

How much biomass do plant communities pack per unit volume?

Raphael Proulx, Guillaume Rheault, Laurianne Bonin, Irene T Roca, Charles A Martin, Louis Desrochers, Ian S Seiferling

Aboveground production in terrestrial plant communities is commonly expressed in amount of carbon, or biomass, per unit surface. Alternatively, expressing production per unit volume allows the comparison of communities by their fundamental capacities in packing carbon. In this work we reanalyzed published data from more than 900 plant communities across nine ecosystems to show that standing dry biomass per unit volume (biomass packing) consistently averages around 1 kg/m^3 and rarely exceeds 5 kg/m^3 across ecosystem types. Furthermore, we examined how empirical relationships between aboveground production and plant species richness are modified when standing biomass is expressed per unit volume rather than surface. We propose that biomass packing emphasizes species coexistence mechanisms and may be an indicator of resource use efficiency in plant communities.

15 *Short title:* Biomass packing in plant communities

16 Abstract

17 Aboveground production in terrestrial plant communities is commonly expressed in amount of carbon,
 18 or biomass, per unit surface. Alternatively, expressing production per unit volume allows the
 19 comparison of communities by their fundamental capacities in packing carbon. In this work we
 20 reanalyzed published data from more than 900 plant communities across nine ecosystems to show that
 21 standing dry biomass per unit volume (biomass packing) consistently averages around 1 kg/m^3 and
 22 rarely exceeds 5 kg/m^3 across ecosystem types. Furthermore, we examined how empirical relationships
 23 between aboveground production and plant species richness are modified when standing biomass is
 24 expressed per unit volume rather than surface. We propose that biomass packing emphasizes species
 25 coexistence mechanisms and may be an indicator of resource use efficiency in plant communities.

26

27 Introduction

28 Uncovering general principles that govern the functioning of ecosystems is a long standing objective of
 29 community ecology. One such principle, the self-thinning rule, predicts that the standing biomass of
 30 plant communities increases with decreasing stem density in crowded stands (Hutchings, 1979,
 31 Westoby, 1984). D.E. Weller (1989) proposed a simple geometric model of the self-thinning rule in
 32 which the standing biomass (g/m^2) of different communities is negatively correlated to stem density.
 33 When expressed per unit volume (g/m^3) however, his model also predicted that standing biomass
 34 should be independent of stem density across the plant kingdom (Weller, 1989).

35 Absence of a general relationship between standing biomass per unit volume and stem density across a
 36 range of ecosystems would have two important implications. First, it would evince that plants cannot
 37 allocate more carbon to aboveground compartments than imposed by competition for volumetric

resources, such as light. Secondly, plant communities would differ from one another in their capacity to grow tall, yet compare in their capacity to pack carbon. Weller (1989) reported a positive relationship between dry biomass per unit volume and stem density, suggesting more efficient carbon packing in communities growing at a higher density. However, Weller's relationship relied on two datasets and, thus, remains inadequately tested.

Aboveground production, or yield, in terrestrial plant communities is commonly measured in amount of dry biomass per unit surface. Alternatively, expressing production per unit volume could better reflect how plants utilize all dimensions of the space in which they grow, hence emphasizing coexistence mechanisms. For instance, plants adapted to grow in the shade may contribute to biomass packing by filling the understorey space more efficiently (Claveau, Messier & Comeau, 2005, Valladares & Niinemets, 2008). Moreover, plants characterized by different growth rates or lifespans may increase biomass packing by acquiring resources on different spatial or time scales (Augspurger, 2008).

Biomass packing can be conceptualized as the amount of standing vegetation living within a sampling box. This box delineates a three-dimensional space, either physical or virtual, within which the vegetation is confined. Thus, biomass packing represents the amount of standing vegetation (expressed as dry biomass or occupied plant volume) scaled per unit of sampled volume.

The present study addresses two questions: Are there fundamental limits to the amount of standing dry biomass that is packed per unit volume in terrestrial plant communities? Is biomass packing affected by community composition and species richness? To investigate these questions we reviewed the scientific literature and compiled data for more than 900 plant communities. This synthesis highlights broad patterns in biomass packing across contrasted ecosystem types. It is not a meta-analysis of the

60 reviewed literature, which would require the inclusion of climatic or edaphic moderator variables as
61 well as accounting for spatial auto-correlation and random (data source) effects.

62

63 **Materials & Methods**

64 We searched the scientific literature for studies reporting both dry standing biomass per unit surface
65 and mean height of canopy plants in vegetation stands. The search targeted studies that monitored
66 vegetation stands close to their peak of biomass production (Table 1). We converted all biomass values
67 to g/m² and height values to m (Table S1). In the literature, we found only Weller's study (1989)
68 reported direct measures of biomass per unit volume in terrestrial ecosystems. As such, Weller's
69 dataset was not used in our analysis, but as a benchmark to compare those results against. From all
70 other aggregated data, we calculated the packing density of each plant community by dividing standing
71 dry biomass per unit surface by community height.

