The foraging niches of seabirds are driven by a variety of factors, including competition for prey that promotes divergence in foraging niches. Bass Strait, south-eastern Australia, is a key region for seabirds, with little penguins *Eudyptula minor*, short-tailed shearwaters *Ardenna tenuirostris*, fairy prions *Pachyptila turtur* and common diving-petrels *Pelecanoides urinatrix* being particularly abundant in the region. The trophic niches of these species were investigated using isotopic values in whole blood and by identifying prey remains in stomach contents. The four species occupied different isotopic niches that varied between 3 years and 3 regions. Little penguins consumed mainly fish whereas the three procellariiforms primarily consumed coastal krill *Nyctiphanes australis*. The dietary similarities between the procellariiforms suggest that food resources are segregated in other ways, with interspecific differences in isotope niches possibly reflecting differential consumption of key prey, divergent foraging locations and depth, and differences in breeding phenology. Because oceanographic changes predicted to occur due to climate change may result in reduced coastal krill availability, adversely affecting these seabird predators, further information on foraging zones and feeding behaviour of small procellariiform species is needed to elucidate more fully the segregation of foraging niches, the capacity of seabirds to adapt to climate change and the potential for interspecific competition in the region.

15 **ABSTRACT**

16 The foraging niches of seabirds are driven by a variety of factors, including competition for prey
17 that promotes divergence in foraging niches. Bass Strait, south-eastern Australia, is a key region
18 for seabirds, with little penguins *Eudyptula minor*, short-tailed shearwaters *Ardenna tenuirostris*,
19 fairy prions *Pachyptila turtur* and common diving-petrels *Pelecanoides urinatrix* being
20 particularly abundant in the region. The trophic niches of these species were investigated using
21 isotopic values in whole blood and by identifying prey remains in stomach contents. The four
22 species occupied different isotopic niches that varied between 3 years and 3 regions. Little
23 penguins consumed mainly fish whereas the three procellariiforms primarily consumed coastal
24 krill *Nyctiphanes australis*. The dietary similarities between the procellariiforms suggest that food
25 resources are segregated in other ways, with interspecific differences in isotope niches possibly
26 reflecting differential consumption of key prey, divergent foraging locations and depth, and
27 differences in breeding phenology. Because oceanographic changes predicted to occur due to
28 climate change may result in reduced coastal krill availability, adversely affecting these seabird
29 predators, further information on foraging zones and feeding behaviour of small procellariiform
30 species is needed to elucidate more fully the segregation of foraging niches, the capacity of
31 seabirds to adapt to climate change and the potential for interspecific competition in the region.

34 Ocean.

35

36 INTRODUCTION

37 Seabirds are major consumers of marine biomass, feeding on a variety of fish, cephalopods and
38 crustaceans (Ridoux 1994). The foraging niche of seabirds is influenced by a range of factors,
39 including environmental conditions (Waugh & Weimerskirch 2003), prey availability (Baird
40 1991), morphological characteristics and their influence on flight performance (Phillips et al.
41 2004, 2005), and interspecific competition (González-Solís et al. 2008, Phillips et al. 2008).
42 Competition is thought to promote foraging niche divergence since species occupying the same
43 ecological niche cannot theoretically coexist through time (Schoener 1974). Seabirds may
44 separate their resources on several dimensions, with studies showing divergence in foraging zone
45 (González-Solís et al. 2008, Barger et al. 2016), diving depth (Mori & Boyd 2004), the timing of
46 breeding, and seasonal patterns of activity (Phillips et al. 2008). In particular, divergence in diet
47 has been proposed as an important mechanism in reducing niche overlap (Ridoux 1994, Surman
48 & Wooller 2003).

49 Bass Strait, the shallow continental shelf area between mainland Australia and Tasmania (Fig. 1),
50 is a key region for Australian seabirds, supporting large breeding populations of at least 11 major
51 species comprising more than 15 million breeding pairs (Table 1; Ross et al. 2001). This area is
52 considered a region of low primary productivity (Gibbs et al. 1986, Gibbs et al. 1991) which
53 occurs at the confluence of three main ocean currents. The warm, oligotrophic waters of the East
54 Australian Current (EAC) flow southward along the eastern edge of Bass Strait (Ridgeway &
55 Godfrey 1997, Sandery & Kämpf 2007) while the South Australian Current (SAC) advects warm
56 water from the west onto the shelf which then flows eastward through Bass Strait (Sandery &
57 Kämpf 2007). The latter is the major source of Bass Strait water and is strongest in winter
58 (Ridgeway & Condie 2004, Sandery & Kämpf 2007). In summer, a weakening or reversal of this

59 eastward-flowing trend occurs (Gibbs et al. 1986, Sandery & Kämpf 2007). Finally, cold,
60 nutrient-rich sub-Antarctic surface water (SASW) enters Bass Strait from the south (Gibbs 1992)
61 where it mixes with the EAC and SAC (Prince 2001). Upwelling of SASW occurs along the
62 shelf edges of Bass Strait (Gibbs et al. 1986), particularly to the west in summer (McClatchie et
63 al. 2006), though upwelling in the east, where enrichment is possible throughout the year (Prince
64 2001), is also important (Gibbs et al. 1986).

65 The relative influence of the currents and upwelling systems affecting Bass Strait varies
66 spatially, seasonally and inter-annually (Prince 2001, Sandery & Kämpf 2005). This affects the
67 reproductive success of seabirds in Bass Strait, presumably due to shifts in prey availability
68 (Mickelson et al. 1992). Additionally, climate change is predicted to weaken the SAC (Feng et
69 al. 2012) and increase the strength of the EAC, resulting in warming along the path of its
70 strengthening (Cai et al. 2005). This is likely to have a considerable impact on the marine
71 ecosystem of Bass Strait. Seabird assemblages in other parts of the world have shown differential
72 responses to shifts in ocean regimes in parameters such as breeding success, population size and
73 survivorship due, at least in part, to changes in prey availability (Croxall et al. 2002). Knowledge
74 of the trophic relationships and diets of Bass Strait seabirds is crucial for predicting their
75 population responses to environmental change. This information is important for the
76 conservation of these marine predators and for the refinement of sustainable fisheries
77 management practices. At present, the trophic structure of Bass Strait seabird community is
78 poorly understood, with trophic niches of most pelagic species not yet described or based on a
79 few localised studies that did not address spatial or temporal variation. Accordingly, it is not
80 known whether, or how, they diverge in foraging niche.

