

## Honey bee success predicted by landscape composition in Ohio, USA

Douglas B Sponsler, Reed M Johnson

Foraging honey bees (*Apis mellifera* L.) routinely travel as far as several kilometers from their hive in the process of collecting nectar and pollen from floral patches within the surrounding landscape. Since the availability of floral resources at the landscape scale is a function of landscape composition, apiculturists have long recognized that landscape composition is a critical determinant of honey bee colony success. Nevertheless, we are aware of no published studies that present quantitative data relating colony success metrics to local landscape composition. We employed a beekeeper survey in conjunction with GIS-based landscape analysis to model colony success as a function of landscape composition in the State of Ohio, USA, a region characterized by intensive cropland, urban development, deciduous forest, and grassland. We found that colony food accumulation and wax production were positively related to cropland and negatively related to forest and grassland, a pattern that may be driven by the abundance of dandelion and clovers in agricultural areas compared to forest or mature grassland. Colony food accumulation was also negatively correlated with the ratio of urban:crop area in sites dominated by urban and agricultural land cover, which does not support the popular opinion that the urban environment is more favorable to honey bees than cropland.

15 Honey bees (*Apis mellifera*, L.) exist in large, eusocial colonies that require massive and  
16 sustained inputs of floral nectar and pollen. They meet this demand by foraging at an extremely  
17 large spatial scale and with rapid responsiveness to changes in the surrounding floral community  
18 (Visscher & Seeley, 1982; Seeley, 1995). Depending on local floral availability, colonies may  
19 routinely forage over an area of more than 100 km<sup>2</sup> (Seeley, 1995), and much larger ranges have  
20 been reported under extreme conditions (Eckert, 1931; Beekman & Ratnieks, 2001).

21 Because honey bee foraging is a decidedly landscape-scale process, one should expect  
22 landscape composition to interact meaningfully with colony nutrition and overall colony success.  
23 While the plausibility of such a relationship is widely acknowledged (Steffan-Dewenter & Kuhn,  
24 2003; Naug, 2009; vanEngelsdorp & Meixner, 2010; Härtel & Steffan-Dewenter, 2014), and the  
25 importance of apiary location is axiomatic among practicing beekeepers, we are aware of no  
26 published studies that quantitatively measure colony success in response to local landscape  
27 variables. As rapid landscape conversion continues as a global phenomenon, and beekeepers in  
28 many regions continue to suffer unsustainable losses, the task of refining and expanding our  
29 knowledge of honey bee landscape ecology takes on obvious urgency.

30 Several studies have indirectly explored the relationship between landscape and colony  
31 success by analyzing the spatial information encoded in the honey bee dance language (von  
32 Frisch, 1967). Waddington et al. (1994) found that colonies located in two suburban landscapes  
33 tended to forage over a smaller area and with a less clumped distribution than a previously  
34 studied colony located in a temperate deciduous forest (Visscher and Seeley, 1982), suggesting  
35 that suburban landscapes provide richer and more evenly distributed resource patches.  
36 Conversely, Beekman and Ratnieks (2001) observed remarkably long-distance foraging under  
37 conditions of apparently scarce local resources in a suburban landscape and highly rewarding  
38 resources in outlying seminatural heather moors. In agricultural landscapes, honey bee foraging  
39 patterns suggest that pollen sources can be scarcer and floral patches less spatially and temporally

63 IRB review by the Ohio State University Office of Responsible Research Practices (Protocol #  
64 2012E0136 and # 2013E0012).

65 In order to standardize the initial strength of the colonies in our study (hereafter “study  
66 colonies”) and minimize the influence of parasites and pathogens, we restricted our study to  
67 colonies that had been started from artificial swarms, known as “package bees”, in the spring of  
68 each study year. Honey bee packages are created by combining a standard quantity of worker  
69 bees (usually 1.36 kg) with a newly mated queen. The initial strength of colonies started from  
70 package bees is, therefore, less variable than that of over-wintered colonies. Moreover, because  
71 they are sold without comb or brood, they tend to have reduced parasite and pathogen loads.

