Forest carbon sequestration offsets are methodologically uncertain, comprise a minor component of carbon markets and do not effectively slow deforestation. The objective of this study is to describe a commercial scale *in situ* measurement approach for determination of net forest carbon sequestration projects, the Direct Measurement Forest Carbon Protocol™, to address forest carbon market uncertainties. In contrast to protocols based on limited forest mensuration, growth simulation and exclusion of CO₂ data, the Direct Measurement Forest Carbon Protocol™ is based on standardized methods for direct determination of net ecosystem exchange (NEE) of CO₂ employing eddy covariance, a meteorological approach integrating forest carbon fluxes. NEE is used here as the basis for quantifying the first of its kind carbon financial products. The DMFCP differentiates physical, project and financial carbon within a System-of-Systems™ (SoS) network architecture. SoS sensor nodes, the Global Monitoring Platform™ (GMP), housing analyzers for CO₂ isotopologues (e.g., ¹²CO₂, ¹³CO₂, ¹⁴CO₂) and greenhouse gases are deployed across the project landscape. The SoS standardizes and automates GMP measurement, uncertainty and reporting functions creating diverse forest carbon portfolios while reducing cost and investment risk in alignment with modern portfolio theory. To illustrate SoS field deployment and operation, published annual NEE data for a tropical (Ankasa Park, Ghana, Africa) and a deciduous forest (Harvard Forest, Petersham, MA, USA) are used to forecast carbon revenue. Carbon pricing scenarios are combined with historical *in situ* NEE annual time-series to extrapolate pre-tax revenue for each project applied to 100,000 acres (40,469 hectares) of surrounding land. Based on carbon pricing of \$5 to \$36 per ton CO₂ equivalent (tCO₂eq) and observed NEE sequestration rates of 0.48 to 15.60 tCO₂eq acre⁻¹

yr⁻¹, pre-tax cash flows ranging from \$230,000 to \$16,380,000 across project time-series are calculated, up to 5x revenue for contemporary voluntary offsets, demonstrating new economic incentives to reverse deforestation. The SoS concept of operation and architecture, with engineering development, can be extended to diverse gas species across terrestrial, aquatic and oceanic ecosystems, harmonizing voluntary and compliance market products worldwide to assist in the management of global warming. The Direct Measurement Forest Carbon Protocol reduces risk of invalidation intrinsic to estimation-based protocols such as the Climate Action Reserve and the Clean Development Mechanism that do not observe molecular CO₂ to calibrate financial products. Multi-national policy applications such as the Paris Agreement and the United Nations Reducing Emissions from Deforestation and Degradation, constrained by Kyoto Protocol era processes, will benefit from NEE measurement avoiding unsupported claims of emission reduction, fraud, and forest conservation policy failure.

60 **Abstract:** Forest carbon sequestration offsets are methodologically uncertain, comprise a minor component of
61 carbon markets and do not effectively slow deforestation. The objective of this study is to describe a commercial
62 scale *in situ* measurement approach for determination of net forest carbon sequestration projects, the Direct
63 Measurement Forest Carbon Protocol™, to address forest carbon market uncertainties. In contrast to protocols
64 based on limited forest mensuration, growth simulation and exclusion of CO₂ data, the Direct Measurement
65 Forest Carbon Protocol™ is based on standardized methods for direct determination of net ecosystem exchange
66 (NEE) of CO₂ employing eddy covariance, a meteorological approach integrating forest carbon fluxes. NEE is
67 used here as the basis for quantifying the first of its kind carbon financial products. The DMFCP differentiates
68 physical, project and financial carbon within a System-of-Systems™ (SoS) network architecture. SoS sensor
69 nodes, the Global Monitoring Platform™ (GMP), housing analyzers for CO₂ isotopologues (e.g., ¹²CO₂, ¹³CO₂, ¹⁴CO₂)
70 and greenhouse gases are deployed across the project landscape. The SoS standardizes and automates GMP
71 measurement, uncertainty and reporting functions creating diverse forest carbon portfolios while reducing cost and
72 investment risk in alignment with modern portfolio theory. To illustrate SoS field deployment and operation, published
73 annual NEE data for a tropical (Ankasa Park, Ghana, Africa) and a deciduous forest (Harvard Forest, Petersham, MA,
74 USA) are used to forecast carbon revenue. Carbon pricing scenarios are combined with historical *in situ* NEE annual
75 time-series to extrapolate pre-tax revenue for each project applied to 100,000 acres (40,469 hectares) of surrounding
76 land. Based on carbon pricing of \$5 to \$36 per ton CO₂ equivalent (tCO₂eq) and observed NEE sequestration rates
77 of 0.48 to 15.60 tCO₂eq acre⁻¹ yr⁻¹, pre-tax cash flows ranging from \$230,000 to \$16,380,000 across project time-
78 series are calculated, up to 5x revenue for contemporary voluntary offsets, demonstrating new economic incentives to
79 reverse deforestation. The SoS concept of operation and architecture, with engineering development, can be extended
80 to diverse gas species across terrestrial, aquatic and oceanic ecosystems, harmonizing voluntary and compliance
81 market products worldwide to assist in the management of global warming. The Direct Measurement Forest
82 Carbon Protocol reduces risk of invalidation intrinsic to estimation-based protocols such as the Climate Action
83 Reserve and the Clean Development Mechanism that do not observe molecular CO₂ to calibrate financial
84 products. Multi-national policy applications such as the Paris Agreement and the United Nations Reducing
85 Emissions from Deforestation and Degradation, constrained by Kyoto Protocol era processes, will benefit from
86 NEE measurement avoiding unsupported claims of emission reduction, fraud, and forest conservation policy failure.

89 conservation, carbon trading, biogenic carbon, fossil fuel emissions

90 **Introduction**

91 Forest landowners and forest communities typically lack economic incentives and social benefits to balance
92 deforestation with conservation and preservation (Duguma et al., 2019). A constellation of factors is responsible for
93 deforestation (Busch & Ferretti-Gallon, 2017), claiming ~50% of tropical forested landscapes (Brancaion et al.,
94 2019; Rozendaal et al., 2019), including contested land rights, carbon project cost and requirements for landowners
95 (Kerchner & Keeton, 2015), failure of payment for ecosystem services (PES) (Fenichel, Adamowicz, Ashton, &
96 Hall, 2018; Lamb, Hansen, Bastian, Nagler, & Jones Ritten, 2019), low or negative payments resulting from the
97 United Nations Reducing Emissions from Deforestation and Degradation (REDD+) programs (Köhl, Neupane,
98 & Mundhenk, 2020), and as we argue here, uncertainty for forest carbon sequestration (Engel, Palmer, Taschini, &
99 Urech, 2015; B. D. Marino, Mincheva, & Doucett, 2019; D. Zhang, 2019). Carbon markets are primarily driven
100 by reduction/avoidance of emissions to the atmosphere from energy production and consumption (Liddle, 2018)
101 while investment in removal of CO₂ from the atmosphere by reforestation and conservation has not gained carbon
102 market traction (Gren & Zeleke, 2016; Laurance, 2007) declining by ~ 72% from 2011 to 2016 (Kelley Hamrick &
103 Gallant, 2017; Molly Peters-Stanley, Gonzalez, & Yin, 2013). Discount pricing for forest carbon (e.g., < \$5 tCO₂e,
104 2017: < 1\$, 2018) (K Hamrick & Gallant, 2018; Kelley Hamrick & Gallant, 2017) results in limited ecological,
105 social and economic benefits of carbon trading to stakeholders due, in part, from risk of offset invalidation
106 intrinsic to estimation protocols.

107
108 Estimation protocols do not directly observe forest CO₂ fluxes; terms for ecosystem photosynthesis and respiration
109 are absent unavoidably introducing uncertainty for annual net forest carbon determination and monetization to carbon
110 markets (Dunlop, Winner, & Smith, 2019; Haya, 2019; B. D. Marino et al., 2019). Invalidation risk for estimation
111 protocols stems from reliance on forest mensuration (e.g., timber survey) conducted every 6 or 12 years (California
112 Air Resources Board, 2015a; Forest Carbon Partners, 2013; Marland et al., 2017) coupled with tree growth simulation
113 models to infer annual changes in net forest carbon offsets. (California Air Resources Board, 2011, 2014, 2015b;
114 Climate Action Reserve, 2018). Forest mensuration uncertainties up to 80% for individual trees, and up to 20 % for
115 plot level estimation of annual forest carbon have been reported (Gonçalves et al., 2017; Holdaway, McNeill, Mason,
116 & Carswell, 2014; Paré, Gertner, Bernier, & Yanai, 2015) suggesting that such uncertainty is unaccounted for in
117 estimation based protocols.