81 The little penguin *Eudyptula minor*, short-tailed shearwater *Ardenna tenuirostris*, fairy prion
82 *Pachyptila turtur* and common diving petrel *Pelecanoides urinatrix* are the most abundant and
83 ubiquitous seabirds in Bass Strait, breeding sympatrically on numerous offshore islands (Ross et
84 al. 2001). They are known to feed on a variety of fish, cephalopod and/or crustacean prey
85 (Harper 1976, Montague et al. 1986, Schumann et al. 2008, Chiaradia et al. 2010). Previous
86 foraging ecology studies indicate that the little penguin is an inshore forager relying mainly on
87 small pelagic schooling fish (Cullen et al. 1992, Chiaradia et al. 2010), while the pelagic short-
88 tailed shearwater, and the smaller, more neritic fairy prion and common diving petrel, feed on a
89 wide range of small prey, concentrating predominantly on coastal krill (*Nyctiphanes australis*)
90 and myctophid fish (Harper 1976, Weimerskirch & Cherel 1998, Schumann et al. 2008).
91 However, in Bass Strait, information on spatial and temporal variation in the ecology of these
92 species is limited to the at-sea foraging behaviour of little penguins and short-tailed shearwaters
93 (e.g. Collins et al. 1999, Chiaradia et al. 2010, Berlincourt & Arnould 2015a, b) and there is
94 almost no information on the small procellariiforms.

95 The aims of the present study, therefore, were to: 1) determine the trophic niche using both
96 stomach contents and stable isotope analysis; 2) assess the degree of niche overlap; and overall
97 3) investigate inter-annual and geographic variation in the isotopic niche of these four abundant
98 species within Bass Strait.

99

100 MATERIAL & METHODS

101 The study was conducted during the winters (July – August) of 2008 – 2010 and summers
102 (January – February) of 2009 – 2011 in three regions of Bass Strait, south-eastern Australia (Fig.

103 1). The trophic niches of little penguins, short-tailed shearwaters, fairy prions and common
104 diving-petrels were determined using two complementary techniques. Trophic information was
105 derived from stable isotope values in whole blood of each species in western, central and eastern
106 Bass Strait, and stomach samples were collected from the seabirds in central Bass Strait to assess
107 the relative importance of prey and inform interpretation of the stable isotope results. All
108 research was conducted under permit from Deakin University (AWC A9-2008) and the
109 Department of Sustainability and Environment (Permit No. 10004530).

110

111 *Dietary analysis*

112 Stomach contents analysis provides information on the composition and abundance of prey
113 consumed (Duffy & Jackson 1986). Stomach samples were collected from the four seabird
114 species on Notch (38°56'S, 146°37'E) and Kanowna (39°10'S, 148°16'E) Islands in central Bass
115 Strait (Fig. 1). Adult common diving petrels were sampled in winter (n = 6), little penguins were
116 sampled in both winter and summer (n = 20 and 22, respectively), and fairy prion and short-
117 tailed shearwater diet samples were collected in summer only (n = 20 and 51, respectively). Due
118 to logistical constraints and few individuals onshore in some years, it was not possible to sample
119 all species in all years.

120 Adult birds were captured as they came ashore at night after foraging at sea. Diet samples were
121 collected using the water-offloading technique. While it is possible that not all stomach contents
122 were retrieved, stomach flushing is an effective technique for diet estimation in seabirds (Gales
123 1987) and, in most cases, the majority of prey remains were ejected on the second (final) flush,
124 as evidenced by clear water being ejected. After flushing, birds were given an electrolyte

125 solution of Vytrate or Lectade (Jurox Pty Ltd, NSW), and placed into boxes for recovery
126 (Chiaradia et al. 2003). Little penguins and short-tailed shearwaters were also provided with a
127 meal, delivered via a stomach tube, of homogenised pilchard (purchased snap-frozen and
128 unsalted) immediately before release.

129 Diet samples were frozen (-20°C) or stored in 70% ethanol after collection. Crustacean remains
130 were initially identified to lower taxonomic levels with reference to Ritz et al. (2003). Sagittal
131 otoliths, scales, fish mouth parts and cephalopod beaks were identified by comparison to
132 reference atlases (Neira et al. 1998, Lu & Ickeringill 2002, Furlani et al. 2007) and collections
133 (held by Phillip Island Nature Parks and Deakin University).

134 Fresh prey items were washed with water and separated from accumulated ones. To estimate the
135 numerical abundance of crustacean prey, the heads of amphipods and whole bodies of copepods,
136 isopods and crab megalopa were counted directly while individual eyes of krill and stomatopods
137 were counted and divided by two. Left and right otoliths were counted and the side comprising
138 the greater number considered representative of the minimum number of each fish taxon per
139 sample. Where otoliths were unidentifiable, their abundance was halved and rounded to the
140 nearest number. Similarly, the highest number of upper or lower beaks in a sample was used to
141 estimate the abundance of cephalopods and only unbroken beaks were measured to estimate size
142 (Tollit et al. 1997). Hard prey remains that could not be quantified, such as fish scales, were
143 assigned a numerical abundance of one. The frequency of occurrence of prey remains was
144 calculated as the proportion of samples containing identifiable remains in which a particular prey
145 type occurred while the numerical abundance was expressed as the mean number of each prey
146 taxon encountered in samples.

147

148 *Stable isotope analyses*

149 Stable carbon ($\delta^{13}\text{C}$) and nitrogen ($\delta^{15}\text{N}$) values in tissues have been used to infer the diet of a
150 range of marine species (Hobson & Welch 1992, Hobson 1993, Cherel et al. 2007). Stable
151 isotope values of $\delta^{13}\text{C}$ values allow discrimination between benthic and pelagic prey (e.g., Cherel
152 et al. 2007) and inshore and offshore feeding (Hobson et al. 1994b), while $\delta^{15}\text{N}$ in tissues show
153 enrichment with increasing trophic levels (Hobson et al. 1994a). Information derived from whole
154 blood, as used in the present study, reflects dietary integration of approximately four weeks
155 (Bearhop et al. 2002).

156 Blood samples (< 0.2 ml) were collected from seabirds resident in western (WBS - Lady Julia
157 Percy Island: 38°25'S, 142°00'E), central (CBS - Notch, Kanowna, Norman: 39°02'S, 146°12'E
158 and Anser Islands: 39°09'S, 146°18'E) and eastern Bass Strait (EBS - Gabo Island: 37°34'S,
159 149°55'E). A total of 278 (167 in summer, 111 in winter), 177 (summer only), 88 (66 in
160 summer, 22 in winter) and 38 (winter only) stable isotope profiles were obtained from little
161 penguins, short-tailed shearwaters, fairy prions and common diving petrels, respectively. Adult
162 individuals (not sampled for diet determination) were captured as they returned to their nesting
163 burrows at night or taken from their burrows during the day. Little penguins and short-tailed
164 shearwaters were captured by hand, common diving-petrels were captured in mist nets, and fairy
165 prions were captured by hand or using hand nets as they approached their burrows. Upon
166 capture, blood was collected into a heparinised syringe via venipuncture of the tarsal vein or an
167 inter-digital vein in the foot.

