. 2016; Feng et al. 2009; Kumral et al. 2014) with stroke recurrence. However, there have also been studies that found a non-significant relationship between hyperlipidemia (Ghandehari et al. 2013; Li et al. 2017; Liu et al. 2015) and diabetes (Li et al. 2017) in the predictive models. Atherogenic dyslipidemia, which is characterized by reduced high-density lipoprotein cholesterol (HDL), increased low-density lipoprotein cholesterol (LDL) and increased triglyceride level, has been identified as an important independent cardiovascular risk marker (Musunuru 2010; Talayero & Sacks 2011). Interestingly, limited number of available studies confirm the hypotheses derived from an exploratory approach based on the primary variables of local clinicians' interest (Counsell & Dennis 2001; Kutner et al. 2004). This study was the natural extension of the aforementioned published studies, which identified glucose and lipid metabolism as the prognostic factors in an exploratory analysis.

Several randomized clinical trials to date have reported consistent benefits exist with reducing total cholesterol and LDL for vascular risk (Ministry of Health Malaysia 2017). It was also suggested that LDL be the primary serum lipid parameter considered for reducing stroke recurrence risk (Park et al. 2014). Besides that, the strong relationship between plasma triglyceride and cardiovascular risk was well-posed in another study; however, as this investigation recruited mostly white and male subjects (Schwartz et al. 2015), the relevancy of authors' findings to other populations was indeterminate. Collectively, the association of the fasting lipid parameters and stroke recurrence may be attributable to their role in promoting the formation of fatty deposits in the arteries.

This study sought to investigate the outcome as well as the time to stroke recurrence using an event history analysis (i.e., regression of longitudinal event data), which is more informative when compared to a mere quantification of whether an event happened or not (George et al. 2014; Singer & Willett 2003). We aimed to estimate the prognostic effects of glucose and lipid profiles on stroke recurrence among first-ever stroke patients in Malaysia using the nationwide registry.

Material and methods

101   This study was a multicenter, retrospective cohort study that employed the data collected from
102 the Malaysia National Stroke Registry. This registry is a national, prospective ongoing cohort investigation
103 conducted actively to collect non-mandatory notification of stroke admissions in Malaysian public
104 hospitals (Nazifah et al. 2012; NNEUR 2013). The study received approval from both the Human Ethics
105 Committee of the Universiti Sains Malaysia (USM/JEPeM/1711-576) and the Medical Research and Ethics
106 Committee of the Ministry of Health Malaysia (NMRR-17-2500-38534). Permission to access the registry
107 database was obtained from the Registry Steering Committee. Confidentiality of the data was kept
108 throughout the study. Only the researchers had access to the data.

109

Case ascertainment

111 The target population were patients admitted to public hospitals. These patients' data were eligible for
112 analysis if they met the following recruitment criteria: (1) the data came from clinically diagnosed stroke
113 subjects aged 18 and above, (2) the data were notified to the registry between July 2009 and December
114 2017, and (3) patients were documented as having a first episode of stroke when notified to the registry.
115 Patients with a principal hospital discharge diagnosis of ischemic stroke, intracerebral hemorrhage and
116 subarachnoid hemorrhage based on the International Statistical Classification of Diseases and Related
117 Health Problems (10th Revision) (World Health Organization 2015) were included, whereas those with a
118 transient ischemic attack, unknown or unclassified stroke type were excluded from the study.