118
119 Estimation based protocols including the California Air Resources Board (CARB) (California Air Resources Board,
120 2014), the Climate Action Reserve (CAR) (Climate Action Reserve, 2017), the American Carbon Registry (ACR)
121 (Winrock International, 2016), the Verified Carbon Standard (VERRA), and the Clean Development Mechanism
122 (CDM) (B. Zhang, Lai, Wang, & Wang, 2018) share offset uncertainty (Köhl, Neupane, & Mundhenk, 2020; A.
123 Kollmuss & Fussler, 2015) in the absence of direct measurement. Approximately 0.9 billion hectares of forests are
124 available worldwide for large-scale restoration opportunities (Bastin, 2019; Brancaion et al., 2019), however, in
125 addition to carbon quantification uncertainties, financing for large-scale projects has proven difficult (Foss, 2018).
126 Complete and direct carbon accounting of forests is required to track biospheric carbon dynamics given the limited
127 and impermanent nature of forest and soil carbon (Dennis Baldocchi & Penuelas, 2019; Schlesinger, 2003; Schlesinger
128 & Amundson, 2018). Here, we address forest carbon accounting uncertainties by linking direct measurement of net
129 ecosystem exchange (NEE) of forest carbon fluxes for a project with carbon market transactions in a Direct
130 Measurement Forest Carbon Protocol (DMFCP).

131
132 The objective of the DMFCP is to efficiently monetize sustainable forest management and direct revenue to
133 landowners and communities in lieu of deforestation. The DMFCP commercializes large-scale (e.g., 1+ million
134 hectares), direct, *in-situ* measurement of vertical gross forest CO₂ fluxes (e.g., photosynthesis and ecosystem
135 respiration) to determine net forest carbon sequestration or net ecosystem exchange (NEE), a universal feature of
136 NEE research platforms (D. D. Baldocchi, 2019; Dennis Baldocchi, Chu, & Reichstein, 2018; Dennis Baldocchi &
137 Penuelas, 2019; Burba, 2013; Foken, Aubinet, & Leuning, 2012b). The DMFCP, employing a network system
138 architecture, the SoS, and a sensor platform, the GMP, account for carbon from measurement-to-monetization of
139 NEE based products as described in Figures 1 (overview) and 2 (annual accounting). NEE has been measured in
140 over 600 locations worldwide ("Fluxnet," n.d.; Novick et al., 2018) but has not been utilized to support commercial
141 SoS networks for realization of verified forest carbon products and carbon market transactions. NEE,
142 notwithstanding limitations intrinsic to the methodology, offers a transformative advancement over estimation
143 protocols for annual net forest carbon sequestration that lack direct CO₂ measurement (e.g., gC m⁻² yr⁻¹). The DMFCP
144 commercial platform is described employing NEE data from two research sites, the Ankasa Park tropical rainforest
145 located in Ghana, Africa (Nicolini, 2012), and the Harvard Forest deciduous forest site located in Petersham,
146 MA, USA (Barford et al., 2001; Munger, 2016; Urbanski et al., 2007). The NEE time series data for each site, in

203 potential revenue for large-scale projects. The extrapolation of NEE data is for illustration purposes only as
204 single tower data for both sites may not be representative of larger forest areas, discussed below. Extrapolated
205 NEE values were combined with carbon prices ranging from \$5 to \$36 tCO₂eq to explore pre-tax revenue
206 scenarios including definition of hypothetical carbon products underlying the projections. Cumulative
207 tCO₂eq is based on summing the annual tCO₂eq for each annual record across the extrapolated area of 100,000
208 acres (40,469 hectares).

209 **Field Sites**

210 Ankasa Park, Ghana, Africa (Figure 3 A). The Ankasa Park (AP) eddy covariance tower (5°17'00"N
211 2°39'00"W: GH-Ank) is located in a wet evergreen forest in south-western Ghana (Fig. 3, A) (Nicolini, 2012)
212 within the Ankasa Conservation Area. The 62-meter-high AP tower equipped with an open path CO₂ analyzer was
213 developed and operated as part of the CarboAfrica project (Stefani et al., 2009) and was operational for four years
214 (2011 to 2014) by the University of Tuscia, Italy (Nicolini, 2012). NEE data used in this analysis are available
215 online from the Fluxnet2015 quality-checked database ([http://fluxnet.fluxdata.org/data/fluxnet2015-](http://fluxnet.fluxdata.org/data/fluxnet2015-dataset/)
216 dataset/) as annual NEE based on the gap filled VUT_NEE_REF values (e.g., Wutzler, Lucas-Moffat, Migliavacca,
217 Knauer, Sickel, Šigut, Menzer, & Reichstein, 2018). The NEE data are gap-filled, filtered and corrected for low
218 friction velocity periods that likely underestimate night time respiration ("Data Processing - Fluxdata," n.d.; Fluxnet,
219 2019; Nicolini, 2012). Uncertainty for the corrected AP 30-minute NEE data was reported as 0.20 μmol m⁻² s⁻¹ or 6.7
220 % of the daily means (Nicolini, 2012). The Ankasa Resource Reserve, established in 1934 (Hall & Swaine, 1981),
221 lies within the administrative rule of the Jomoro district in the Western region of Ghana and is under the paramount
222 chief of Beyin (Bandoh, 2010). The reserve was managed as a protected timber producing area until 1976 at which
223 time it was designated as the Ankasa Resource Reserve (Damnyag et al., 2013). The forest area is comprised of
224 ~500 km² surrounded by deforested landscapes; the area is ~90m above sea level with mean annual temperature of
225 ~25°C. According to Hawthorne & Abu-Juam (1995), the Ankasa Resource Reserve has an average Genetic Heat
226 Index (GHI) of 301, compared to a maximum of 406 (Janra & Aadrean, 2018; Vanclay, 1998), designating the reserve
227 as a global priority conservation area that should be permanently removed from timber production. Hilly portions
228 of the reserve showed the highest GHI score of 406 (Hawthorne & Abu-Juam, 1995). The high GHI scores in Ghana
229 are amongst the "hottest" patches of genetic rarity in Africa, many of the species concerned being found elsewhere
230 only across the border in Southern La Cote D'Ivoire. Official records on timber logging activities in the Ankasa
231 Resource Reserve are incomplete as the management objective has been primarily for protection and resource
232 conservation, however, illegal logging in the reserve may have occurred during the period of observation. Poor soils
233 of the area have generally discouraged commodities (i.e. cocoa) production and food farmers. The population
234 around the reserve has been historically low for a forest area (Hall & Swaine, 1981), but has experienced dramatic
235 population increase. For example, in 1960, the estimated population was 45,162 but declined to 37,685 by 1970. The
236 results of Ghana's 1984 population census recorded a jump in population of 70,881, an increase of 88%. According
237 to the 2000 population census, the population of the Jomoro district had increased significantly to 111,348 an
238 increase of 57% since 1984 (Bandoh, 2010). In the recent 2010 census, the population recorded for the district was
239 150,107 (Bandoh, 2010) representing an increase of 34%. The red color in Figure 3 A, denoting deforestation over
240 approximately the last decade, illustrates the anthropogenic pressure the reserve faces in the future.

241
242 Harvard Forest, Petersham, MA, USA (Figure 3 B). The Harvard Forest (HF) Environmental Measurement Site tower
243 (42.537755°N, 72.171478°W; US-Ha1) is a component of the Harvard Forest Long Term Ecological Research
244 (LTER) site in Petersham, Massachusetts (*Harvard Forest Long Term Ecological Research Site*, 2019) and a core site
245 in the AmeriFlux network (US-Ha1). The elevation of the research area of ~16.18 km² ranges from 320 to 380 meters
246 above sea level (Fig. 1a). NEE data used in this analysis are available online from the Fluxnet2015 database
247 (<https://fluxnet.fluxdata.org/doi/FLUXNET2015/US-Ha1>). Additionally, current data are available from AmeriFlux
248 data repository (<http://dx.doi.org/10.17190/AMF/1246059>) and LTER data archives (Environmental Data Initiative;
249 <https://doi.org/10.6073/pasta/74fe96d1571db7f15bf6f1c4f53c0c02>). The HF tower measurements, initiated in Oct
250 1991 with closed path CO₂ analyzers, provide the longest continuous set of flux measurements in the US (Barford
251 et al., 2001; Urbanski et al., 2007). The mixed deciduous forest stand surrounding the tower has been regenerating
252 on abandoned agricultural land since the late 1890's punctuated by a major hurricane disturbance in 1938. The
253 Harvard Forest, US-Ha1 data are NEE quality-checked (e.g., Pastorello et al., 2014), gap-filled, filtered and corrected
254 for low friction velocity periods (e.g., friction velocity (u*) less 0.4 m/s) that underestimate nighttime respiration flux
255 (e.g., Urbanski 1996). Uncertainty for US-Ha1 gap-filled data for the years 1992-2004 was reported as ± 0.03 tCO₂
256 yr⁻¹ (95% Confidence Interval) relative to a mean NEE for the period of -2.42 tCO₂ ha⁻¹ yr⁻¹, determined by random
257 sampling of NEE error populations (Richardson et al., 2006; Urbanski et al., 2007). US-Ha1 data are corrected for