168 Blood samples were stored frozen (-20°C) and, prior to analysis, oven dried (60°C) and
169 homogenised using a mortar and pestle. The low lipid content of whole blood does not typically
170 necessitate lipid extraction (Cherel et al. 2005a). Indeed, all mean values of C:N mass ratio

171 encompassed a narrow range (3.1-3.7) indicating low lipid content and, thus, allowing accurate
172 comparisons of $\delta^{13}\text{C}$ values among groups. Isotope ratios in whole blood were measured using a
173 continuous-flow isotope ratio mass spectrometer, with analyses conducted by the Isotope Ratio
174 Mass Spectrometry service in the Research School of Biology, Australian National University
175 (Canberra, Australia). The values of stable isotope abundances were expressed in δ -notation as
176 the deviation from standards in parts per thousand according to the equation:

177

$$178 \quad \delta X = [(R_{\text{sample}}/R_{\text{standard}}) - 1]$$

179

180 where X is ^{15}N or ^{13}C and R represents the corresponding $^{15}\text{N}/^{14}\text{N}$ or $^{13}\text{C}/^{12}\text{C}$ ratios (Hobson et al.
181 1994a). R_{standard} values were based on Vienna Pee Dee Belemnite for ^{13}C , and atmospheric
182 nitrogen (N_2) for ^{15}N . Based on variation between repeats of a standard material, measurement
183 error was estimated to be ± 0.20 and ± 0.15 ‰ for $\delta^{15}\text{N}$ and $\delta^{13}\text{C}$, respectively.

184

185 *Statistical analyses*

186 All statistical analyses were conducted in the R statistical environment 3.5.1 (R Core Team
187 2018). To investigate the effect of geographic, inter-annual and seasonal variations in stable
188 isotope values, generalised linear models (GLM) were fitted using the *lme4* package (Bates et al.
189 2014). Terms were added sequentially, model selection was based on Akaike's information
190 criterion (AIC), and the global models were checked to ensure normality and homoscedasticity
191 of the residuals. Post-hoc tests were conducted using analyses of variance (ANOVA) and *t*-tests,

192 or Kruskal-Wallis and Wilcoxon rank sum tests where transformations did not improve data
193 distributions. The stable isotope Bayesian ellipses in R (*SIBER* package; Jackson et al. 2011)
194 were used to determine the isotopic niche width of each species in each region, for each year and
195 season. The Standard Ellipse Area corrected (SEAC; 40% probability of containing a
196 subsequently sampled datum regardless of sample size) was used to quantify niche width. The
197 Bayesian estimate of the standard ellipse and its area (SEAB) were used to measure the overlap
198 of the isotopic niches between groups (Jackson et al. 2011).

199

200 **RESULTS**

201 *Diet*

202 Stomach content samples were obtained from individuals between August 2008 and January
203 2011 in CBS order to inform interpretation of the stable isotope results. Samples were collected
204 from little penguins in both winter and summer (2008-2009), from short-tailed shearwaters in
205 summer 2009 and 2010, from fairy prions in summer 2011 and from common diving petrels in
206 winter 2008 and 2009. Overall, 79, 84, 95 and 40 % of little penguin, short-tailed shearwater,
207 fairy prion and common diving-petrel samples, respectively, contained identifiable fresh prey
208 remains.

209 Stomach samples of studied seabird species contained remains of fish, cephalopods and
210 crustaceans (Table 2). Not all taxa could be identified to species level. Crustacean remains,
211 comprising isopods, amphipods and/or copepods were ingested by little penguins, but consumed
212 mainly jack mackerel in winter and Australian anchovy *Engraulis australis* in summer, though
213 high numbers of post-larval fish were also ingested in summer (Table S1 in the Supplement).

214 The diets of all three procellariiform species were dominated by euphausiids, particularly coastal
215 krill, which represented 78 – 96 % of the mean number of prey items consumed by these species
216 (Table S2 and Table S3 in the Supplement). Other important prey taxa included *Euphausia* sp.
217 and the hyperiid amphipod *Themisto australis* for short-tailed shearwaters, the megalopa stage of
218 a swimming crab species *Ovalipes* sp. for fairy prions and hyperiid amphipods for common
219 diving-petrels. For short-tailed shearwaters, the abundance of crustaceans was significantly
220 higher in 2010 than in 2009 (Wilcoxon-test, $w = 126.5$, $p\text{-value} < 0.01$), mainly driven by the
221 variation in number per samples of coastal krill ($n = 118.9 \pm 52.6$ and $n = 969.6 \pm 194.2$ in 2009
222 and 2010, respectively).

223

224 ***Stable isotopes analysis***

225 Blood samples were collected from all four species in WBS and CBS, and from little penguins
226 and short-tailed shearwaters in EBS (Table 3 and 4). Values of $\delta^{13}\text{C}$ range between -20.6 and -
227 18.1 ‰ for little penguins, between -23.7 and -20.4 ‰ for short-tailed shearwaters, between -
228 21.0 and -18.3 ‰ for fairy prions and between -21.4 and -19.4 ‰ for common diving petrels.
229 Whole blood $\delta^{15}\text{N}$ values range between 10.8 and 16.0 ‰ for little penguins, between 7.8 and
230 11.4 ‰ for short-tailed shearwaters, between 8.8 and 14.8 ‰ for fairy prions and between 10.9
231 and 14.5 ‰ for common diving petrels (Figure in the Supplement).

232 For all four species, stable isotope values in whole blood showed intraspecific variation between
233 regions and years (Fig. 2 and 3). Inter-annual variations of $\delta^{13}\text{C}$ values were significant in all
234 species in most regions (Paired t -test or Wilcoxon-test: $P < 0.01$) except for short-tailed
235 shearwater and common diving petrel in CBS (t -test: $P > 0.07$). While there was no pattern in

236 $\delta^{13}\text{C}$ differences between regions for the short-tailed shearwater, for the three other species
237 values in CBS were generally lower than those from WBS (0.56 ‰ to 1.40 ‰ lower) (Tables 3
238 and 4). Indeed, for the little penguin, fairy prion and common diving petrel, the variable “region”
239 explained, respectively, 63, 42 and 58 % of the variance for the $\delta^{13}\text{C}$ model, and only 2 % for the
240 short-tailed shearwater. For $\delta^{15}\text{N}$, the best models retained, with interactions, the $\delta^{13}\text{C}$, the region
241 and the year as significant variables explaining 57 % to 93 % of the deviance (Table S4 in the
242 Supplement). Significant inter-annual differences were recorded in all regions (Paired *t*-test or
243 Wilcoxon-test: $P < 0.01$), but no clear pattern was detected in the values or the isotopic niche
244 metrics (Tables 3 and 4). Similarly, for each year, the $\delta^{15}\text{N}$ values varied significantly between
245 region for the little penguin, fairy prion and common diving petrel (Paired *t*-test or Wilcoxon-
246 test: $P < 0.01$). For the short-tailed shearwater, a spatial difference in $\delta^{15}\text{N}$ values was detected
247 between WBS and EBS in 2010 (Paired *t*-test $t_{37} = -2.19$, $P < 0.05$), but no other significant
248 differences were found. The models for $\delta^{13}\text{C}$ retained the region and year as significant variables
249 for all the study species, explaining 58.6 % to 79.3 % of the variance (Table S4 in the
250 Supplement).