Variables

120 Each subject was identified using their unique registration number (with the Malaysian National Stroke
121 Registry), as well as their full name and date of birth to determine if they had a subsequent notification.
122 If patients experienced several recurrence events, only data from the first recurrence episode available
123 on the MNSR were taken. In assessing survival, the outcome variable was the time-to-stroke recurrence
124 after the first-ever stroke throughout the study period. The survival time (in years) was measured from
125 the date of the first-stroke diagnosis to the subsequent recurrence, during which both admissions were
126 notified to the registry. The event was defined as a failure (stroke recurrence, coded as 1) or censored
127 (coded as 0). Patients who were lost to follow-up, and who have not developed recurrence during the
128 study period, were considered as censored observations in the time-to-event analysis (Singer & Willett
129 2003). The primary variables referred to the glucose and lipid profiles. Abnormal glucose level was defined
130 with the cut-off values of glucose in the emergency department (ED) > 11.0 mmol/L (198 mg/dL), fasting
131 plasma glucose ≥ 7.0 mmol/L (125 mg/dL) or random plasma glucose >11.0 mmol/L (Ministry of Health
132 Malaysia 2016). A standard lipid profile was the measurement of plasma or serum in the fasting state, and
133 it contained four parameters. Abnormal lipid parameter measurement referred to total cholesterol > 5.2
134 mmol/L (201 mg/dL), HDL < 1.0mmol/L (39 mg/dL) in males or 1.2 mmol/L (46 mg/dL) in females, LDL
135 >1.8mmol/L (70 mg/dL, established cardiovascular risk) or triglyceride > 1.7 mmol/L (151 mg/dL) (Ministry
136 of Health Malaysia 2017).

Statistical analyses

138 Data from the Malaysian National Stroke Registry were downloaded in a comma separated values format
139 and were read and analysed using the RStudio IDE version (RStudio Team 2015) by running the R software
140 version 3.5.1 (survival package) (R Core Team 2018; Therneau & Lumley 2015). A purposeful selection of

141 variables was done based on the crude analysis using the univariable Cox proportional hazard regression
142 and previous literature (which was biologically or clinically important) (Bursac et al. 2008). The covariates
143 with a significance level of less than 0.25 (two-tailed) were included manually in the process of
144 multivariable Cox (proportional hazard) regression modelling (Hosmer et al. 2013). The results of the Wald
145 test were examined to compare a series of the built Multivariable Cox regression models. The statistical
146 significance level was set at 0.05 (two-tailed). The crude and adjusted hazard ratios (HR), 95% confidence
147 intervals (CI) and corresponding p values were all reported.

148

Results

150   We have analyzed the data of 8,576 first-ever stroke patients, all of whom were enrolled in the
151 Malaysian National Stroke Registry. The primary endpoint event in this study was the first-notified
152 recurrent stroke. A total of 394 (4.6%) subjects have had their stroke recurrence registered during the
153 follow-up. Moreover, 95.4% of the subjects were censored at the end of the study. The mean (SD) age at
154 first-stroke diagnosis was 61.9 (12.59). The characteristics of the study subjects are presented in Table 1,
155 in totality and based on the recurrence status (recurred/censored).
156   Through the univariable Cox proportional hazard regression analysis, ten candidate variables were
157 identified as potential prognostic factors, demonstrating both a *p*-value of less than 0.25 and clinical
158 importance. Among these variables, we considered the fasting glucose, glucose in ED, abnormal glucose,
159 triglyceride and total cholesterol levels as the primary variables (i.e., the variables that we hypothesized
160 to be critical prognostic variables), whereas the included confounding variables were age, ethnicity, and
161 the presence of hypertension, DM and dyslipidaemia (Table 2). Other variables (i.e., glycosylated
162 haemoglobin, random glucose level, body mass index, abnormal HDL and LDL levels) demonstrated non-
163 significance at p=0.25.
164   Four models were built using the multivariable Cox (proportional hazard) regression analysis to
165 explain if the glucose profile was an independent prognostic factor for stroke recurrence when other
166 confounders were adjusted. Since the primary variable, glucose profile, is often related to the premorbid
167 diagnosis of DM, the DM diagnosis was the first covariate to be controlled. Table 3 presents a series of
168 multivariable Cox regression models that included the glucose parameters and DM diagnosis. The glucose
169 profile was consistently not associated with an increased risk of stroke recurrence when DM was adjusted.
170   In a series of the multivariable Cox regression models that included the total cholesterol variable
171 and one additional variable (i.e. dyslipidemia, hypertension, DM and ethnic), the total abnormal
172 cholesterol level was not associated with an increased risk of stroke recurrence (Table 4). The triglyceride
173 level, moreover, was found to be a significant prognostic variable based on the crude analysis. Triglyceride
174 level could significantly prognosticate stroke recurrence at crude HR 1.45 (1.22-1.88); adjusted HR 1.36
175 (1.05, 1.77) when dyslipidemia was adjusted in TG model 1; adjusted HR 1.34 (1.03, 1.73) when
176 dyslipidemia and hypertension were adjusted in TG model 2. After adjustment for DM (TG model 3), an
177 abnormal triglyceride level did not longer reach statistical significance in prognosticating stroke
178 recurrence. Table 5 reports that patients with an abnormal triglyceride level had 5 to 77% increase hazard
179 of developing stroke recurrence as compared to those without an abnormal triglyceride level when other
180 variables were adjusted.