72 Data for each study colony were gathered using a two-part survey consisting of spring and  
73 fall components (hereafter “spring survey” and “fall survey”). The spring survey was made  
74 available beginning in early March, and participants were instructed to complete the survey  
75 immediately after installing their honey bee packages. In the spring survey, we gathered the  
76 geographic location of each study colony and the years of experience of each participating  
77 beekeeper (see S1 for full spring survey questionnaire). The fall survey was made available in  
78 mid-September and completed by mid-October. To complete the fall survey, each participant  
79 performed a frame-by-frame hive inspection and reported the number of frames in the study hive  
80 belonging to the following categories: (1) more than half honey/nectar, (2) more than half pollen,  
81 (3) more than half brood, (4) more than half empty wax comb, (5) more than half bare foundation  
82 (no wax comb). Participants also reported the quantity of sugar syrup that had been given to their  
83 hives as supplemental feeding, a common beekeeping practice that could be affect colony  
84 success. See S2 for full fall survey questionnaire.

85 **Survey Processing.** Each beekeeper was instructed to submit data for only one study hive  
86 at one apiary site. The data quality of all surveys was carefully vetted prior to analysis, and  
87 surveys missing critical data or having irreconcilable inconsistencies were discarded. Fall surveys

88 reporting hives that had died since spring installation were also discarded. The final numbers of  
 89 surveys included in analyses for 2012 and 2013 were 32 and 18, respectively; these were selected  
 90 from a pre-processing total of 55 surveys in 2012 and 33 in 2013.

91 From our survey data, we derived four metrics to represent colony success: *net food*  
 92 *accumulation*, *net wax production*, *adult population*, and *brood population*. For consistency, all  
 93 metrics were recorded in units of standard deep frames.

94 *Net food accumulation:*

$$95 \quad Food = H + H_{harv} - H_{add} + P$$

96 where  $H$  = honey/nectar frames in hive at time of inspection,  $H_{harv}$  = honey frames  
 97 harvested prior to inspection,  $H_{add}$  = honey frames added to the hive prior to inspection, and  $P$  =  
 98 frames of pollen in hive at time of inspection. This variable will hereafter be abbreviated *Food*.

99 *Net wax production:*

$$100 \quad Wax = H + H_{harv} + P + B + B_{rm} + D - H_{add} + B_{add} + D_{add}$$

101 where  $B$  = brood frames in hive at time of inspection,  $B_{rm}$  = brood frames removed prior  
 102 to inspection,  $D$  = drawn but mostly empty frames in hive at time of inspection,  $B_{add}$  = brood  
 103 frames added to the hive prior to inspection, and  $D_{add}$  = drawn but mostly empty frames added to  
 104 hive prior to inspection. This variable will hereafter be abbreviated *Wax*.

105 *Adult population* (hereafter, *AdultPop*) was measured as the number of frames “more than  
 106 half covered” with adult bees at time of inspection. *Brood population* (hereafter, *BroodPop*) was  
 107 simply the number of “mostly brood” frames reported by the inspecting beekeeper.

108 We also measured two hive management variables: years of beekeeping experience of the  
 109 participating beekeeper (*years*) and quantity of sugar syrup fed to the study hive since its  
 110 installation (*syrup*).

111           **Landscape Analysis.** Geographic coordinates for each study hive were determined and  
112 mapped using QGIS v. 2.1 (QGIS Development Team, 2014). To encompass a range of spatial  
113 scales at which landscape effects on colony success might be seen, we defined the landscape of  
114 each hive using six nested buffers having radii of 0.5, 1, 2, 3, 4, and 5 km, respectively. Land  
115 cover data for the State of Ohio were obtained from the 2006 dataset provided by the National  
116 Land Cover Database (NLCD 2006) (Fry et al., 2011). The NLCD 2006 land cover layer for Ohio  
117 is comprised primarily of seven land cover classes: *cultivated crops*, *pasture/hay*, *deciduous*  
118 *forest*, and four levels of urban development (*open space*, *low intensity*, *medium intensity*, *high*  
119 *intensity*). Minor classes, present only at very low abundance, include *evergreen forest*, *mixed*  
120 *forest*, *woody wetland*, *herbaceous wetland*, *grassland/herbaceous*, *shrub/scrub*, *barren land*, and  
121 *open water*. To simplify our analysis of landscape composition, we condensed the non-crop land  
122 cover classes (ignoring *barren land* and *open water*) into three aggregate classes: Forest  
123 (*deciduous* + *evergreen* + *mixed* + *woody wetland* + *shrub/scrub*), Grassland (*pasture/hay* +  
124 *grassland/herbaceous* + *herbaceous wetland*), and Urban (*open space* + *low intensity* + *medium*  
125 *intensity* + *high intensity*). The landscape composition of each study site, measured in terms of  
126 the total land cover of Crop (*cultivated crop*) and each aggregate class, was determined at each  
127 spatial scale using LECOS (Jung, 2013), a QGIS plugin for calculating patch-based landscape  
128 metrics. As a measure of overall landscape heterogeneity, we also calculated Simpson's Diversity  
129 Index (*D*) based on the original, non-aggregated land cover classes.