258 horizontal advection of CO₂ reported of up to 35% of the CO₂ budget during summer intervals from 1999 to 2002
259 (Staebler and Fitzjarrald, 2004) and up to 40% loss of daytime CO₂ flux depending on wind speed (Sakai, Fitzjarrald
260 and Moore, 2001). Corrections are routinely applied to account for incomplete flux emphasizing the importance of
261 understanding site conditions at each location to assess optimal and representative flux results. The dataset was read
262 in line by line and processed using Python Libraries (Pandas, NumPy) with txt format. Year, month, day, hour and
263 NEE data were selected for this study. NEE was determined by calculating the mean of 48 half-hour data for each
264 day as $\mu\text{mol CO}_2 \text{ m}^{-2} \text{ s}^{-1}$, converting the value to $\text{gC m}^{-2}\text{d}^{-1}$, and summing daily NEE to calculate annual NEE for each
265 year. The US-Ha1 NEE data over the period of record (e.g., 2000 – 2019) has been interpreted in the context of
266 historical land use including agriculture, reforestation and hurricane disturbance, demonstrating the impact of weather,
267 climate and human activity on NEE (Cogbill, 2000; Compton and Boone, 2000; Barford *et al.*, 2001; Bellemare,
268 Motzkin and Foster, 2002; Urbanski *et al.*, 2007). The Harvard Forest project area has been studied using a variety of
269 remote sensing data to assess species composition across the project area and to understand short and long term
270 responses to climate change (Kim *et al.*, 2018). Hyperspectral and lidar data (<https://glihtdata.gsfc.nasa.gov/>) (e.g.,
271 Kampe 2010), Airborne Visible InfraRed Imaging Spectrometer (AVIRIS) imagery
272 (<https://aviris.jpl.nasa.gov/dataportal/>), and Landsat data (Melaas *et al.*, 2016) are also available for the US-Ha1
273 project area.

274
275 DMFCP Technical Description. The DMFCP is comprised of hardware and software components designed
276 to function as an automated commercial field sensor network (Figures 1, 2), the System of Systems. (B.
277 D. V. Marino, 2011, 2012, 2016c, 2016d, 2017a, 2017b, 2017c, 2018a, 2018b, 2018c, 2019, 2013, 2014a, 2014b,
278 2014c, 2015a, 2015b, 2016a, 2016b). An integrated sensor platform, the Global Monitoring Platform, is
279 positioned at each node of the network. The Software components of the SoS are configured to interact
280 with all nodes for automated reporting of data and instantaneous third-party verification of systems,
281 processes, uncertainties and results. The SoS summarizes measurements of GHG fluxes against local,
282 regional and global reference materials for bulk and isotopic composition, providing the basis for
283 calculation of verified tradeable GHG financial products for forests and anthropogenic net carbon fluxes
284 for fossil fuel derived CO₂. The DMFCP provides the operational framework for underlying contract terms defining
285 project time periods, land area, management objectives, measurements and cases for intentional and unintentional
286 forest carbon reversals, conditions beyond the scope of this study. Additional details for the SoS, GMP and related
287 field equipment for NEE flux determinations, in addition to typical project agreement and contract terms, are described
288 in Supplement S1. A comparative summary of the features and benefits of the DMFCP and widely employed
289 estimation protocols is presented in Table 1.

290 291 **Results**

292 Figure 4 illustrates the annual (tCO₂eq) NEE for HF (24 years) and AP (4 years) sites relative to a zero-reference
293 baseline established by instruments (i.e., open or closed path CO₂ analyzers) and standard calibration protocols at
294 both sites and to a zero-emissions baseline defining negative (e.g., net CO₂ sequestered), positive (e.g., net CO₂
295 emissions released to the atmosphere) or neutral carbon balance (e.g., 0 sequestration/emissions). Annual NEE
296 values for HF and AP were negative over the intervals shown resulting from active forest carbon sequestration and
297 generation of carbon credits (Figure 4 A). Annual NEE for HF ranged from a minimum of -0.53 (2010) to a
298 maximum of -9.09 (2008) tCO₂. The mean and standard deviation (SD) for the HF site for 24 years was -4.5 tCO₂
299 $\text{acre}^{-1} \text{ yr}^{-1} \pm 2.3$ (SD). Annual NEE for AP ranged from a minimum of -6.74 (2013) to a maximum of -15.2
300 (2011) tCO₂. The mean and standard deviation (SD) for the AP site for 4 years was -10.2 tCO₂ $\text{acre}^{-1} \text{ yr}^{-1} \pm 3.6$
301 (SD). Pre-tax revenue annual variance and risk are illustrated in the HF 2010 NEE (Fig. 2a), emphasizing a reversal
302 of $+4.79$ tCO₂eq relative to 2009, equivalent to a one-year loss of \$4,790,00 (\$10 tCO₂eq), but again reversed the
303 following two years attaining -5.04 tCO₂eq and revenue of \$4,510,000 (\$10 tCO₂eq). Figure 4 (B) shows the
304 corresponding cumulative NEE across the observational periods recorded for each site extrapolated to 100,000
305 acres (40,469 hectares). The HF and AP linear cumulative NEE provides insight into the potential short and long-
306 term sequestration capacity of the respective forest landscapes. The AP NEE slope of $-8.40x$ is 1.7 times that of the
307 HF suggesting that in this case, the tropical wet evergreen forest site experienced consistently greater sequestration
308 of carbon than the temperate deciduous forest. However, caveats apply in that tropical forests may not result in
309 larger long-term carbon sinks, nor is continued net negative carbon sequestration guaranteed or required for forest
310 carbon trading markets. For example, tropical forests typically have larger gross production but a corresponding
311 larger respiration (Dennis Baldocchi, Chu, & Reichstein, 2018; Dennis Baldocchi & Penuelas, 2019). Additionally,

312 the two forest locations differ in stand age and history of disturbance, factors that are known to affect NEE
313 (D. Hollinger, Davidson, Richardson, Dail, & Scott, 2013; Ouimette et al., 2018; Urbanski et al., 2007). However,
314 NEE provides a quantitative record of daily and annual sums of carbon sequestration characterizing the
315 fundamental nature of derivative carbon products that cannot be replicated by proxies for forest carbon
316 sequestration (e.g., estimation-based protocols). Annual NEE trends may also be difficult to characterize for sites with
317 less than five years of NEE data emphasizing the importance of establishing new and sustained NEE observation
318 platforms (D. D. Baldocchi, 2019; Dennis Baldocchi et al., 2018).

319 Figure 5 illustrates landowner pre-tax cash flow (millions USD) relative to variable carbon pricing of tCO₂eq (\$5,
320 \$10, \$15, \$36) for cumulative NEE consisting of 24 and 4 years for the HF and AP sites, respectively. The values
321 represent extrapolations of measured local NEE to 100,000 acres (40,469 hectares) multiplied by the annual NEE
322 record for each site. Two cases are represented in which the landowner receives a single upfront payment (Case
323 1) or an upfront payment plus annual royalty on sales (Case 2). Case 1 pre-tax cash flow estimates range from upfront
324 payments (e.g., 10%) of \$230,000 to \$1,670,00 and \$510,000 to \$3,680,000 for HF and AP, respectively, across
325 carbon prices of \$5 to \$36 tCO₂eq. Case 2 pre-tax cash flow estimates range from an upfront payment (e.g., 8%)
326 plus deferred payouts based on realized revenue from the sale of all carbon products (e.g., 6%) of \$3,520,000 to
327 \$25,360,000 and \$1,640,000 to \$11,790,000 for HF and AP, respectively, across carbon prices of \$5 to \$36 tCO₂eq.
328 A variance for the total pre-tax sales value of ± 20% of realized revenues is indicated by vertical bars to reflect
329 uncertainty in the sale of carbon products for Case 2.

330
331 Figure 6 illustrates cases of pre-tax cash flow change for a decrease/increase in native carbon sequestration strength
332 based on the minimum, mean and maximum values of NEE observed for each site's historical record (extrapolated
333 to 100,000 acres or 40,469 hectares). Local sequestration strength is expected to vary annually in response to
334 rainfall and related ecological factors. We use the minimum, mean and maximum values for NEE recorded at each
335 site to illustrate the effect of annual sequestration rate on pre-tax revenue. Project value ranges from \$760,000
336 to \$13,830,000 and from \$2,140,000 to \$4,860,000 across the minimum, mean and maximum values for the annual
337 records of the HF and AP sites, respectively.

338
339 Figure 7 illustrates pre-tax cash flows for mixed carbon product types and pricing for Case 2; example product
340 inventory and pricing for the products is indicated below each set of bars. Note that the hypothetical carbon
341 products range in price from \$12 tCO₂eq for compliance offsets to \$50 tCO₂eq for carbon products with the
342 additional element of biodiversity (e.g., Genetic Heat Index and conservation of floral and faunal species). Total
343 pre-tax cash flow for Case 2 is \$16,380,000 and \$7,610,000 for the HF and AP sites, respectively. These data
344 illustrate the higher potential revenue based on sale of mixed products and pricing for voluntary, compliance and
345 regulatory markets. The vertical bars for Case 2 represent 20% variance in market uncertainty.