181

Discussion

As noted previously, the impact of diabetes mellitus (Chandratheva et al. 2011; Ghandehari et al. 2013; Li et al. 2017; Long et al. 2016) and dyslipidemia (Callaly et al. 2016; Feng et al. 2009; Ghandehari et al. 2013; Kumral et al. 2014) on the prognosis of stroke recurrence has been studied before, but the evidence on this relationship remains inconclusive. To our knowledge, the present research is the first relatively large, multicenter, retrospective cohort study to confirm the prognostication of glucose and lipid profiles on stroke recurrence among first-ever stroke patients in Malaysia. These findings are useful for secondary prevention efforts. The present study demonstrated three key findings: first, the glucose profile or abnormal glucose level could not prognosticate stroke recurrence; second, the total cholesterol level could not prognosticate stroke recurrence; and third, the triglyceride level could independently prognosticate stroke recurrence.

Contrary to previous findings, we found no association between impaired glucose metabolism and stroke recurrence in the time-to-event analysis. When comparing our results to previous studies, it is notable that such paradoxical results might have occurred due to the use of different operational definitions. For example, in the present and previous studies, the timing of the fasting blood samples obtained during/after the acute stroke event was varied, the model specifications were dissimilar, and the conducted statistical analyses diverged (i.e., Cox versus logistic regression) (Ghandehari et al. 2013; Liu et al. 2015; Mi et al. 2012). The present study showed that the comorbidity of diabetes mellitus affected the prognostication of impaired glucose metabolism for stroke recurrence. It is difficult to explain such results if diabetes mellitus is a mediator, and it is challenging to establish whether the disturbances of glucose metabolism constitute a stress response to the acute neurological insult or an indication of underlying diabetes (Matz et al. 2006; Vancheri et al. 2005).

In the present study, comorbid dyslipidemia was a reliable prognosticator of stroke recurrence. A similar conclusion was reached in studies conducted abroad, including the West China Hospital stroke registry-based study (Feng et al. 2009), the Ege stroke registry-based study in Turkey (Kumral et al. 2014), and a population stroke study in North Dublin (Callaly et al. 2016). Hence, this justifies the inclusion of dyslipidemia as a confounding factor in the multivariable analysis. The weak prognostication of HDL and stroke recurrence also confirms the results of a previous study (Liu et al. 2015). The recurrence risk associated with higher plasma total cholesterol levels disappeared after adjusting for comorbid dyslipidemia. At this stage of understanding, we believe that total cholesterol and dyslipidemia confound each other. This is because, from our observations and experience in Malaysia, physicians tend to diagnose dyslipidemia based on the total cholesterol level but not other lipid parameters, and a similar phenomenon has been noted in China (Feng et al. 2009).