251 The four study species occupied different isotopic niches in all years and each region (Figure in
252 the Supplement). Values of $\delta^{13}\text{C}$ and $\delta^{15}\text{N}$ in whole blood of short-tailed shearwaters were
253 significantly lower (with no isotopic niche overlap) than those of the other species in each region
254 all three years (paired *t*-test or Wilcoxon-test: $p < 0.01$, Table 3). In contrast, mean $\delta^{15}\text{N}$ values in
255 blood of little penguins typically showed the greatest enrichment in both winter and summer,
256 though this varied spatially and inter-annually (Table 3 and 4). Isotopic $\delta^{13}\text{C}$ values of little
257 penguins and fairy prions were relatively similar, but tended to be higher than those of common
258 diving-petrels in winter, particularly in CBS. While the isotopic niche of the fairy prion

259 overlapped sparsely with the common diving petrel (SEA_B overlap $< 8.1\%$), and with little
260 penguin in 2009 and 2011 (SEA_B overlap $< 4.9\%$), niche overlap with the little penguin was
261 important in 2010 (maximum SEA_B overlap = 21.8% in winter 2010 in WBS, Table 3 and 4).

262

263 **DISCUSSION**

264 Sympatric seabird species diverge in their foraging niche in a variety of spatial and temporal
265 ways (Waugh & Weimerskirch 2003, González-Solís et al. 2008, Davies et al. 2009). Bass Strait
266 is occupied by an abundant marine avifauna (Ross et al. 2001), with little previously known of
267 the trophic niches of most species. Combining stomach contents and stable isotope analyses, the
268 present study has shown that the four most abundant and ubiquitous species generally occupy
269 different trophic niches that vary among regions, years and season.

270

271 ***Diet***

272 The little penguin is considered an inshore generalist forager relying mostly on small pelagic
273 prey such as Clupeiformes (Cullen et al. 1992, Chiaradia et al. 2010, Sutton et al. 2015). In the
274 present study, stomach contents of little penguins in summer were similar to that previously
275 reported, with Australian anchovy and post-larval fish contributing the majority of samples. In
276 contrast, winter stomach contents were dominated by jack mackerel, highlighting a seasonal
277 switch in the availability of the main prey of little penguins. Such differences have also been
278 shown in little penguins from Albatross Island in southern Bass Strait (Gales & Pemberton 1990)
279 and Phillip Island in northern Bass Strait (Cavallo et al. 2018). While recent studies have
280 observed that jellyfish can contribute a substantial proportion of the little penguin diet (Sutton et

281 al. 2015, Cavallo et al. 2018), no evidence of such prey were found in the present study. This
282 could potentially be due to rapid digestion of gelatinous prey in comparison to fish or
283 crustaceans (Cavallo et al. 2018), emphasising the limitation of traditional stomach content
284 analyses, or reflect inter-annual differences in available prey types.

285 Stomach contents of short-tailed shearwaters in the present study were similar to those of
286 individuals from Tasmania (Weimerskirch & Cherel 1998, Cherel et al. 2005b). The main
287 identified prey was the coastal krill, indicating that sampled birds were mostly returning from
288 short foraging trips over the continental shelf (Blackburn 1980, Weimerskirch & Cherel 1998).
289 Indeed, during the breeding season, short-tailed shearwaters alternate between short (1-2 d) local
290 trips within 35-70 km of the colony and long trips (10-20 d) to Antarctic waters (Weimerskirch
291 & Cherel 1998, Einoder et al. 2011, Berlincourt & Arnould 2015b) where they feed mainly on
292 coastal krill, and myctophid fish and sub-Antarctic krill, respectively (Montague 1986,
293 Weimerskirch & Cherel 1998). In the 2010 samples, a limited number of birds ($n = 4$) had
294 stomach contents dominated by stomach oil and digested *Euphausia* sp, suggesting they had
295 returned from long trips to Antarctic waters (Weimerskirch & Cherel 1998).

296 Coastal krill occurs in neritic waters of eastern Australia, where other krill species are rare or
297 absent (Blackburn 1980). Due to its abundance, it plays a key role in the coastal ecosystem,
298 reflected by its dominance in the diets of various cetacean, seabirds and fish species (O'Brien
299 1988, Gill et al. 2011). Despite limited data on the diet of fairy prions and common diving petrels
300 in Bass Strait, their stomach contents confirmed the importance of coastal krill to these species in
301 the Australasian region (Harper 1976, Schumann et al. 2008). These results, together with
302 estimates of trip duration in previous studies (1-3 d trips at sea, Harper 1976, Bocher et al.

303 2000a, b, Navarro et al. 2013, Zhang et al. 2018), suggest that both fairy prions and common
304 diving petrels most likely forage within Bass Strait or in the vicinity of the continental shelf.

305

306 *Spatial variability in isotopic niche*

307 Since whole blood integrates dietary information over approximately four weeks (Bearhop et al.
308 2002), it might be expected that isotopic values for short-tailed shearwaters would reflect a
309 combination of both their local and Antarctic foraging areas (Berlincourt & Arnould 2015b),
310 thereby masking any differences in blood isotope values between foraging zones. However,
311 Cherel et al. (2005b) showed that while most of the food consumed by short-tailed shearwaters
312 during short local trips is allocated to their chick, adults feed for themselves when foraging
313 further south and, therefore, have a truly Antarctic blood isotopic signature. In the present study,
314 values of $\delta^{13}\text{C}$ in whole blood of short-tailed shearwaters were comparable to those of other
315 procellariiforms foraging in subantarctic waters (Cherel et al. 2002a, Cherel et al. 2002b,
316 Quillfeldt et al. 2005) but were slightly higher than those in plasma of short-tailed shearwaters
317 from south Tasmania (Cherel et al. 2005b).

318 Interestingly, the $\delta^{13}\text{C}$ values of short-tailed shearwaters varied significantly between the three
319 study regions in Bass Strait, indicating possible foraging spatial segregation within the Southern
320 Ocean by individuals from the different regions. As $\delta^{13}\text{C}$ values are higher in subtropical than in
321 Antarctic waters (Cherel & Hobson 2007, Cherel et al. 2007, 2010, Jaeger et al. 2010), this
322 suggests a latitudinal segregation in the foraging areas between the three sampled populations.
323 However, this variation was not consistent across years, with strong inter-annual variability in
324 $\delta^{13}\text{C}$ values for birds from WBS and EBS compared to CBS. This could suggest not only colony-
325 specific niche segregation but also density-dependent competition (Wakefield et al. 2013), with

326 the smallest colonies having a more flexible foraging area. Indeed, the CBS population is
327 considerably bigger than the WBS and EBS populations, with 755,400, 30,000 and 6,000
328 breeding pairs, respectively (Bowker 1980, Pescott 1976, Fullagar & Heyligers 1996, Schumann
329 et al. 2014). This is in accordance with previous tracking studies (Berlincourt & Arnould 2015b)
330 that observed inter-annual longitudinal and latitudinal variation in the long trip foraging areas of
331 short-tailed shearwater from the small populations in WBS and EBS. Despite the geographic and
332 temporal differences in $\delta^{13}\text{C}$ observed, there were no major differences in the $\delta^{15}\text{N}$ values
333 between regions in the present study, highlighting the consistency of the diet of short-tailed
334 shearwaters in the Southern Ocean.