346 Discussion

347
348
349 The SoS and DMFCP features continuous eddy covariance measurements for determination of NEE for forest
350 carbon providing standardized commercial methods and operations (Figures 1 and 2) in contrast to estimation based
351 protocols that do not observe CO₂ assimilation via photosynthesis or efflux via respiration. Shared calibration of
352 instruments and reliance on a shared zero-emissions flux baseline (e.g., carbon negative, neutral or positive) ensures
353 that all analyzers and results (e.g., SoS and GMP sensor nodes) within a network or between networks (e.g., SoS)
354 are comparable, inclusive of analytical uncertainties (Table 1). The near real-time data (i.e., 30-minute average of
355 10 Hz CO₂ measurements) for forest NEE achievable with the eddy covariance sensor of the DMFCP offers insights
356 into forest carbon dynamics and ecosystem function previously unavailable to landowners, investors and related
357 stakeholders (D. D. Baldocchi, 2019). The result is a first of its kind pooled portfolio of diverse forest projects and
358 harmonized products for sale to voluntary and compliance buyers worldwide transacted as tCO₂eq (Figures 1, 2). The
359 DMFCP incentivizes forest conservation efforts, communities and management of atmospheric CO₂ emissions
360 compared to estimation-based protocols (Table 1) and REDD+ platforms that rely on such protocols (Köhl, Neupane,
361 & Mundhenk, 2020). NEE uncertainties can be quantified and corrected for each project (e.g., single, multiple
362 networks) according to established and evolving methods within the forest carbon research community (e.g., Vitale,
363 Bilancia and Papale, 2019b), particularly in conjunction with remotely sensed data. Commercialization of established
364 forest carbon research methodologies is feasible and applicable to forest projects worldwide.

365

366 The NEE sites described in this work representing tropical and deciduous forests, when pooled as a portfolio,
367 provide species and ecological diversification with respect to NEE source strength, vulnerability to climate change,
368 population pressure and external risks (e.g., currency value, national/sub-national environmental regulation)
369 (Tarnoczi, 2017), a common investment risk reduction approach employed in modern portfolio theory (Busby,
370 Binkley, & Chudy, 2020; Paut, Sabatier, & Tchamitchian, 2020). For example, while HF experienced the lowest NEE
371 during 2010 ($-0.59 \text{ tCO}_2 \text{ acre}^{-1} \text{ yr}^{-1}$, $-0.4 \text{ tC ha}^{-1} \text{ yr}^{-1}$), a period known to be associated with anomalous drought and
372 up to 86% respiration relative to gross primary productivity (Gonsamo, Croft, Chen, Wu, & Staebler, 2015; Munger,
373 Whitby, & Wofsy, 2018), AP experienced the highest NEE of the available record ($-15.2 \text{ tCO}_2 \text{ acre}^{-1} \text{ yr}^{-1}$, 10.2 tC ha^{-1}
374 yr^{-1}), in part offsetting the HF loss. A portfolio with diverse projects would be similarly buffered from extreme
375 changes. Landowner agreements and contracts could also specify options for aggregation of annual data intervals to
376 buffer extreme weather conditions (excluding catastrophic events such as wildfire, multiyear drought, and hurricane)
377 (see Supplement S1). The upfront and royalty revenue structure resulting from sale of DMFCP products, proposed
378 in this study, provide financial incentive for the landowner to rapidly enter into reforestation and forest
379 management projects in lieu of deforestation (e.g., legal and illegal) and increased anthropogenic disturbance. Given
380 the high rates of population growth within the AP reserve area (~298% population increase from 1970 to 2010),
381 revenue programs may be uniquely suited for preservation and management of protected areas in conjunction with
382 community based efforts (e.g., Bempah, Dakwa and Monney, 2019). Long-term forest carbon projects are likely to
383 increase harvest ages and management of forest stocking for optimal forest growth while promoting carbon benefits
384 of active sustainable forestry (Bastin, 2019; R. Chazdon & Brancalion, 2019; R. L. Chazdon, 2008). Enhancement
385 of biodiversity, food webs and cultural engagement may also accrue as forests grow (Bremer et al., 2019; Li et al.,
386 2019; Watson et al., 2018). Conservation and commercial forestry operations, although likely to have different goals,
387 are accommodated by the features and benefits of the DMFCP for effective carbon management.
388

389 The hypothetical financial structure and cases for pre-tax revenue potential for landowners illustrate the potential
390 impact of the DMFCP. The long-term cumulative value of both sites, shown in Figures 4 (B) and 7 (e.g., Total
391 revenue from mixed products and pricing), benefit landowner property valuation and reduces cost of delayed
392 reforestation in-line with indices for value of timber land operations (Ferguson, 2018; Keith, Vardon, Stein, &
393 Lindenmayer, 2019; D. Zhang, 2019). Figure 7 emphasizes the revenue potential of mixed forest carbon products
394 incorporating features of project biodiversity, such as noted for AP by high Genetic Heat Indices of up to 401
395 (Hawthorne & Abu-Juam, 1995), and allocation of offsets for specific markets. Pre-tax revenue for mixed carbon
396 products and pricing is projected at up to \$16,380,000 for the HF over the 24-year period (Figure 6), an ~5x and ~2x
397 return compared to pricing of \$5 and \$10 tCO_2eq (Figure 5, Case 2), respectively, covering voluntary and compliance
398 carbon pricing levels (K Hamrick & Gallant, 2018; World Bank and Ecofys., 2018). The two sites, irrespective of the
399 differing time-series length, actively sequester carbon at different rates; it is not known if the observed trends will
400 reverse as a result of climate change and/or anthropogenic activity. The requirement for long term CO_2 measurement
401 cannot be understated for determination of variance in annual changes of NEE and for creation of corresponding
402 annual forest carbon financial products resulting from NEE (Dennis Baldocchi & Penuelas, 2019; B. D. Marino,
403 Mincheva, & Doucett, 2019; Munger, Whitby, & Wofsy, 2018). For present purposes we assume that 100% of the
404 products are sold in each case covering the cost of the DMFCP.

405
406 There is no single figure of merit for NEE uncertainty. One of the main concerns with eddy covariance based NEE,
407 applicable to establishing networks of eddy covariance towers as proposed, is the upscaling of limited footprints for
408 individual EC towers to surrounding ecosystems (Table 1, #22) (D. Baldocchi, 2003; Kumar, Hoffman, Hargrove, &
409 Collier, 2016; Ran et al., 2016; Román et al., 2009). Up-scaling is particularly important for mixed forest projects
410 wherein changing wind direction alters the source weight of heterogeneous land cover (Kim, Hwang, Schaaf, Kljun,
411 & Munger, 2018) and remains a challenge to large-scale NEE determinations including use of very tall towers (e.g.,
412 > 300m) and mesonet configurations to expand eddy covariance footprints (Andrews et al., 2014; Chi et al., 2019;
413 Goulden et al., 2006). SoS architecture and sensor placement details will vary for each project addressing sources of
414 uncertainty established by initial survey and temporary placement of SoS platforms for evaluation. Scale-up of eddy
415 covariance flux tower data combined with remote sensing data is under active study and directly relevant to developing
416 approaches for the SoS (Fang, Lei, Zhang, Quan, & Yang, 2020; Kenea et al., 2020; Peltola et al., 2019; Xiao et al.,
417 2008). In actual DMFCP implementation for HF and AP sites reported here (Figure 3), remote sensing data would be
418 used to establish reliability of data extrapolation from a single tower and to guide the placement of additional towers
419 to fill spatial gaps in NEE measurement. A minimum two-tower configuration or paired GMP sensor nodes for larger
420 networks, would provide redundancy and cross-checks to report SoS NEE combined uncertainty (e.g., He *et al.*, 2010;

421 Post *et al.*, 2015; Griebel *et al.*, 2020). In addition, the use of open source eddy covariance processing software such
422 as ONEFlux (<https://ameriflux.lbl.gov/data/download-data-oneflux-beta/>; see Supplement S1, Eddy Covariance) and
423 commercial software (e.g., https://www.licor.com/env/products/eddy_covariance/software.html), applied uniformly
424 across the SoS would harmonize data treatment including uncertainties for CO₂ and CH₄ flux (e.g., Richardson *et al.*,
425 2019).