Concerning the implicative lipid profile parameters for stroke recurrence, we have demonstrated that the triglyceride level consistently confers an increased risk of stroke recurrence, when adjusting for dyslipidemia and hypertension. Recent randomized, double-blinded clinical trials showed that fasting plasma triglyceride level predicted both short-term and long-term cardiovascular risk, despite the background statin treatment occurring in patients with the acute coronary syndrome. Moreover, this association remained significant after adjusting for conventional risk factors usually associated with the triglyceride level (Schwartz et al. 2015). However, our finding is in contrast with that from a single hospital-based study with a three-month follow-up period (Liu et al. 2015) - a difference which can perhaps be

223 attributed to the cohort duration. On top of that, our data addressed the weak prognostication of
224 triglyceride level to stroke recurrence after adjusting for the comorbidity diabetes mellitus. Under certain
225 assumptions, this can be construed as the unaccountable effect of insulin resistance in the relationship
226 between triglyceride level and cardiovascular risk (Schwartz et al. 2015; Taskinen 2005; van de Woestijne
227 et al. 2013), in which insulin resistance played an important role in the pathogenic basis of atherogenic
228 dyslipidemia (Zhao et al. 2015). In short, we believe that our finding indicates a need to encourage
229 physicians to emphasize triglyceride monitoring, and we recommend marking the triglyceride level as a
230 potential treatment target, particularly in nondiabetic stroke patients.

231   Our results also offer several clinical implications for current stroke management. Impaired
232 glucose metabolism has no prognostic effect on stroke recurrence. However, stroke patients with
233 abnormal glucose level on admission and previously undiagnosed diabetes should be tested with a simple,
234 inexpensive oral glucose tolerance test at discharge (i.e., in the post-acute phase). Furthermore, an oral
235 glucose tolerance test is a better predictor of cardiovascular events than a fasting plasma glucose
236 evaluation, and those with abnormal glucose metabolism without a previous diagnosis of diabetes
237 mellitus are more insulin-resistant than those with a healthy glucose metabolism (Vancheri et al. 2005).
238 This suggestion was made in the past based on the finding that diabetic patients experience a relatively
239 more severe stroke and a poorer prognosis when compared to nondiabetic patients (Matz et al. 2006).

240   One significant repercussion of the present study relates to the emphasis on the prognostication
241 of triglyceride level on stroke recurrence, whereby insufficient attention has been paid in our clinical
242 practices when patients were admitted for their first stroke event. Per previous suggestions (Schwartz et
243 al. 2015; Talayero & Sacks 2011), nonpharmacological management and medication prescriptions should
244 be initiated in Malaysia stroke populations, as per the clinical practice guidelines (Ministry of Health
245 Malaysia 2017). Maybe nutritional counselling could also be offered to stroke patients during
246 hospitalization so they could make alterations in their diet that could influence (i.e., reverse or attenuate)
247 their atherogenic dyslipidemia (Musunuru 2010). It is commonly argued that the cholesterol content of
248 triglyceride-rich remnant lipoproteins confers atherogenicity, thus reflecting the burden of
249 hypertriglyceridemia on the vascular risk, despite the background risk factors being effectively treated
250 and other lipid levels being at an ideal level (Feingold & Grunfeld 2018; International Chair on
251 Cardiometabolic Risk 2019; Schwartz et al. 2015; van de Woestijne et al. 2013). Furthermore, the
252 inflammatory component associated with remnant cholesterol contributed to the atherosclerosis
253 progression (Varbo & Nordestgaard 2016).

Limitations

255   The present study is constrained by the shortcomings of the registry (i.e., the source of secondary
256 data), the quality and accuracy of the data, as well as a possibly occurring information bias (Gliklich et al.
257 2014; Krumholz 2009). An incomplete follow-up after the first-stroke event might have resulted in
258 misclassification and a potentially underestimated recurrence event. Nevertheless, this pitfall is unlikely
259 to cause a significant problem, as survival analysis can account for censoring, wherein other outcomes
260 (e.g. death, loss to follow-up) were treated as censored observations (George et al. 2014). The second
261 limitation relates to the variable of selection in building prognostic models, such as the presence of cardiac
262 disease (including atrial fibrillation and the use of anti-coagulant therapy), quality of life, and the use of