130           **Data Analysis.** We first reduced the dimensionality of our landscape data using principal  
131 components analysis (PCA) based on the covariance between the variables *Crop*, *Forest*,  
132 *Grassland*, and *Urban*. This step was repeated for each spatial scale. For all scales, the first two  
133 principal components (*PC 1* and *PC 2*) explained > 96% of total variance.

134 To model the relationship between landscape composition and colony success, accounting  
135 also for the management variables *years* and *syrup*, we conducted model selection using Akaike's  
136 Information Criterion corrected for small sample size (AIC<sub>c</sub>) (Burnham & Anderson, 2002). Each  
137 success metric--*Food*, *Wax*, *AdultPop*, and *BroodPop*--was modeled separately. Fourteen  
138 candidate linear models were constructed for each success metric at each spatial scale; these  
139 included all combinations of the landscape variables (*PC 1*, *PC 2*, *D*) and the coupled  
140 management variables *years* and *syrup*, a year-only model, and an intercept-only model. For each  
141 success metric, we present the candidate model having the lowest AIC<sub>c</sub> score at each scale along  
142 with any competing models having an AIC<sub>c</sub> difference of < 2 (Table 1) (Burnham & Anderson,  
143 2002). We then selected a single best model for each success metric by choosing the model with  
144 the lowest AIC<sub>c</sub> score across all spatial scales.

145 To evaluate the prediction that urban land cover favors honey bee success relative to  
146 agricultural land cover, we first extracted the subset of our sites for which *Urban* + *Crop* was  
147 greater than 50% of total landcover; then, we calculated the ratio of *Urban* : *Crop* for each of  
148 these sites, thus representing the relative dominance of *Urban* vs. *Crop* in sites dominated by  
149 some combination of the two. To avoid infinite or undefined results for sites having a value of  
150 zero for either *Urban* or *Crop*, a constant of 0.001 (i.e. 0.1% land cover) was added to each value.  
151 We then set up separate linear regression models for *Food* and *Wax* with the log-transformed ratio  
152 of *Urban* : *Crop* as the explanatory variable Only *Food* and *Wax* were analyzed because the  
153 results of the PCA described above indicated that only these two success metrics should be  
154 expected to respond to landscape variables. We did not use *years* and *syrup* as covariates because  
155 previous analysis showed they were not predictive of *Food* or *Wax*. Regression analysis was  
156 repeated for each spatial scale.

157 All analysis was performed in R statistical software (R Core Team, 2014). AIC<sub>c</sub> model  
158 selection used the package AICcmodavg (Mazerolle, 2014).

## 159 **Results**

160 **Landscape analysis.** The landscapes surrounding the colonies in our survey represented a  
161 broad range of landscape composition in terms of the major land cover classes *Crop*, *Forest*,  
162 *Grassland*, and *Urban* (Fig. 1). Principal components analysis of these four variables yielded  
163 two readily interpretable axes that explained greater than 96% of total variance (Fig. 2). *PC 1* was  
164 essentially an urban-rural axis, with sites dominated by *Urban* scoring low and sites dominated  
165 by combinations of *Crop*, *Forest*, and/or *Grassland* scoring high. *PC 2* partitioned non-urban  
166 landscapes into those characterized by *Crop* and those characterized by *Forest* and, to a lesser  
167 extent, *Grassland*.