426
427 Accepting NEE uncertainties (e.g., Methods section), we argue that the approach is a game-changer for creation and
428 verification of forest carbon financial products compared to estimation and model simulation-based protocols. For
429 example, terms defined in (1) and (2) (Methods section) are not defined or measured in estimation protocols (e.g.,
430 CARB, CAR, CDM, ACR), unavoidably introducing fundamental uncertainties in NEE rendering the basis for
431 reporting gC m⁻² yr⁻¹ for NEE as problematic and unverifiable (B. D. Marino, Mincheva, & Doucett, 2019). Moreover,
432 interpreting estimation based timber inventory protocols as representing only above ground carbon (e.g.,
433 photosynthetic assimilation) likely results in over crediting errors given that ecosystem respiration accounts for up to
434 ~82% of gross carbon flux from the soil to the atmosphere (Dennis Baldocchi & Penuelas, 2019; Bond-Lamberty,
435 Bailey, Chen, Gough, & Vargas, 2018; Giasson *et al.*, 2013; Richardson *et al.*, 2013). The HF year 2010 demonstrates
436 the requirement for ecosystem respiration measurement for NEE. NEE establishes 30-minute flux data comprising
437 detailed baseline resolved time-series for each project yielding annual mean data based on 17,520 such intervals for
438 each CO₂ analyzer. To our knowledge, estimation protocols have not been directly compared with CO₂ measurements,
439 or peer reviewed, (e.g., California Air Resources Board, 2011, 2014, 2015) limiting scientific acceptance and
440 demonstrating a need for improved and peer reviewed NEE methods.

441
442 In addition to potential revenue for landowners, the DMFCP simplifies the forest carbon protocol process
443 compared to traditional approaches that differ in methods, assumptions and allowance for discretionary
444 revisions (A. Kollmuss & Fussler, 2015; B. D. Marino *et al.*, 2019). A summary of DMFCP protocol features and
445 benefits to landowners is provided in Table 1, with reference to Figures 1, and 2. Equivalent units of tCO₂e_q or
446 units as converted are employed for the DMFCP and traditional protocols (#1), noting that estimation protocols do
447 not report carbon sequestration according to project area, potentially misleading landowners. Items #2 - 7 have
448 been covered above, defining the insuperable differences between direct measurement of CO₂ versus the use
449 of proxies (i.e., CO₂ is not directly observed at any time in the estimation protocol process) that do not provide
450 data for quantifying NEE (e.g., ecosystem photosynthesis and respiration) according to accepted universal scientific
451 practice (i.e., Item 4, Table 1, equations (1) and (2), Methods section).

452
453 Revenue and time-to-revenue are key factors in landowner forest carbon project participation. Traditional protocols
454 (e.g., CAR, CDM) require lengthy periods (e.g., 2-5 years) of fee-based project certification and registration
455 prior to payment, limiting landowner participation (Kerchner & Keeton, 2015; Köhl, Neupane, & Mundhenk,
456 2020). In contrast, the DMFCP process can provide an upfront payment and annualized payment (e.g., case 2,
457 Figures 5, 7) in a no-fee agreement (Figure 2) available immediately according to a governing agreement (e.g.,
458 contract) that also include no-fee listing in an open source registry (summarized by #8,9,10, Table I). The
459 DMFCP embodied in the SoS and GMP obviates three features intrinsic to traditional protocols including
460 elimination of baseline estimation (#11), tests for additionality (#12), and a multiyear invalidation period (#13)
461 linked to compliance testing and third-party verification (#14). Direct measurement establishes forest carbon flux
462 as either negative (e.g., CO₂ sequestration), positive (e.g., CO₂ efflux), or zero (sequestration balances efflux)—
463 measurements cannot be made retrospectively. It follows that a zero-emissions baseline is intrinsic to a time-series
464 of positive/negative/zero NEE measurements (Figure 2 A) integrating forest tree species, vegetation and carbon
465 fluxes across and within the project area including all above and below ground carbon fluxes (DiRocco, Ramage,
466 Evans, & Potts, 2014; Urbanski *et al.*, 2007). DMFCP carbon accounting is not subject to uncertainty related to
467 selection for species distribution and growth simulation models typical of traditional protocols (A. Kollmuss &
468 Fussler, 2015). Additionality tests require a counterfactual argument (Ruseva *et al.*, 2017) that cannot be validated
469 and is subject to discretionary adjustment. A credit is considered additional if the emissions reduction that underpins
470 the credit would not have occurred in the absence of the activity that generates the credit (A. Kollmuss & Fussler,
471 2015). In contrast, the DMFCP results in near-real time (30-minute average of 10 Hz measurements) NEE time
472 series and trends (Dou & Yang, 2018), obviating reliance on uncertain project scenarios and an impractical prediction
473 of future emissions against possible forest disturbance. Further, tests of net emission reduction across project areas
474 or jurisdictions for specified periods of time can be readily calculated from DMFCP results for independent
475 projects, establishing simple numerical additionality (Figure 2 B) rules for established private and public
476 lands, as could be adopted by municipal and private entities. The DMFCP does not require an invalidation

477 period (# 13) compared to estimated forest carbon offsets. In contrast to long inspection intervals for traditional
478 forest carbon protocols (e.g., 6 or 12 years; California Air Resources Board, 2011, 2015), the DMFCP results are
479 subject to instantaneous invalidation by third party inspection and routine flags for anomalous operation within the
480 SoS. The DMFCP is subject to replication of equipment and system performance standards, precision and
481 accuracy of universal references and review of NEE from raw data to financial products at any time. The DMFCP
482 employs a real-time wireless reporting and verification concept of operations architecture including third-party
483 independent observers of all data developed for each SoS network (Anadiotis, Galluccio, Milardo, Morabito, &
484 Palazzo, 2019) with invalidation authority (#13). In contrast, third party validation for CAR projects, for example,
485 is based on desk and paper review of unobserved CO₂ (e.g., proxies) and are not readily amenable to spontaneous
486 invalidation testing and enforcement.

487
488 Once a project is in operation, a switch from carbon negative to carbon positive ecosystem function is key to project
489 management, revenue projections, accounting and contract terms and to an understanding of ecosystem function in
490 relation to climate change and anthropogenic activity. Traditional forest carbon protocols do not appear capable of
491 determining when a forest project switches to net positive emissions to the atmosphere on an annual basis; the
492 DMFCP NEE measurements provide this diagnostic (#15). Item #15 is also linked to demonstration of
493 project permanence (#16) and termination of a project (#17). Traditional protocols require an arbitrary 100-
494 year period of monitoring and maintenance for project carbon with a punitive penalty for early termination; lack
495 of CO₂ measurement renders both factors indeterminate, impractical and biased against the landowner. The
496 DMFCP employs ton-year accounting, an IPCC recognized method that does not impose an artificial time
497 horizon for tree growth (e.g., 100 years) opening forest carbon sequestration projects to a wider range of forest
498 project types and project intervals (Cunha-e-Sá, Rosa, & Costa-Duarte, 2013; Levasseur, Lesage, Margni, Brandão,
499 & Samson, 2012). The ton-year accounting method accommodates combined budgets of CO₂, CH₄ and N₂O
500 resulting in a comprehensive and realistic project net GHG budget (Alice Courtois et al., 2019; Richardson et al.,
501 2019), an approach that can be applied to the spectrum of projects from pure conservation to working forests, however,
502 not achievable with estimation-based forest carbon denominated protocols.

503
504 Items 1 to 17 for existing protocols address two key factors favoring deforestation engagement: transaction
505 requirements and liquidity. Forestland as a timber asset requires long periods of growth to harvest and is generally
506 financially illiquid until harvested (Mei, 2015). It is argued here that business development of forest carbon projects,
507 as practiced according to traditional protocols, is overly cumbersome and lengthy to establish offset transactions,
508 and financially inviable to compete with the short time intervals of deforestation often resulting from illicit transactions
509 (Alam, Herawati, Hidayat, & Wyatt, 2019; Tacconi, Rodrigues, Maryudi, & Muttaqin, 2019; Tellman, 2016). In
510 addition, with the use of satellite imagery, illegal and non-conforming deforestation can be detected in near real-
511 time, with spatial resolution of meters limiting potential gaming of the system and uncertainty in the sources of CO₂
512 flux (Hayek et al., 2018; Tang, Bullock, Olofsson, Estel, & Woodcock, 2019). Rapid set-up of the SoS direct
513 measurement platform, no-fee based agreements, upfront and annualized payments, discrete revenue intervals of 10
514 years, and reasonable exit terms align landowner business operations (private and commercial) within realistic
515 financial frameworks to potentially deter rapid deforestation within culturally diverse transactional and
516 transnational frameworks (Fenichel, Adamowicz, Ashton, & Hall, 2018). Additional points of comparison
517 concern the limitation of traditional protocols to accommodate the spectrum of relevant GHG's (e.g., N₂O, CH₄,
518 PFC's, HFC's, SF₆, NF₃) (#18), isotopologues of GHG's (e.g., ¹³CO₂, ¹⁴CO₂) (#19), the inclusion of aquatic
519 features (e.g., rivers, lakes ponds, wetlands, oceans) (#20) and the lack of contribution to ecosystem science and
520 climate change studies and models (#21). Traditional forest carbon protocols (A. Kollmuss & Fussler, 2015)
521 were developed for singular application to forests, incorporating methodology employed for timber management and
522 primarily restricted to capturing above ground carbon. As a result, algorithms developed for forest CO₂ are not
523 readily applicable to other GHG species and diverse biospheric landscapes. Based on the comparisons, the
524 insuperable shortcomings of traditional protocols do not provide data that contribute to the evolving science
525 of forest carbon sequestration, climate change studies and related model development that are well established in
526 the growing NEE methodology (D. D. Baldocchi, 2019). Climate change impacts on forest carbon storage are not
527 included in project risk for estimation based protocols (California Air Resources Board, 2015b) even though soil
528 carbon efflux over the 100-year required period is likely to respond to global warming and changes in precipitation
529 (Amundson & Biardeau, 2018; Bond-Lamberty, Bailey, Chen, Gough, & Vargas, 2018; Schlesinger & Amundson,
530 2018).