263 complementary and alternative medicines post-stroke that were not recorded in the registry (Kadir et al.
264 2015; Rachpukdee et al. 2013). We also did not model the serial measurement of glucose and lipid profiles
265 from post-discharge to the recurrent stroke event, even though the incorporation of serial covariate
266 measurements was recommended in time-to-event analysis through the analysis of the joint model
267 (Ibrahim et al. 2010). The extent of the degree to which the exclusion of these variables could influence
268 the prognostication is indefinite, and we included the majority of the important covariates that were
269 recognized to our literature search.
270

271 ## Conclusion

272 Out of all parameters in the glucose and lipid profiles, the triglyceride level was revealed as a consistent
273 prognostic factor for stroke recurrence in first-ever stroke patients. This finding supports the hypothesis
274 that having an abnormal triglyceride level at the time of the first stroke event signals a predisposition for
275 stroke recurrence and emphasizes the contribution that triglyceride treatment and monitoring may play
276 in tertiary stroke prevention. Consistent with the recommendations mentioned above, we suggest that
277 further investigations should be conducted in first-ever stroke patients with impaired glucose and lipid
278 profiles, and we call for further discussion on lifestyle changes and the development of therapeutic
279 interventions that will target all lipid markers including hypertriglyceridemia.

The baseline characteristics of study subjects at first-stroke event, in overall and based on the recurrence status (n=8576)

1 Table 1: The baseline characteristics of study subjects at first-stroke event, in overall and based on the
2 recurrence status (n=8576)

Variables	Category	Total	Overall	Recurred n=394	Censored n=8182
		n	Mean (SD), n(%)	Mean (SD), n(%)	Mean (SD), n(%)
Age		8539	61.9 (12.59)	59.9 (11.64)	62.0 (12.62)
Sex	Female	8576	3796 (44.3)	174 (44.1)	3622 (44.3)
	Male		4780 (55.7)	220 (55.8)	4560 (55.7)
Ethnic	Malay	8576	6909 (80.6)	353 (89.6)	6556 (80.1)
	Non-Malay		1667 (19.4)	41 (10.4)	1626 (19.9)
Stroke subtype	Intracerebral hemorrhage	8576	1245 (14.5)	51 (12.9)	1194 (14.6)
	Ischemic		7272 (84.8)	340 (86.3)	6932 (84.7)
	Subarachnoid hemorrhage		59 (0.7)	3 (0.8)	56 (0.7)
Hypertension	No	8576	2658 (31.0)	93 (23.6)	2565 (31.3)
	Yes		5918 (69.0)	301 (76.4)	5617 (68.7)
Diabetes Mellitus	No	8576	5107 (59.5)	199 (50.5)	4908 (60.0)
	Yes		3469 (40.5)	195 (49.5)	3274 (40.0)
Dyslipidemia	No	8576	6583 (76.8)	252 (64.0)	6331 (77.4)
	Yes		1993 (23.2)	142 (36.0)	1851 (22.6)
Body mass index		744	25.5 (6.75)	24.7 (4.53)	25.6 (6.79)
Glasgow coma scale (over 15)	Mild (≥ 13)	8490	6865 (80.9)	330 (84.2)	6535 (80.7)
	Moderate (9-12)		1238 (14.6)	51 (13.0)	1187 (14.7)
	Severe (≤ 8)		387 (4.5)	11 (2.8)	376 (4.6)

3 **Abbreviations**: SD, Standard deviation

Univariable Cox (proportional hazard) regression analysis for the prognostic factors for stroke recurrence among first-ever stroke patients.

1 Table 2: Univariable Cox (proportional hazard) regression analysis for the prognostic factors for stroke

2 recurrence among first-ever stroke patients. Models showing regression coefficients (b), crude hazard

3 ratios (HR) with 95% confidence intervals (CI), Wald test and the corresponding p-values. The outcome

4 variable was a time-to-event variable; where the event was stroke recurrence (present or absent) and the

5 time was the number of years to develop the event (n=8576).