335 For little penguins, fairy prions and common diving petrels, temporal and geographic differences
336 in isotopic signatures are likely to reflect differences in prey availability associated with the
337 strength of the prevailing of ocean currents and upwelling systems in the different regions of
338 Bass Strait. For example, in summer, the SAC may transport prey and nutrient-enriched waters
339 from the west into Bass Strait (Mickelson et al. 1992, Sandery & Kämpf 2007), weakening
340 towards the east (Sandery & Kämpf 2007) where the EAC increases in prevalence, bringing
341 warmer nutrient-poor water into north-eastern Bass Strait (Gibbs 1992). This was reflected in
342 $\delta^{13}\text{C}$ values in the whole blood of little penguins and fairy prions, where values were
343 systematically lower in CBS than in WBS and EBS. Similar observations have been reported for
344 Australian fur seals where $\delta^{13}\text{C}$ values in blood plasma of individuals from CBS were
345 consistently lower than those from EBS (Arnould et al. 2011), highlighting the influence of
346 SASW (depleted in $\delta^{13}\text{C}$) on CBS waters (Gibbs 1992). In winter, however, spatial differences in
347 isotopic values declined. This may reflect the greater influence of the SAC in Bass Strait during
348 the winter period (Sandery & Kämpf 2007).

349

350 ***Inter-annual trophic variability***

351 The isotope values in the whole blood of little penguins from WBS and CBS in summer are
352 within the range previously reported from Phillip Island in CBS (Chiaradia et al. 2010, Chiaradia
353 et al. 2012), with the exception of 2010 when $\delta^{15}\text{N}$ values were significantly lower in both
354 regions. This could reflect fluctuations in isotopic baseline signatures due to different water
355 masses and variable strength of the currents influencing the regions where individuals foraged.
356 Indeed, as reported by Polito et al. (2019), variations in oceanic factors such as chlorophyll-*a*
357 concentration can substantially alter mean isotope values independently of any change in the diet
358 of the species. However, this could also reflect a variation in main prey species consumed, with
359 little penguins known to have important inter-annual variability in their diet (Gales & Pemberton
360 1990, Cullen et al. 1992, Chiaradia et al. 2010). In the present study, individuals from CBS in
361 summer 2009 consumed predominantly Australian anchovy, a species exploiting higher trophic
362 levels than other prey targeted by little penguins (Espinoza et al. 2009, van der Lingen et al.
363 2009). As previously highlighted by Chiaradia et al. (2010), $\delta^{15}\text{N}$ values are higher during years
364 with an important proportion of anchovy in little penguin diet. Therefore, it is likely that the low
365 $\delta^{15}\text{N}$ values in summer 2010 in the present study was due to a depletion of Australian anchovy in
366 the diet, potentially due to a reduced availability in the region. This is consistent with previous
367 reports indicating inter-annual flexibility in little penguin at-sea foraging behaviour in relation to
368 environmental conditions that directly influence prey abundance (Berlincourt & Arnould 2015a,
369 Camprasse et al. 2017). Indeed, in WBS and CBS, the niche space occupied by little penguins in
370 2010 was much larger than in 2009 and 2011, indicating a larger trophic diversity (Layman et al.
371 2007), possibly due to the absence of the usual main prey. Similarly, for both fairy prions and

372 common diving petrels, $\delta^{15}\text{N}$ values in the whole blood of both species in the region varied
373 substantially between years, suggesting variation in the consumption of their main prey, coastal
374 krill. Significant inter-annual differences in the density and biomass of coastal krill in southern
375 Bass Strait have previously been observed (Young et al. 1993).

376

377 *Trophic and isotopic niche segregations*

378 In the present study, interspecific comparisons of stomach contents and $\delta^{15}\text{N}$ values revealed that
379 little penguins typically occupied the highest trophic positions of the four seabird species while
380 short-tailed shearwaters always occupied the lowest. High little penguin $\delta^{15}\text{N}$ values were
381 nevertheless lower to those of the top predators shy albatross and Australian fur seal (Arnould et
382 al. 2011; Cherel et al. 2013), but were close to the values of the large Australasian gannet (Angel
383 et al. 2016), which predominantly consumes pilchards and anchovy (Bunce 2001) (Figure 4). In
384 contrast, $\delta^{15}\text{N}$ values of short-tailed shearwaters, fairy prions and common diving petrels were
385 remarkably lower than those of the much smaller white-faced storm petrels (Figure 4), which
386 consume a significant proportion of fish in addition to coastal krill (Underwood 2012). These
387 results indicated that coastal krill was a key prey taxon in all three procellariiforms in central Bass
388 Strait. During breeding, both fairy prions and common diving petrels return to the nest every
389 night (Harper 1976, Payne & Prince 1979), suggesting that they forage mainly on the shelf near
390 their colonies. Elsewhere, fairy prions take prey from the surface waters (Harper 1987, Prince &
391 Morgan 1987) whereas common diving petrels exploit depths averaging 2-4 m (Navarro et al.
392 2013, Navarro et al. 2014, Dunphy et al. 2015). Likewise, despite isotopic signatures showing
393 self-maintenance feeding in the Southern Ocean, short-tailed shearwaters forage on coastal krill
394 over the shelf near colonies during short trips (Einoder et al. 2011, Berlincourt & Arnould

395 2015b), resulting in the potential for interspecific overlap in the foraging zones of the three
396 procellariiforms. However, short-tailed shearwaters forage at deeper depths (average 13 m)
397 during local trips (Weimerskirch & Cherel 1998). While the foraging zones and dive depths of
398 little penguins may overlap with those of short-tailed shearwaters (Berlincourt & Arnould 2015a,
399 2015b), the limited distance travelled per trip and fish-based diet of little penguins would reduce
400 competition with procellariiforms.

401 In addition to segregation of diet and foraging behaviour, the four species differ in their breeding
402 phenologies. Common diving petrels, fairy prions and short-tailed shearwaters lay their eggs in
403 late July, late October and late November, respectively (Harris 1979, Marchant & Higgins 1990).
404 Thus, there is limited overlap in the breeding periods of the three procellariiforms. However, the
405 protracted and variable breeding season of little penguins (Reilly & Cullen 1981, Cullen et al.
406 1992) may overlap with the other species. Interspecific competition may, therefore, intensify in
407 years of low fish prey availability. Indeed, previous studies have documented the presence of
408 coastal krill in the diet of little penguin during years of low prey availability (Cullen et al. 1992).