168 **Modeling colony success metrics by landscape principal components.** *Food* and *Wax*  
169 were best modeled with *PC 2* as the only explanatory variable. Almost all competing models  
170 ( $\Delta AIC_c < 2$ ) included *PC 2* alongside other explanatory variables, further supporting the  
171 conclusion that *PC 2* was the single most important predictor (Table 1). For *Food*, the optimal  
172 spatial scale was a 1 km radius, while *Wax* was best predicted at a 2 km radius. In both cases, the  
173 relationship was negative and the linear regression models were statistically significant (*Food*:  $p$   
174 = 0.033, *Wax*:  $p$  = 0.016) (Fig. 3). *AdultPop* was best modeled with the coupled management  
175 variables *years* and *syrup* as the only explanatory variables. The relationship was positive and the  
176 linear regression model was significant ( $p$  = 0.004), with significant contributions from both  
177 *years* ( $p$  = 0.005) and *syrup* ( $p$  = 0.017) (Fig. 4). *BroodPop* was best predicted by the intercept-  
178 only model, indicating that none of our measured explanatory variables were good predictors of  
179 this success metric.

204 Interestingly, our finding that colony productivity is favored by cropland relative to  
205 forest/grassland is strikingly consistent with an anecdotal description of regional honey  
206 production in Ohio published nearly forty years ago (Goltz, 1975). In Goltz' account, the areas of  
207 "primary" and "secondary" importance for honey production are in the heavily cultivated glacial  
208 plains that comprise most of the state, while the forest-dominated Appalachian Plateaus in the  
209 southeast are described as only "marginally" productive.

210 The positive response of *AdultPop* to the management variables *years* and *syrup* is  
211 difficult to interpret. In early spring, when new colonies are very small and limited in their  
212 foraging ability, it is standard practice to supplement colony nutrition with sugar syrup. All  
213 workers produced during the period of spring build-up, though, died long before colonies were  
214 inspected in the fall, so any positive effect of the springtime management on *AdultPop* at time of  
215 inspection would have to be mediated by factors that allow colonies to increase reproduction later  
216 in the year. An alternative interpretation is plausible if we allow that significant feeding may have  
217 occurred later in the year. While supplemental feeding is normally concentrated in early spring,  
218 some Ohio beekeepers also feed their colonies in mid-late summer, a period of perceived dearth  
219 in natural forage. Feeding during the summer dearth period might trigger a population increase  
220 that would persist until fall inspection. Our survey did not distinguish between feeding at  
221 different times during the season.

222 By late September and early October, when beekeepers were inspecting their colonies for  
223 the fall survey, the bees had likely already begun to reduce brood rearing in preparation for winter  
224 (Graham, 1992). This would explain the failure of both landscape and management variables in  
225 predicting *BroodPop*.

226 The negative relationship observed between *Food* and the ratio of *Urban* : *Crop* does not  
227 support the popular opinion that urban landscapes favor honey bee success relative to agricultural  
228 landscapes. At least in Ohio, the relationship appears to be the opposite, and the fact that *Food*

\*p < 0.05, \*\*p < 0.01; **bold** = best model for given success metric

**Figure 1** (on next page)

Landscape composition of study sites at 2 km radius

**Figure 1: Landscape composition of study sites at 2 km radius.** Sites are depicted in order of increasing urban (red) land cover. Other major land cover classes include crop (gold), forest (dark green), and grassland (light green). Remaining land cover (grey) consisted of barren land and open water.