Variables	Category / unit	b	Crude HR (95% CI)	Wald test	p-value
Age	years	-0.013	0.99 (0.98, 0.99)	11.00	<0.001*
HbA1c	%	0.012	1.01 (0.93, 1.10)	0.07	0.790
Glucose in ED	mmol/L	0.023	1.02 (1.00, 1.05)	3.20	0.075*
Random glucose	mmol/L	0.0003	1.00 (0.95, 1.05)	0	0.990
Fasting glucose	mmol/L	0.037	1.04 (1.01, 1.07)	5.80	0.016*
Body mass index	kg/m²	-0.030	0.97 (0.88, 1.08)	0.32	0.570
Sex	Female	0	1	0.10	0.750
	Male	0.032	1.03 (0.85, 1.26)		
Ethnic	Malay	0	1	16.00	<0.001*
	Non-Malay	0.659	1.93 (1.40, 2.67)		
Hypertension	No	0	1	9.80	0.002*
	Yes	0.371	1.45 (1.15, 1.83)		
Diabetes Mellitus	No	0	1	12.00	<0.001*
	Yes	0.350	1.42 (1.17, 1.73)		
Dyslipidemia	No	0	1	24.00	<0.001*
	Yes	0.510	1.66 (1.35, 2.05)		
Abnormal glucose level	No	0	1	11.00	0.001*
	Yes	0.377	1.46 (1.16, 1.83)		
Abnormal triglyceride	No	0	1	8.10	0.004*
	Yes	0.374	1.45 (1.12, 1.88)		
Abnormal TC	No	0	1	2.80	0.096*
	Yes	0.234	1.26 (0.96, 1.67)		
Abnormal HDL	No	0	1	0.10	0.750
	Yes	-0.043	0.96 (0.73, 1.25)		
Abnormal LDL	No	0	1	0.37	0.540
	Yes	0.174	1.19 (0.68, 2.08)		

6 **Notes**: HR, Hazard ratio = exp (β); 95% CI = exp(β-1.965*SE(β)), exp(β+1.965*SE(β));

7 * level of significance, p = 0.25

8 **Abbreviations**: HbA1c, Glycosylated hemoglobin; ED, Emergency department; TC, Total cholesterol;

9 HDL, High-density lipoprotein (cholesterol); LDL, Low-density lipoprotein (cholesterol)

Multivariable Cox (proportional hazard) regression analysis for glucose profile prognosticating stroke recurrence among first-ever stroke patients in Malaysia.

1 Table 3: Multivariable Cox (proportional hazard) regression analysis for glucose profile prognosticating

2 stroke recurrence among first-ever stroke patients in Malaysia. Models show estimated regression

3 coefficient (b), standard error (SE), adjusted hazard ratios (Adj HR) with 95% confidence intervals (CI) and

4 the corresponding p-values (n=8576). The outcome variable was a time-to-event variable; where the

5 event was stroke recurrence (present or absent) and the time was the number of years to develop the

6 event. Model 1 is the crude model with only one primary variable (abnormal glucose level).

Variables	Model 1[a] (n=7123)		Model 2 (n=7123)		Model 3 (n=4729)		Model 4 (n=3355)	
	b (SE)	Crude HR (95% CI)	b (SE)	Adj HR (95% CI)	b (SE)	Adj HR (95% CI)	b (SE)	Adj HR (95% CI)
No. of events	310		310		170		179	
Abnormal glucose level	0.38 (0.12)	1.46* (1.16, 1.83)	0.25 (0.13)	1.28 (1.00, 1.65)				
Fasting glucose							0.02 (0.02)	1.02 (0.99, 1.06)
Glucose in ED					0.01 (0.02)	1.01 (0.98, 1.04)		
Diabetes mellitus			0.28 (0.13)	1.33* (1.04, 1.70)	0.38 (0.17)	1.46* (1.05, 2.04)	0.37 (0.16)	1.44* (1.05, 1.98)

7 **Notes**: HR, Hazard Ratio = exp (β); 95% CI = exp(β-1.965*SE(β)), exp(β+1.965*SE(β));

8 [a] Unadjusted model; * level of significance, p = 0.05

9 **Abbreviations**: ED, Emergency Department

10 Interactions were unlikely for the adjusted models.

11 Scaled and non-scaled Schoenfeld residuals test were applied to check the proportional hazard

12 assumption of the model.