409 The dependence of these seabird species on relatively few prey types (such as coastal krill,
410 pilchard or anchovy) may increase the impacts of reductions in prey abundance. Climate models
411 have described an intensification of the EAC due to large-scale changes in ocean circulation in
412 the Southern Hemisphere (Cai 2006), produced in association with an increasing trend in the
413 Southern Annular Mode (Cai et al. 2005). During years of intensified EAC, Young et al. (1993)
414 reported a dramatic drop in coastal krill biomass. This is likely to adversely affect seabirds in the
415 region. Similarly, significant mortality events, poor chick growth and population declines in
416 short-tailed shearwaters in Bass Strait have been previously attributed to local prey shortages
417 (Vertigan 2010). Declines in coastal krill availability may also indirectly impact little penguins

418 since this species is an important dietary component of several of their prey taxa (Harris et al.
419 1979, O'Brien 1988). The predicted increase in the strength of the EAC with climate change (Cai
420 et al. 2005) could, therefore, have severe negative consequences for the Bass Strait seabird
421 community.

422

423 **CONCLUSIONS**

424 In summary, the present study has shown that the isotopic niches of seabirds in Bass Strait vary
425 significantly between regions, years and seasons. These differences are likely to result from
426 changes in prey availability driven by variations in ocean currents and local productivity. Despite
427 interspecific similarities in diet, divergence in the relative foraging niche is likely to reduce
428 interspecific competition for prey, though this may become more important in years of low prey
429 availability. The low diversity of prey taxa ingested by these seabirds suggests that they are
430 vulnerable to changes in the availability of key prey. In order to better understand the foraging
431 niches of the Bass Strait community of seabirds, as well as their capacity to adapt to changing
432 environmental conditions, more detailed information on their foraging zones and feeding
433 behaviour is required. This is particularly important for the small procellariiforms in light of the
434 paucity of information in south-eastern Australia, in contrast to the numerous studies that have
435 been conducted on little penguins and short-tailed shearwaters in the region (*e.g.* Ropert-Coudert
436 et al. 2004, 2009, Berlincourt & Arnould 2015a, b). Such information may help elucidate the
437 likelihood of interspecific competition in this assemblage of seabirds.

438

439 **ACKNOWLEDGEMENTS**

440 The contribution of Dr Roger Kirkwood and Dr Michael Lynch who collected blood samples
441 from Lady Julia Percy Island during some seasons, and Dr Tom Montague who provided
442 information on identification of fish prey remains using mouth parts and scales is gratefully
443 acknowledged. We thank Dr Alice Carravieri who provided useful comments on the later version
444 of the manuscript, and Dr Tim Poupart and Dr Paul Tixier for their respective help on statistical
445 analysis and R code.

Table 1 (on next page)

Main species of seabirds breeding in Bass Strait, indicating the estimated number of breeding pairs, the proportion of total Australian populations (based on Ross et al. 2001), and the major group of prey consumed.

1

Species	Abundance (number of breeding pairs)	% of the Australian population	Groups of main prey	Reference
Shy albatross	5 200	35 %	Fish/cephalopods	Alderman et al. 2011, Hedd & Gales 2001
Short-tailed shearwater*	14 600 000	75 %	Crustaceans/Fish	Weimerskirch & Chere1 1998, Brothers et al. 2001, Schumann et al. 2014
Common diving petrel*	98 500	63 %	Crustaceans	Brothers et al. 2001, Schumann et al. 2008, Schumann et al. 2014
Fairy prion*	97 000	7 %	Crustaceans	Brothers et al. 2001, Schumann et al. 2014
White-faced storm petrel	94 500	25 %	Crustaceans	Brothers et al. 2001, Underwood 2012
Little penguin*	353 000	82 %	Fish	Cullen et al. 1992, Brothers et al. 2001, Dann & Norman 2006, Schumman et al. 2014
Australasian gannet	16 800	85 %	Fish	Bunce et al. 2002, Bunce 2001
Black faced cormorant	4 400	55 %	Fish	Brothers et al. 2001, Taylor et al. 2013
Pacific gull	1 500	82 %	Scavenge - polyvorous	Brothers et al. 2001, Leitch et al. 2014
Silver gull	50 000	35 %	Scavenge - polyvorous	Brothers et al. 2001, Leitch et al. 2014
Crested tern	10 400	13 %	Fish	Brothers et al. 2001, Chiaradia et al. 2012

*study species

2

Table 2 (on next page)

Percentage of numerical abundance of the main groups of prey recovered from stomach contents of little penguins, short-tailed shearwaters, fairy prions and common diving petrels in Central Bass Strait.

1

	Little penguin (n = 42)	Short-tailed shearwater (n = 51)	Fairy prion (n = 20)	Common diving petrel (n = 6)
Fish (%)	74.1	1.8	>0.1	-
Cephalopods (%)	4.8	0.2	-	-
Crustaceans (%)	21.1	98.0	99.9	100

2

Table 3(on next page)

Summer mean (\pm SD) $\delta^{13}\text{C}$ and $\delta^{15}\text{N}$ values (‰) in whole blood and isotopic niche metrics of little penguins, short-tailed shearwaters and fairy prions from western, central and eastern Bass Strait.

Standard ellipse area corrected (SEA_c); Bayesian standard ellipse area (SEA_B); Total convex hull area (TA). Ecological explanations for Layman metrics are provided in the Supplement. The samples were collected in summer (January-February) 2009, 2010 and 2011.

2

Figure 1

Simplified representation of the three study areas and the major water masses influencing the region.

Western Bass Strait (WBS); Central Bass Strait (CBS); Eastern Bass Strait (EBS); Lady Julia Percy Island (LJPI); Norman Island (NorI); Kanowna Island (KI); Answer Island (AI); Notch Island (NotI); Gabo Island (GI); South Australian Current (SAC); Sub-Antarctic Surface Water (SASW); East Australian Current (EAC) from Sandery & Kämpf 2005. The solid line indicates the location of the 300 m isobath.