72 In addition to biomass and height, three of the data sources also included the species richness of their
73 respective plant community (Table S1): meadow, wetland and grassland. This data subset of 533
74 communities allowed us to examine how expressing standing biomass per unit surface or unit volume
75 modifies the relationship between biomass production and plant species richness.

76 To determine whether standing dry biomass approximates the volume occupied by plants, we compiled
77 a dataset on 42 wetland plant communities from the Lac St-Pierre ecosystem (Québec, Canada). In
78 August 2014, we sampled vegetation quadrats of 0.5 x 0.5m covering a broad range of species
79 assemblages and vegetation types. In each quadrat we clipped all the vegetation standing above 2cm
80 from the ground. We then evaluated plant volume using the water displacement method in a bucket of
81 12.6 cm radius. We expressed the amount of water displaced by the submersed vegetation in cubic

82 meters. We then oven dried the vegetation at 70°C for 48h and weighed the dry biomass. Finally, we
83 report the relationship between plant volume (m^3/m^2) and standing dry biomass (g/m^2) to evaluate their
84 association.

85

86 Results

87 From our analysis of the reviewed data we found that standing dry biomass per unit surface varied by
88 over three orders of magnitude across the plant kingdom (Fig. 1). In forest ecosystems, dry biomass per
89 unit surface typically ranged between 10 and 100 kg/m^2 , with pacific and tropical forest communities
90 consistently reaching higher values than that of temperate and boreal forests. In contrast, the standing
91 biomass of croplands and grasslands was comparable to one another, falling just above 1 kg/m^2 on
92 average. Lastly, meadows cumulated around 0.3 kg/m^2 standing dry biomass, though biomass increased
93 with increasing species richness, up to 0.5 kg/m^2 in the 60-species communities (slope = 0.0037, $R^2 =$
94 0.06, $df = 338$, $t = 4.5$, $p < 0.001$).

95 When expressing the standing dry biomass of the 971 communities in our dataset per unit volume,
96 biomass packing varied around 1 kg/m^3 (the average 50th percentile being 0.88 kg/m^3) and by less than
97 an order of magnitude across ecosystems (Fig. 1). The 75th percentile for biomass packing across
98 ecosystems ranged from 0.81 kg/m^3 in croplands up to 1.82 kg/m^3 in pacific forests, suggesting high
99 overall consistency relative to measures of biomass per unit surface (Fig. 1). Biomass packing reached
100 an overall maximum at 4.7 kg/m^3 in one pacific forest plot.

101 The positive relationship between plant species richness and biomass production among experimental
102 meadow communities vanished when standing dry biomass was expressed per unit volume rather than
103 surface (slope = 0.0004, $R^2 < 0.01$, $df = 338$, $t = 0.3$, $p = 0.738$, Fig. 1). In other herbaceous ecosystems

(Fig. 2), the relationship between plant species richness and biomass production shifted from negative, when biomass was expressed per unit surface (slope = -0.063, $R^2 = 0.12$, $df = 191$, $t = -5.2$, $p < 0.001$), to nonexistent when expressed per unit volume (slope = 0.018, $R^2 < 0.01$, $df = 191$, $t = 1.3$, $p = 0.180$).

We compared two methods of quantifying the amount of standing vegetation for wetland plant communities. The relationship between dry biomass and plant volume was strong and linear (Pearson's $r = 0.86$), indicating that standing biomass is a good proxy for the volume occupied by plant modules, at least for wetland communities (Fig. 3).

Discussion

Fundamental limits to biomass packing

The literature review highlights that if plant community biomass is represented as dry biomass per unit surface area, major ecosystem types are drastically different. However, when accounting for height and expressing standing dry biomass per unit volume, plant communities from different ecosystems appear remarkably similar in their capacity to pack biomass. Biomass packing across plant communities peaked just below 5 kg/m³, with an average median across ecosystems close to 1 kg/m³. These values are strikingly similar to those originally reported by Weller (1989) for mono-specific stands; reporting a maximum value of 5.2 kg/m³ (median of 1.2 kg/m³) in the first dataset and 5.3 kg/m³ (median of 0.6 kg/m³) in the second. We feel confident that the inclusion of more plant communities would not alter these general results.