Multivariable Cox (proportional hazard) regression analysis for total cholesterol prognosticating stroke recurrence among first-ever stroke patients in Malaysia.

1 Table 4: Multivariable Cox (proportional hazard) regression analysis for total cholesterol prognosticating

2 stroke recurrence among first-ever stroke patients in Malaysia. Models show estimated regression

3 coefficient (b), standard error (SE), adjusted hazard ratios (Adj HR) with 95% confidence intervals (CI) and

4 the corresponding p-values (n=8576). The outcome variable was a time-to-event variable; where the

5 event was stroke recurrence (present or absent) and the time was the number of years to develop the

6 event.

Variables	TC Model 1 (n=5062)		TC Model 2 (n=5062)		TC Model 3 (n=5062)		TC Model 4 (n=5043)	
	b (SE)	Adj HR (95% CI)	b (SE)	Adj HR (95% CI)	b (SE)	Adj HR (95% CI)	b (SE)	Adj HR (95% CI)
Events	241		241		241		240	
Abnormal TC	0.04 (0.15)	1.04 (0.77, 1.38)	0.23 (0.14)	1.25 (0.95, 1.65)	0.23 (0.14)	1.26 (0.96, 1.66)	0.19 (0.14)	1.19 (0.90, 1.57)
Dyslipidemia	0.65 (0.14)	1.92* (1.47, 2.50)						
Hypertension			0.44 (0.15)	1.55* (1.15, 2.09)				
Diabetes Mellitus					0.37 (0.13)	1.45* (1.13, 1.87)		
Ethnic							0.60 (0.22)	1.81* (1.18, 2.80)

7 **Notes:** HR, Hazard Ratio = exp (β); 95% CI = exp(β-1.965*SE(β)), exp(β+1.965*SE(β));

8 * level of significance, p = 0.05

9 **Abbreviations:** TC, Total cholesterol

10 Interactions were unlikely.

11 Scaled and non-scaled Schoenfeld residuals test were applied to check the proportional hazard

12 assumption of the model.

Multivariable Cox (proportional hazard) regression analysis for triglyceride prognosticating stroke recurrence among first-ever stroke patients in Malaysia.

1 Table 5: Multivariable Cox (proportional hazard) regression analysis for triglyceride prognosticating stroke

2 recurrence among first-ever stroke patients in Malaysia. Models show estimated regression coefficient

3 (b), standard error (SE), adjusted hazard ratios (Adj HR) with 95% confidence intervals (CI) and the

4 corresponding p-values (n=8576). The outcome variable was a time-to-event variable; where the event

5 was stroke recurrence (present or absent) and the time was the number of years to develop the event.

Variables	TG Model 1 (n=5074)		TG Model 2 (n=5074)		TG Model 3 (n=5074)	
	b (SE)	Adj HR (95% CI)	b (SE)	Adj HR (95% CI)	b (SE)	Adj HR (95% CI)
Events	246		246		246	
Abnormal triglyceride	0.31 (0.13)	1.36* (1.05, 1.77)	0.29 (0.13)	1.34* (1.03, 1.73)	0.25 (0.14)	1.28 (0.98, 1.66)
Dyslipidemia	0.61 (0.13)	1.84* (1.43, 2.37)	0.58 (0.13)	1.78* (1.39, 2.30)	0.58 (0.13)	1.78* (1.38, 2.30)
Hypertension			0.36 (0.15)	1.43* (1.06, 1.92)		
Diabetes Mellitus					0.31 (0.13)	1.36* (1.05, 1.76)

6 **Notes:** HR, Hazard Ratio = exp (β); 95% CI = exp(β-1.965*SE(β)), exp(β+1.965*SE(β));

7 * level of significance, p = 0.05

8 Interactions were unlikely.

9 Scaled and non-scaled Schoenfeld residuals test were applied to check the proportional hazard

10 assumption of the model.