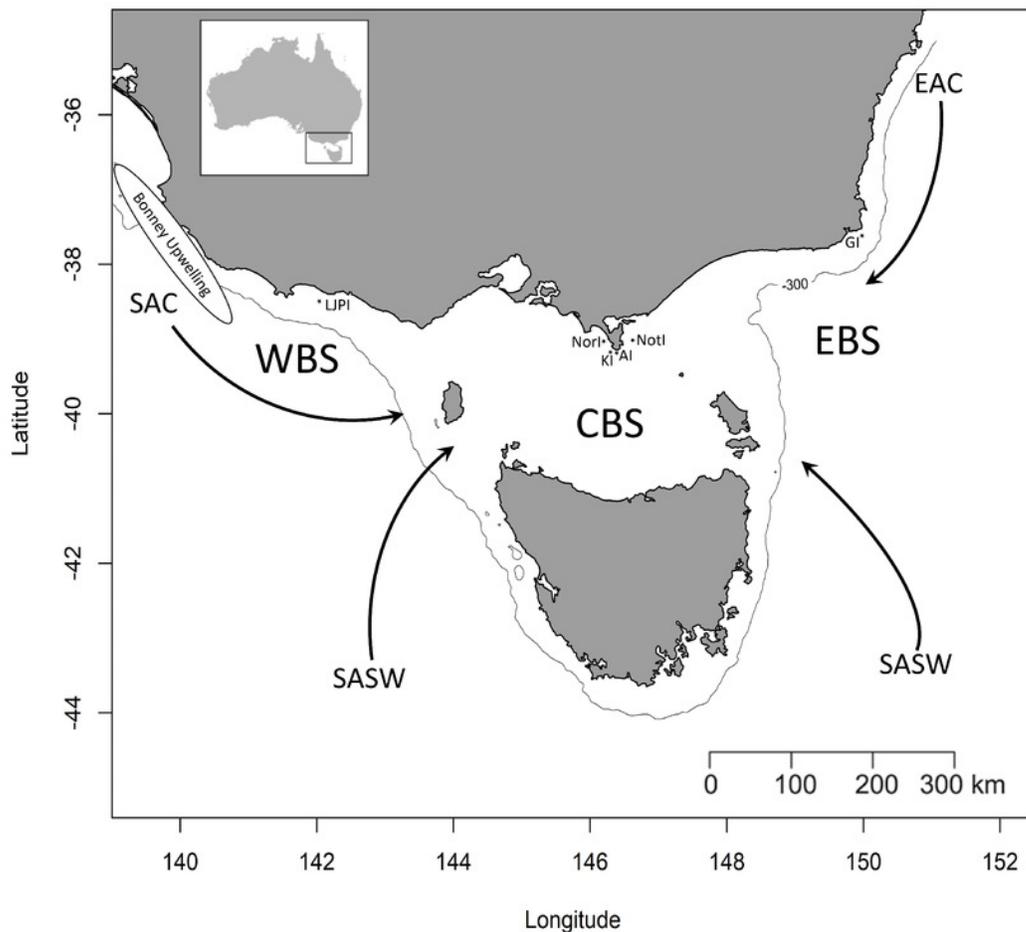

Figure 2

Summer inter-annual variation of $\delta^{13}\text{C}$ and $\delta^{15}\text{N}$ values (‰) in whole blood of little penguins, short-tailed shearwaters and fairy prions: western Bass Strait (WBS), central Bass Strait (CBS) and eastern Bass Strait (EBS).

Solid lines represent the standard ellipses corrected for sample size (SEAc) based on $\delta^{13}\text{C}$ and $\delta^{15}\text{N}$ values in summer 2009, 2010 and 2011. Note that the ranges for x and y axes are different for each species.