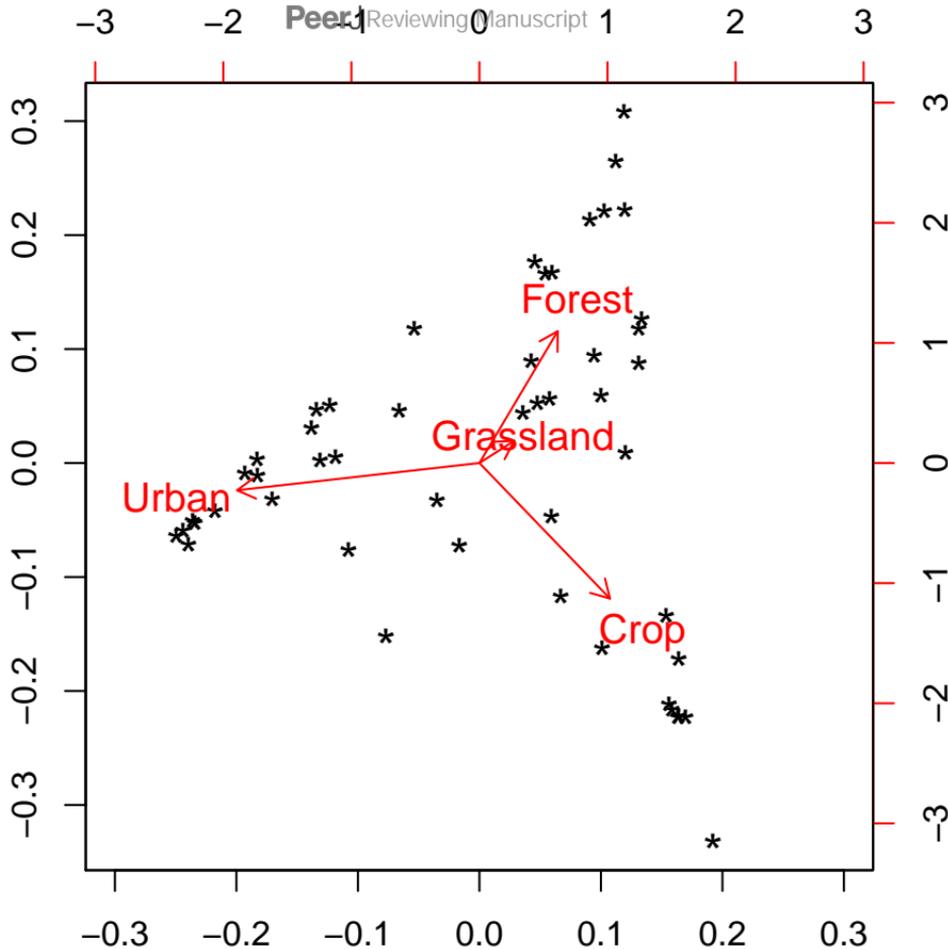

**Figure 2** (on next page)

Principal components biplot of major land cover classes at a radius of 2 km

**Figure 2: Principal components biplot of major land cover classes at a radius of 2 km.** Principal component 1 (PC 1) comprises an urban-rural axis, with lower scores corresponding to higher urbanness. Principal component 2 (PC 2) forms an axis that separates sites characterized by forest/grassland from those characterized by cropland. This pattern was consistent at all spatial scales with only minor variation.