531

532 The DMFCP can be applied to international emission reduction policies recognizing scientifically accepted methods,
533 shared data processing algorithms, elucidation of uncertainties (#22), standardized terms and contracts for voluntary
534 and compliance offsets (#23, Supplement S1) including clauses for reversal of net forest carbon sequestration due to
535 intentional or unavoidable natural conditions (e.g., fire, hurricane, drought). For example, the expansion of
536 measurement networks, data integration and carbon trading are key but unrecognized components of the
537 Paris Agreement (Clemencon, 2016; Rimmer, 2020), and REDD programs (Foss, 2018). For example, Article 10 of
538 the Paris Agreement, lacks guidance on how pledged and claimed reductions that are non-binding will be verified
539 and traded (Ollila, 2019; Rimmer, 2020; Spash, 2016), shortcomings that are mitigated by the DMFCP. The estimation
540 approach remains embedded in the United Nations Framework Convention on Climate Change (UNFCCC)
541 (UNFCCC, 2013) that promulgated reporting of emissions based on estimation, rather than direct measurement,
542 an approach constraining advancement of carbon credit trading. According to the UNFCCC approach, estimates
543 of greenhouse gas emissions are inventoried and multiplied by an emission factor to yield a national emission rate for
544 each source and each greenhouse gas (Cheewaphongphan et al., 2019; van Vuuren et al., 2009). Emissions of
545 Kyoto gases are multiplied by the Global Warming Potential for each gas specifying the radiative efficiency as
546 a warming agent for each gas relative to that of carbon dioxide over a 100-year time horizon (A. Kollmuss
547 & Fussler, 2015). The resulting estimation for national emission inventories, used by vendors and policy platforms
548 (e.g., REDD), are widely acknowledged as flawed and inaccurate (Jonas et al., 2019; Pacala, 2010). Importantly, the
549 estimation data are not directly comparable across diverse ecosystems lacking shared standards and universal
550 measurement methodology. The DMFCP updates the UNFCCC and REDD methods to validate and monetize
551 claims of emission reduction and to determine GHG budgets across diverse ecological landscapes at the
552 national and sub-national levels fulfilling the Paris Agreement (e.g., Article 10) and REDD goals and objectives.
553 The DMFCP normalizes forest emission reduction determinations for voluntary and compliance markets bridging
554 the gap between methods, project types and outcomes for stakeholders.
555

556 **Conclusions**

557
558 The DMFCP comprises a commercial standardized measurement-to-monetization system for the determination
559 of net ecosystem exchange (NEE). NEE enables creation of verified forest carbon financial products
560 contributing to the improvement of methods that underpin large-scale forest conservation and reforestation, a global
561 problem of high importance in the management of anthropogenic climate change. The SoS and GMP components
562 can be applied to GHG's across large-scales and diverse locations, corrects traditional carbon credit gaps in
563 validation and recalibrates equivalent voluntary and compliance programs that rely on them such as the CARB,
564 REDD, CDM, and the Paris Agreement. The DMFCP, coupled with contributions of the forest carbon research
565 community to commercialization efforts, and updated policies, can address the ~0.9 billion hectares of restorable
566 landscapes, offering a viable approach to retain the Earth's natural protective capacity to sequester atmospheric
567 CO₂ now and for future generations.

980

981 ⁱ The term isotopologue refers to chemical species that differ only in the isotopic composition of
 982 their molecules or ions.

983

984 ⁱⁱ “Carbon dioxide equivalent” or “CO₂eq” is a term for describing different
 985 greenhouse gases in a common unit. For any quantity and type of greenhouse gas,
 986 CO₂eq signifies the amount of CO₂ which would have the equivalent global warming
 987 impact.

988

989 ⁱⁱⁱ The term stable isotope has a similar meaning to stable nuclide but is preferably used when
 990 speaking of nuclides of a specific element. The expression "stable isotope ratio" is used to refer

991 to isotopes whose relative abundances are affected by isotope fractionation in nature. The stable
992 isotopic compositions of low-mass (light) elements such as oxygen, hydrogen, carbon, nitrogen,
993 and sulfur are normally reported as "delta" (δ) values in parts per thousand (denoted as ‰)
994 enrichments or depletions relative to a standard of known composition. The symbol ‰ is spelled
995 out in several different ways: permil, per mil, per mill, or per mille. The term "per mill" is the ISO
996 term, but is not yet widely used. δ values are calculated by:

$$997 \quad (\text{in } \text{‰}) = (R_{\text{sample}}/R_{\text{standard}} - 1)1000$$

1000 where "R" is the ratio of the heavy to light isotope in the sample or standard. For the elements
1001 sulfur, carbon, nitrogen, and oxygen, the average terrestrial abundance ratio of the heavy to the
1002 light isotope ranges from 1:22 (sulfur) to 1:500 (oxygen); the ratio $^2\text{H}:^1\text{H}$ is 1:6410. A positive δ
1003 value means that the sample contains more of the heavy isotope than the standard; a negative δ
1004 value means that the sample contains less of the heavy isotope than the standard. A $\delta^{15}\text{N}$ value
1005 of +30‰ means that there are 30 parts-per-thousand or 3% more ^{15}N in the sample relative to the
1006 standard.
1007
1008

Table 1 (on next page)

Comparison of features and benefits for existing forest carbon protocols and the DMFCP Protocol features such as inclusion/exclusion of soil respiration CO₂ flux, measurement time intervals and compatibility with expanded forest carbon flux measurements of CH₄ and N₂O are compared for existing forest carbon protocols and the DMFCP. Each feature is discussed in the text.

	Protocol Feature	Existing Protocols*	DMFCP	Benefit to Landowner
1	Project tradable units	Total tCO ₂ equivalent (tCO ₂ eq) is reported for projects without reference to project area	Tons CO ₂ equivalent (tCO ₂ eq), gC m ⁻² yr ⁻¹ (derived from 10Hz CO ₂ data, daily, weekly, monthly and annual sums)	Project reporting on an area basis is a fundamental metric of forest carbon sequestration per area, per time period, a metric not reported in estimation-based protocols
2	CO ₂ observations by direct measurement	No	Yes; infrared and laser-based gas analyzer methods for CO ₂ (10Hz)	Direct measurement of GHG's reduces risk of invalidation, increases quality of forest carbon offsets and offers management information
3	Monitoring implementation	A timber cruise is completed followed by forward and/or backward tree growth model simulations across arbitrary time intervals	A network of observation platforms is established across the project area, the System of Systems (SoS), with diverse sensors including high precision gas analyzers for CO ₂ , N ₂ O, CH ₄ and micrometeorological data comprising the Global Monitoring Platform (GMP); the SoS automates data and reporting for GMP network nodes, including analytical uncertainty	The SoS and GMP commercial products are standardized and designed to deploy as turn-key engineered operations in the field, lowering the cost of NEE measurements and improving the coverage of NEE across large landscapes; estimation protocols are not standardized and do not directly measure CO ₂ and other gases of interest
4	Calculation of net forest carbon sequestration	Plot based timber inventory conducted every 6 or 12 years employing non-standardized tree growth simulation models	Use standardized scientifically accepted equation for NEE ($NEE = GPP + Reco$ ($Reco = Ra + Rh$)), where $GPP =$ gross primary production or photosynthetic assimilation, $Reco =$ ecosystem respiration, $Ra =$ autotrophic respiration by plants,	Landowners and stakeholders can rely upon an accepted universal approach to quantify net forest carbon sequestration (NEE) in contrast to estimation protocols that do not employ actual CO ₂ measurement at any time during the protocol process