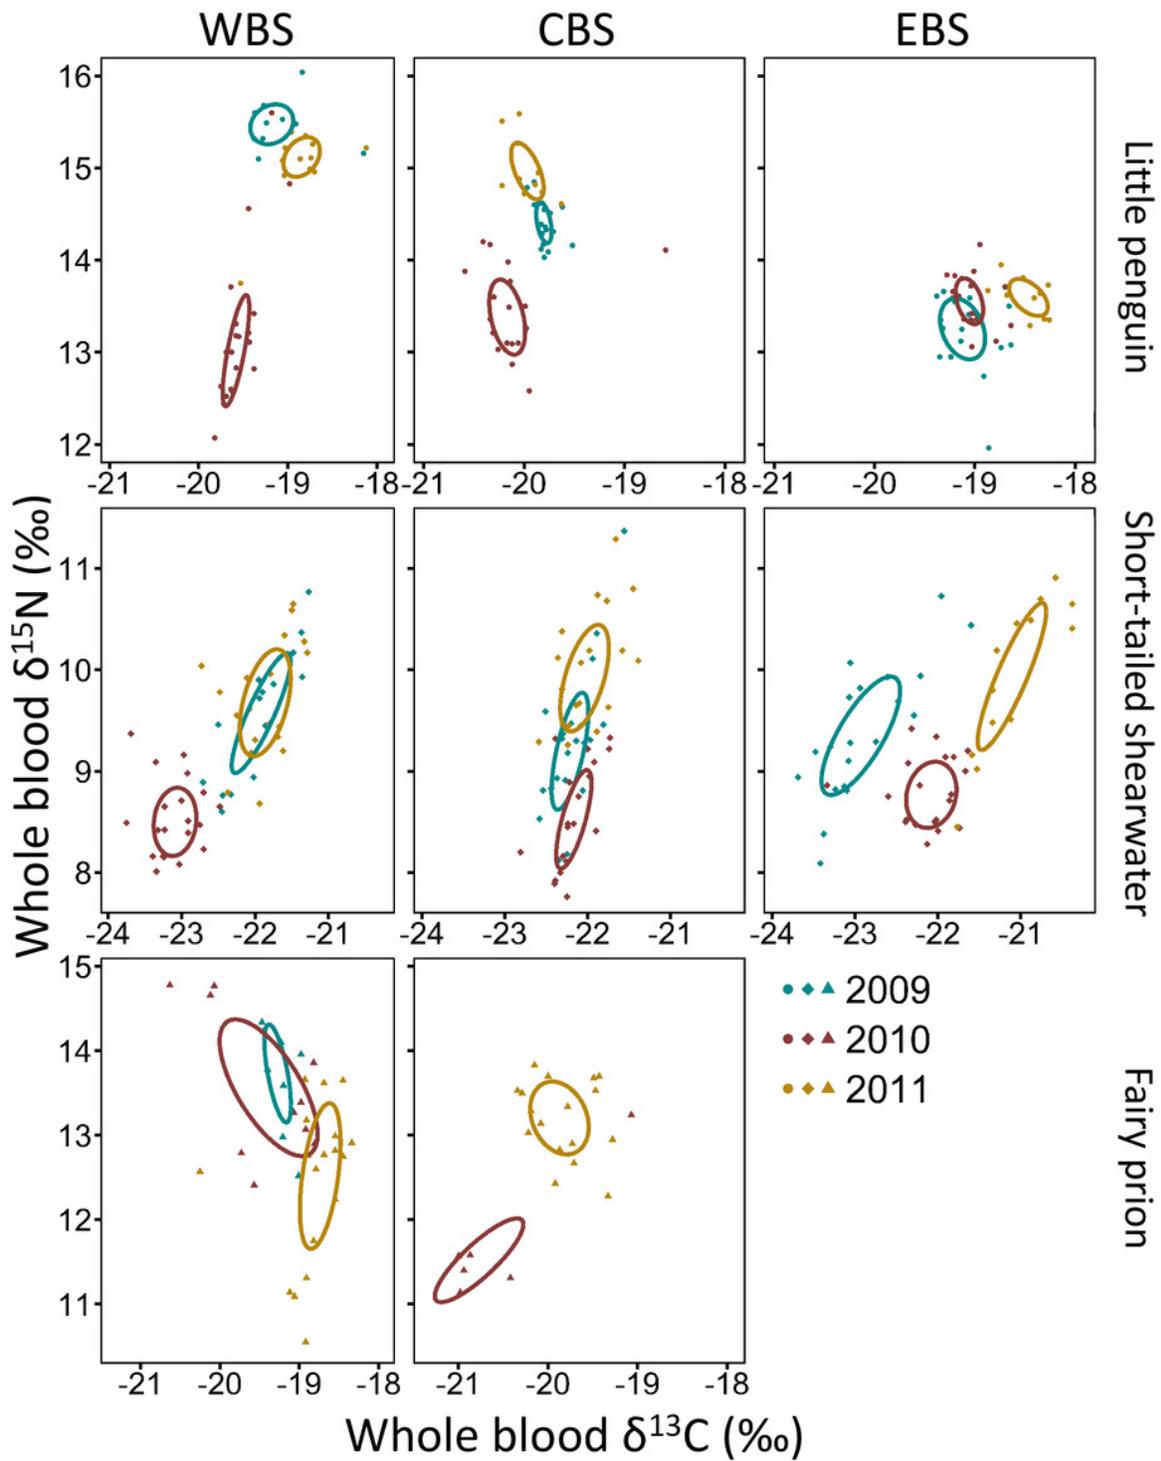

Figure 3

Winter inter-annual variation of $\delta^{13}\text{C}$ and $\delta^{15}\text{N}$ values (‰) in whole blood of little penguins and common diving petrels: western Bass Strait (WBS), central Bass Strait (CBS) and eastern Bass Strait (EBS).

Solid lines represent the standard ellipses corrected for sample size (SEAc) based on $\delta^{13}\text{C}$ and $\delta^{15}\text{N}$ values in winter 2008, 2009 and 2010. Note that the range for x and y axes are different for each species.

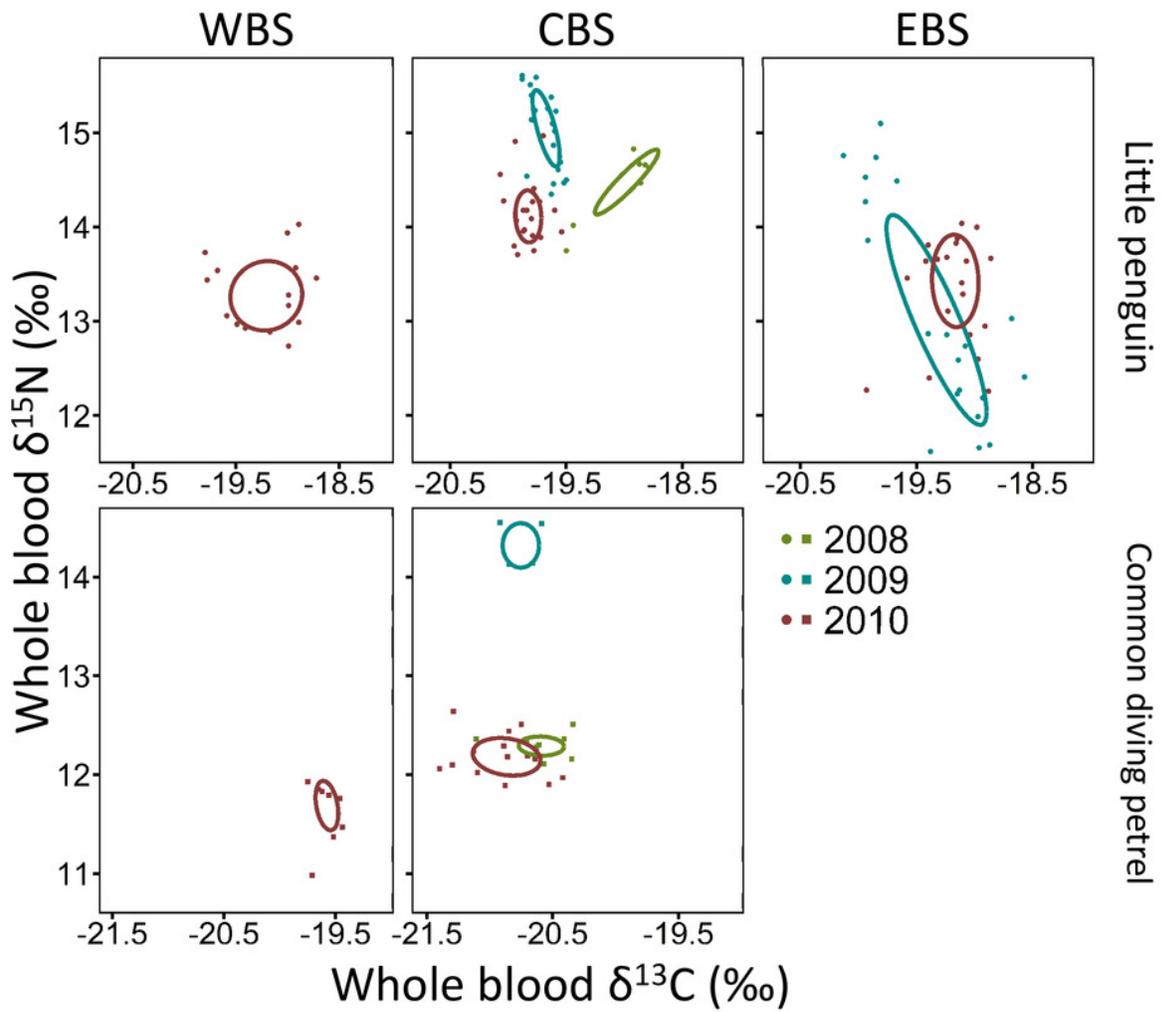

Figure 4

Summary of $\delta^{13}\text{C}$ and $\delta^{15}\text{N}$ values (‰) in whole blood of the main marine predators in Bass Strait region.

Little penguin (LP, $n = 278$; present study), short-tailed shearwater (STSW, $n = 177$; present study), fairy prion (FP, $n = 88$; present study), common diving petrel (CDP, $n = 38$; present study), Australasian gannet (GA, $n = 27$; Angel et al. 2016), white-faced storm petrel (WFST, $n = 17$; Underwood 2012), shy albatross (SA, $n = 8$; Cherel et al. 2013) and Australian fur seal (AFS, $n = 242$; Arnould et al. 2011). The isotopic values of WFST and SA were calculated from data on chick feathers (Underwood 2012) and adult feathers (Cherel et al. 2013), respectively, and corrected using mean correction factors in Cherel et al. 2014.