Principal component 2

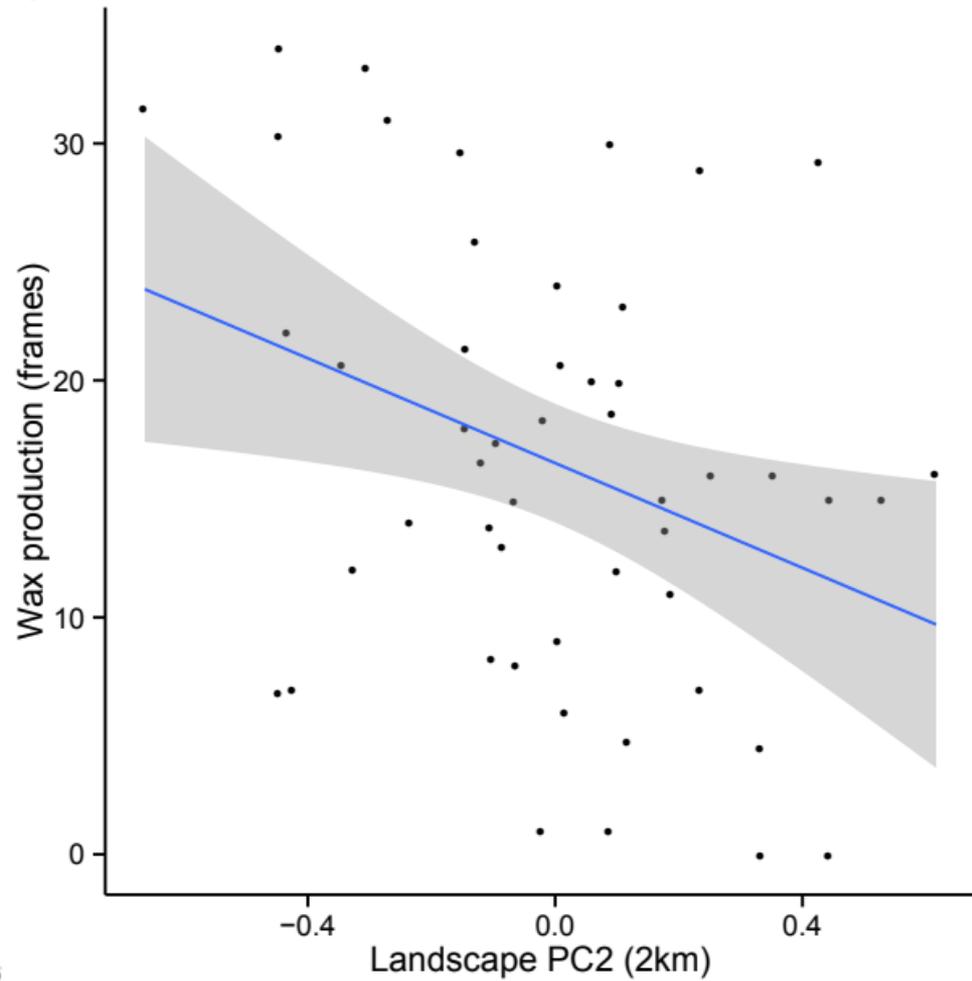

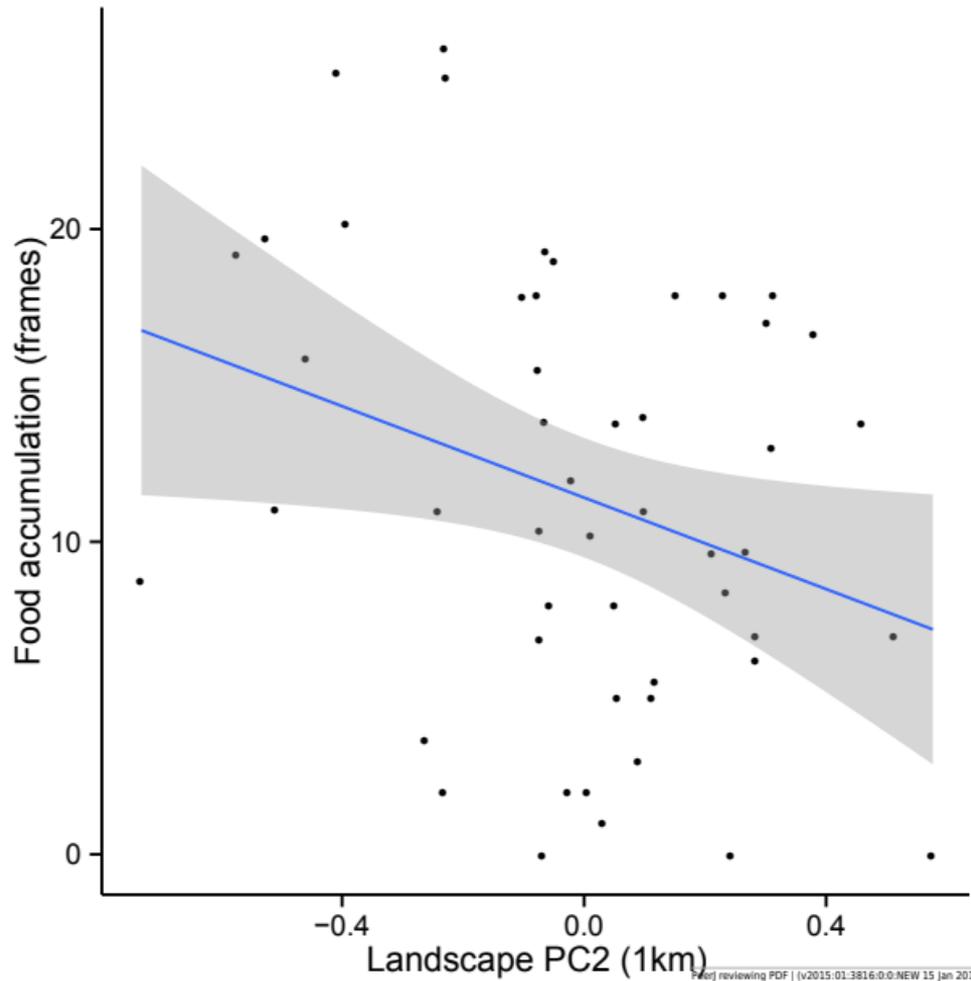

Principal component 1

**Figure 3** (on next page)

Food accumulation and wax production negatively correlated with PC 2

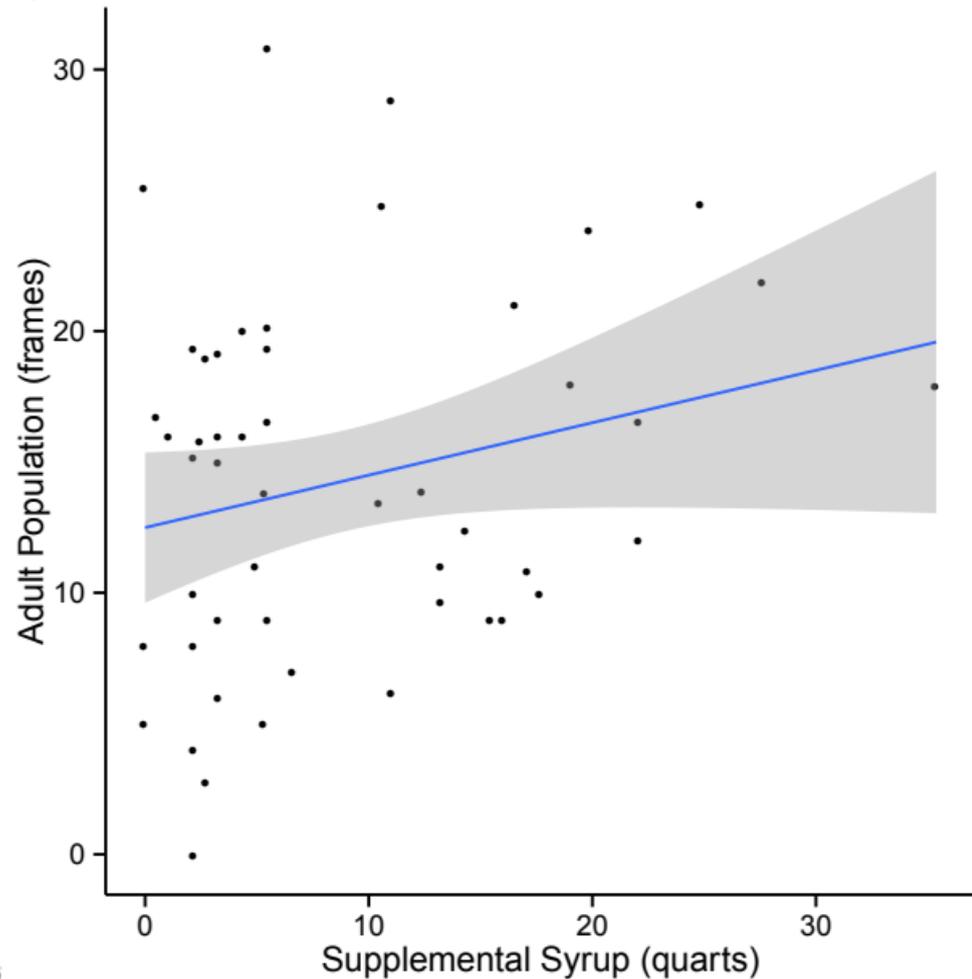

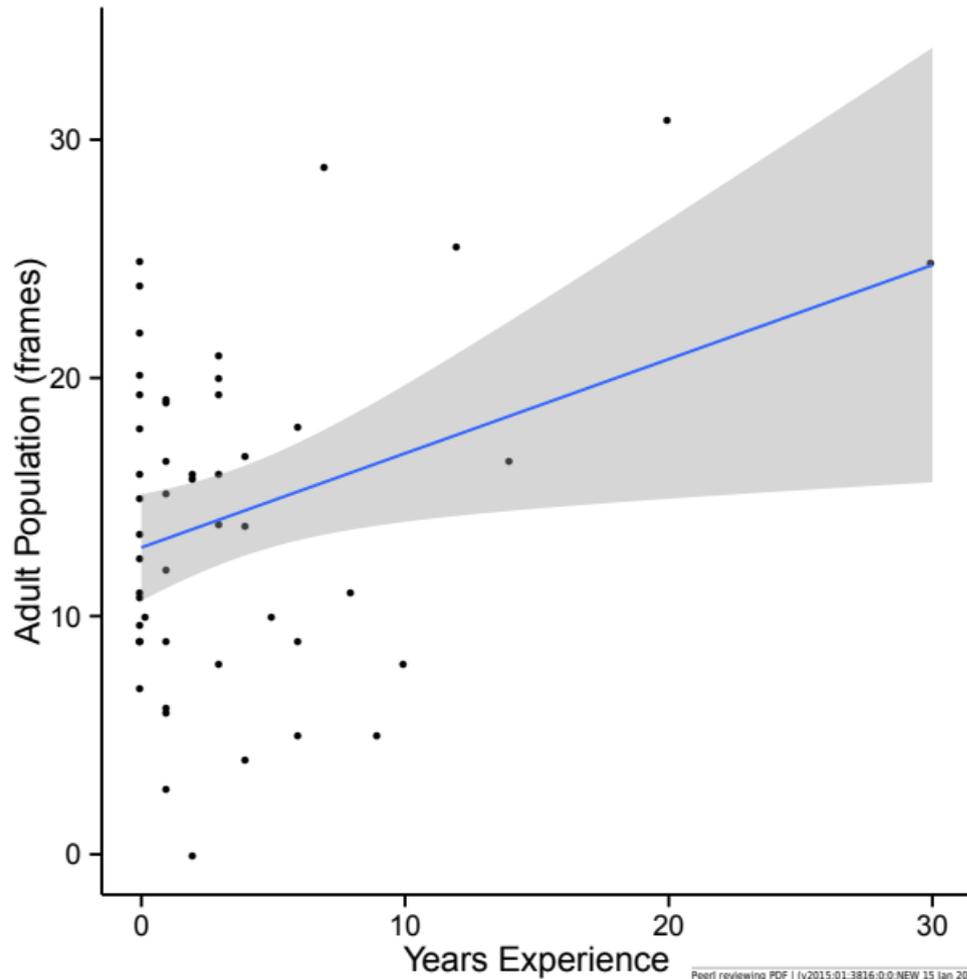

**Figure 3: Food accumulation and wax production were negatively correlated with PC 2.** This indicates that productivity in terms of food and wax increased in the direction of cropland and decreased in the direction of forest/grassland. This relationship was likely driven by the critical clover nectar flow, which is likely strongest in agricultural areas. A 95% confidence band is shaded in gray.

**Figure 4**(on next page)

Adult population positively correlated with beekeeper years of experience and supplemental syrup feeding.

**Figure 4:** Adult population was positively correlated with beekeeper years of experience and supplemental syrup feeding. A 95% confidence band is shaded in gray.

**Figure 5** (on next page)

Colony food accumulation decreased significantly with increasing Urban : Crop ratio.

**Figure 5: Colony food accumulation decreased significantly with increasing Urban : Crop ratio.** This pattern was strongest at a 1 km radius (shown above), and may have been driven by the late-season goldenrod bloom that is often very strong agricultural areas but is typically weak in urban areas. A 95% confidence band is shaded in gray.