Our results revealed that cropland and meadow communities were equally capable of packing biomass per unit volume. However, the caveat to this result is that it is true only when plant communities are

125 compared at their peak of biomass production. For instance, cornfields sown in widely spaced rows
 126 attain their maximum of biomass packing only towards the end of the growing season. Likewise,
 127 meadows are repeatedly harvested within a year, after which a regrowth period of sparse vegetation
 128 and low biomass packing initiates. Moreover, while tropical and temperate forests may show similar
 129 packing values at their peak of production, air temperature and sunlight duration impose stronger
 130 seasonal variations in the biomass packing of temperate ecosystems. Such examples illustrate the
 131 importance of accounting for changes in biomass packing over time and, perhaps, the inaccuracy of
 132 treating it as a static metric.

133 Perhaps the most contentious issue when assessing biomass packing is how the vertical dimension of
 134 the sampling box is measured. Here, the upper boundary of that box was defined as the mean height of
 135 canopy plants. In our review, one case study did use a physical, rather than a virtual, sampling box to
 136 assess the biomass packing of young (< 18 years old) forest stands (Peterson et al., 1982). In this study,
 137 sampling boxes of 1m^3 were placed in 107 woody stands, such that stems would fill the frames from
 138 top to bottom. Overall, the maximum biomass packing measured across stands and vegetation types
 139 varied from 3 kg/m^3 in poplar and birch forests to 6 kg/m^3 in pine and spruce forests (Peterson et al.,
 140 1982). Since sampling frames in this study were systematically placed in the densest portions of the
 141 forest, the above values represent upper bounds of dry biomass per unit volume. Hence, although
 142 measures of community height among studies might differ slightly, the biomass packing limit of ca. 5
 143 Kg/m^3 that we identified is in fair agreement with the upper bounds independently reported by Peterson
 144 et al. (1982) and Weller (1989).

145 *Species richness and biomass packing*

146 Garnering much attention in the literature, positive relationships between species richness and biomass
 147 production have been repeatedly reported in experimentally manipulated plant communities (e.g.,
 148 Reich et al. 2012). Further analyses of such experiments have determined that the relationship arises
 149 from a more efficient use of resources in species-rich communities over that of species-poor ones, or
 150 the so-called complementarity effect (Cardinale et al. 2007, Reich et al. 2012). Plant communities in
 151 the Jena Biodiversity Experiment, also used here as a data source, are no exception to this trend
 152 (Marquard et al. 2009). In contrast to the positive relationship between species richness and biomass
 153 per unit surface, our results show that species-rich meadows in the Jena Experiment do not pack more
 154 biomass per unit volume; that is, the richness-packing relationship is flat.

155 Divergent from those aforementioned biodiversity experiments, a negative relationship between plant
 156 species richness and biomass production can be observed in freely assembled herbaceous communities,
 157 wherein the productive stands are dominated by fewer species (Waide et al. 1999). The negative tail of
 158 the richness-production relationship has been explicated by facilitation and competitive exclusion
 159 processes among plant species growing in the most fertile situations (e.g., Michalet et al. 2006). In the
 160 present study, we did observe a higher biomass per unit surface in species-poor herbaceous
 161 communities, and therefore a negative richness-production relationship, but again the relationship
 162 vanished when standing dry biomass was expressed per unit volume. Stated simply, plant species
 163 richness had no effect on the biomass packing of plant communities at their peak of production.

164 To understand why the richness-biomass relationship flattens when expressing biomass per unit
 165 volume, we examined how much of the variation in standing biomass per unit surface is explained by
 166 community height. Among our 971 plant communities, height explains 88% of the variation in
 167 standing biomass when the axes are on a logarithmic scale (Table S1). This strong correlation suggests
 168 that, both, community height and biomass per unit surface are likely driven by similar factors affecting

resource use and availability (Moles et al. 2009). Dividing standing dry biomass by community height would emphasize the local species coexistence processes that are independent of stand fertility and climate conditions, but the assertion remains to be fully tested.

Conclusions

Our reanalysis of the literature casts a new light on how plant biomass accumulates in terrestrial ecosystems. Specifically, while the widespread metric of biomass per unit surface highlights differences between plant communities, expressing their standing dry biomass per unit of volume reveals their striking similarity. Expressing biomasses per unit volume goes against a longstanding tradition of measuring primary production per unit surface in terrestrial ecosystems, probably reflecting our utilitarian view of ecosystems conditioned by questions such as: how much crop (e.g., wood, hay, or grain) can be produced and harvested per hectare of land?

Our findings suggest that biomass packing is influenced less by baseline climatic and edaphic conditions, but rather emphasizes local plant-plant interactions. We propose that a fundamental limit might exist to the amount of dry biomass that natural plant communities pack per unit volume in terrestrial ecosystems; since the long-term maintenance of standing dry biomass beyond this point may be biologically unsustainable (Hutchings 1979). It is likely that this approximate limit of 5 kg/m³ can be exceeded in communities grown under controlled conditions, although croplands did not reach higher biomass packing values over that of other ecosystems in our dataset. Biomass packing may thus represent a simple and generic indicator of resource use efficiency in plant communities.