			and R_h = heterotrophic respiration by soil microbes. (see Methods section, equations (1) and (2) in the text)	
5	Vertical gross and net flux observations	No	Yes; eddy covariance methods are applied resulting in 30" averages of gross vertical CO_2 fluxes used to calculate daily/annual net carbon flux (NEE)	Direct measurement reduces risk of invalidation, increases quality of forest carbon offsets and offers management information
6	Universal metric for Annual Net ecosystem exchange (NEE) or net forest carbon sequestration	No, forest carbon sequestration is based on regionally applied estimation algorithms and growth models as proxies for annual changes in net forest carbon	Yes; vertical CO_2 fluxes are used to calculate daily, seasonal and annual NEE reported as $ppm\ CO_2\ m^{-2}\ time^{-1}$	Net changes in annual forest carbon sequestration are based on 30" interval data providing daily, weekly, monthly and annually resolved changes in NEE, in contrast estimation-based model runs start and end subject to user discretion and without validation by direct measurement of CO_2
7	Soil CO_2 flux	No	Integrated in vertical fluxes	Complete accounting of carbon flux is required for NEE; the DMFCP provides data on soil ecosystem dynamics
8	Cost to Landowner	Substantial fees are incurred from inception to registry listing of carbon credits; fees increase with size of project	No direct fees from inception to listing on a registry; upfront payments and annual royalty payments may be structured within a project agreement and contract between landowner and service provider	Elimination of direct fees to initiate a forest carbon project incentivizes landowners to engage in forest carbon programs with economic, ecological and business advantages
9	Time interval to achieve positive revenue	Years (1-5)	Daily to yearly, subject to project agreement and contract	Revenue to landowner is achievable, in practice, based on daily NEE but more typically would be

				paid annually, or over multiple years resulting in long term incentivizes for sustainable management; traditional protocols may require years to receive initial payment
10	Marketing and sales of GHG offsets	Responsibility of landowner (e.g., fee-based listing on a registry); voluntary and compliance offsets are priced differently based on discretionary criteria	Projects and products are pooled into portfolios and listed in a no-fee registry for sale to voluntary and compliance buyers worldwide, subject to project agreement and contract	Relieves landowner from handling carbon offsets once issued and from additional cost; direct measurement creates equivalent voluntary and compliance offsets
11	Baseline	Estimated and uncertain; based on counterfactual arguments and proxy data; positive values are not permitted, or default value is used	Baseline is the zero-emissions point from which positive, negative or neutral emissions of CO ₂ flux occur; the zero baseline is shared across analyzers via calibration with shared standards and references	All NEE results are instrumentally and financially comparable providing improved management of multiple project landscapes; a measured zero baseline eliminates estimation invalidation risk
12	Additionality	Based on uncertain counterfactual arguments regarding unobserved CO ₂ or default values and other criteria	Simple mass balance of carbon (e.g., NEE) across designated areas can be summed to determine overall carbon balance, or test for differences between pooled portfolios offering measured and numerical tests of additionality management plans or contracts	Eliminates uncertainty associated with this factor; provides near real time data for NEE and forest project management planning across additional landscapes and property ownership (e.g., municipal, private)
13	Invalidation period and compliance testing	Up to 8 years based on 5% invalidation rule	No invalidation period is required as validation with shared universal standards is conducted every 30"; invalidation can be triggered at any time instrument performance is	Elimination of an invalidation period with a near-real time system check will attract more project participants and buyers of carbon project products

			reported as faulty	
14	Third party verification	Third party validates calculations and estimation protocols reported in project documents; it does not include validation by independent direct measurement	Third party validation is made by independent direct measurements by an unaffiliated group as specified in the governing project agreement and contract	True independent third-party validation will support pricing of GHG products and market transactions as well as provide strict testing for invalid and fraudulent claims of GHG reductions based on direct measurement records
15	Test for switch to net positive emissions	No	Yes; NEE identifies transitional net negative (i.e., carbon offset producing) to net positive forest carbon dynamics	Switch to positive emissions may suggest landowner management practices to attain net neutral or net negative balance and may indicate changes in forest ecosystem function due to climate change
16	Permanence	100-year requirement	Up to 100 years but achievable in decadal increments; a 100-year time horizon is an arbitrary project interval	A 100-year forest carbon permanence requirement is a primary barrier to landowner and investor participation; 10-year interval project planning allows extensions or exit and is compatible with short term financial forecasting
17	Project exit or termination	High penalty	Ton-year accounting is employed to adjust exit penalty based on project impact of atmospheric emissions sequestered over time	Barriers to forest carbon management are lowered when reasonable exit strategies are available based on an accepted accounting method
18	Monitoring of CH ₄ , N ₂ O and other gases	Not applicable as estimation protocols based on forest mensuration are not intrinsically linked to CH ₄ and N ₂ O emissions	Eddy covariance can be used to determine next flux for CH ₄ , N ₂ O and other gases employing commercially available instrumentation, similar to the method used for	A three-gas GHG budget offers landowners more options to manage GHG neutral budgets and will expand areas of project applications and increase product options

			CO ₂ ; eddy covariance provides a combined three-gas GHG budget	
19	Incorporate isotopologues of CO ₂ and other GHG's	Not applicable as estimation protocols based on forest mensuration are not intrinsically linked to GHG isotopologues	Eddy covariance can be used to determine net Isolux for any isotopologues, similar to the method used for CO ₂ creating new product categories	Isotopologues of CO ₂ , CH ₄ and N ₂ O, among others, may offer the landowner additional options to manage projects for net or negative GHG impacts and will increase the diversity of forest carbon product options
20	Wetland, aquatic and oceanic emissions	Not applicable as estimation protocols based on forest mensuration are not intrinsically linked aquatic/oceanic sources for CO ₂ and CH ₄	Eddy covariance can be applied to wetlands, aquatic and estuarine features and to oceanic systems by measurement of CO ₂ and CH ₂ exchange with the water surface	Landowners with wetland and aquatic features will benefit from inclusion of these aquatic sources as associated forest GHG products; all stakeholders benefit from expanded knowledge of Earth system function including oceanic GHG dynamics
21	Contribution to forestry & atmospheric science and climate change studies and models	Lack of publications employing estimation-based protocol data with numerical climate change studies and models	All GHG flux data are relevant to evolving ecosystem function relative to climate change and human activity; all data may be incorporated in climate change research and atmospheric transport models based on calibrated and standardized measurement protocols	All stakeholders benefit from understanding the mechanisms affecting forest GHG dynamics the policies; landowners may employ model data to develop climate change mitigation strategies

22	Uncertainty and errors	Uncertainty and error sources are estimated at up to ~82%, representing the contribution of ecosystem respiration to NEE, a quantity not measured with estimation protocols; errors for N ₂ O and CH ₄ are unknown as forest growth models are not parameterized for these gases and direct measurements are not made	Uncertainties and errors for eddy covariance methodology and calculation of up to ~20% annual NEE have been reported, and include instrumentation, set up, data processing, and up-scaling NEE from a single tower, to yield 30 minute CO ₂ flux averages; corrective measures are typically applied to sources of uncertainty resulting in errors of $\sim \pm 0.03 \text{ tCO}_2 \text{ yr}^{-1}$	Up-scaling from eddy covariance tower data can be addressed by increasing the number of observation platforms and heights within the SoS sensor architecture; widely accepted corrections for NEE uncertainties and errors can be uniformly applied to NEE data across the SoS harmonizing uncertainty analysis and corrections that are under active and evolving study in contrast to estimation protocols that, to the best of our knowledge, have not undertaken comparison with directly measured CO ₂
23	Underlying Financial Terms and Contract	Estimation Protocols employ typical contract terms but do not include standardized performance metrics based on direct measurement of GHG's	Project terms and contract language will be standardized including performance metrics, pricing metrics and exit strategies (e.g., item 17) including <i>force majeure</i> clauses and technology performance specifications (Figures 1,2; Supplement S1)	Standardized measurement performance terms and contracts apply to all projects, voluntary and compliance, harmonizing efforts for forest conservation and reforestation

Figure 1

Figure 1 Showing an overview of the DMFCP structure and process

Figure 1. The Direct Measurement Forest Carbon Protocol (DMFCP) measures gross vertical fluxes of carbon forest ecosystems important for carbon trading shown as: geographical project boundary (dashed line); NEE, net ecosystem exchange of CO₂ fluxes; AGC, above ground carbon; BGC, below ground carbon; Photosynthesis, the total carbon uptake by plants or gross primary productivity (GPP); Respiration of ecosystem (R_{eco}), total sources of CO₂ released to the atmosphere from plants (AGC, R_a) and soil microbes (BGC, R_h); SoS sensor network; and, a Global Monitoring Platform (GMP). The SoS network and GMP's are deployed across the project landscape, according to an engineering plan specifying number, height and placement of sensors, to determine net ecosystem exchange (NEE) representing net forest carbon sequestration for a project. Forest carbon gross fluxes (GPP, R_{eco}) measured *in situ* and resulting in NEE is designated as *Physical Carbon*, total land area and time period of project performance are designated as *Project Carbon*, and annual accounting and registration of project carbon provides the basis (e.g., quantity of tCO₂eq available) and pricing for sale of *Financial Carbon*. Multiple projects and resulting forest carbon products are combined in a Pooled Portfolio and listed in a registry detailing project accounting and verification criteria. Pooled Portfolio carbon products, based on equivalent carbon accounting, can be sold to voluntary and compliance buyers worldwide. Pooled Portfolio products may also incorporate additional greenhouse gases (e.g., CH₄, N₂O) and isotopic forms that can be measured with precision in the field. The geographical project boundary may be comprised of local, regional or larger land areas (e.g., state, country). Project types include: R, reforestation refers to a project that plants trees on a site previously forested; AD, avoided deforestation refers to a project that prevents deforestation; FM, forest management refers

to a project that improves the net carbon sequestration; AF, afforestation refers to a project that establishes trees on land that otherwise would not be planted; AG, agroforestry refers to a project that combines forest conservation and or tree planting with agriculture; TM, timber/wood products involves sustainable harvest of timber within the project area resulting in wood products for construction and manufacturing. Traditional protocols do not directly observe CO₂ but rely on proxies and estimation. The DMFCP is formalized with standardized intake forms listing a project (e.g., project listing application) and a project management plan defining terms and conditions for carbon product operations across multiple 10-year intervals. NEE records reductions in photosynthesis caused by fire and deforestation should these events occur in the project areas. Standing carbon inventory derived from biometric or remote sensing methods will be employed to augment and cross-check project NEE data. The SoS and GMP's operate as an integrated autonomous system to monitor, measure and transform GHG flux data relative to local, regional and global reference materials for bulk and isotopic composition, providing the basis for calculation of verified tradeable GHG financial products that differentiate biogenic from anthropogenic net GHG fluxes. (B. D. V. Marino, 2013, 2014a, 2017b, 2017a, 2014b, 2014c, 2015b, 2015a, 2016b, 2016d, 2016c, 2016a; Bruno D. V. Marino, 2019) .

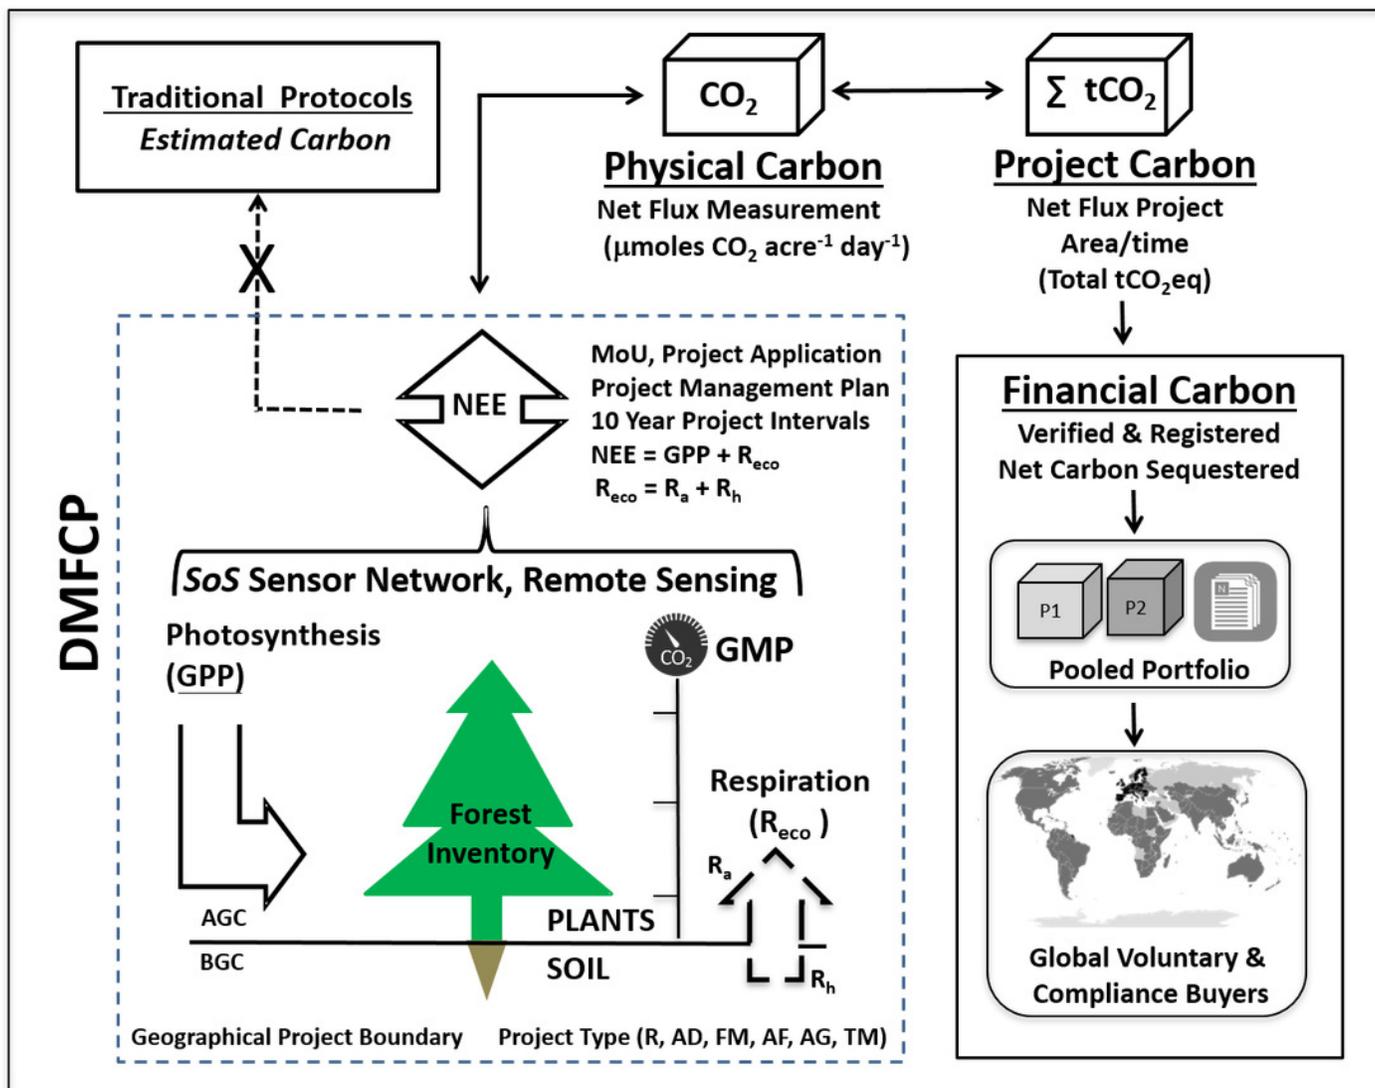

Figure 2

Figure 2 Showing DMFCP components and time series

Figure 2. A Features and benefits of the DMFCP comprised of the SoS and GMP's include: 1) direct field measurement of NEE (CO_2 , CH_4 and N_2O) relative to a zero-emission baseline showing positive, negative or neutral GHG emission employing an SoS and one or more GMP's; a positive NEE indicates a GHG source or emission to the atmosphere from the biosphere, whereas a negative NEE indicates a CO_2 sink or emission reduction from the atmosphere and results in carbon credits or offsets, 2) *ex ante*, annual accreditation periods that can be applied to multiple GHG's, 3) exits from a landowner agreement after 10 years with a penalty according to a ton-year accounting calculation, 4) landowner benefit from initial upfront payment (t_0) and annual royalty on sales payment (t_1). (B) Multiple projects subsequent to data quality checks by a data center can be listed in a registry and grouped into pooled portfolios; verification of system performance by external third-party verifiers of reference values and calibration of GHG analyzers is performed according to operation of the SoS. Products can be purchased by voluntary and compliance buyers worldwide through multiple sales channels. The hypothetical values shown for CO_2 , CH_4 and N_2O (bars) resulting from a field sensor platform are negative in year one and mixed in years 2 and 10. Simple addition of the values for each GHG for annual periods result in a positive, negative or neutral GHG balance. Multiple projects located in specified property boundaries can be grouped to address simple numerical additionality. The DMFCP process simplifies existing protocols for forest carbon sequestration (Table 1). Traditional protocols rely on proxies for CO_2 (i.e., unobserved or measured at any time in the protocol process) to establish a baseline and test for additionality. NEE records reductions in photosynthesis caused by fire and deforestation should these events occur in the project areas. Standing carbon inventory

derived from biometric or remote sensing methods will be employed to augment and cross-check project NEE data. The SoS and GMP's operate as an integrated autonomous system to monitor, measure and transform GHG flux data relative to local, regional and global reference materials for bulk and isotopic composition, providing the basis for calculation of verified tradeable GHG financial products that differentiate biogenic from anthropogenic net GHG fluxes. (B. D. V. Marino, 2013, 2014a, 2017b, 2017a, 2014b, 2014c, 2015b, 2015a, 2016b, 2016d, 2016c, 2016a; Bruno D. V. Marino, 2019) .

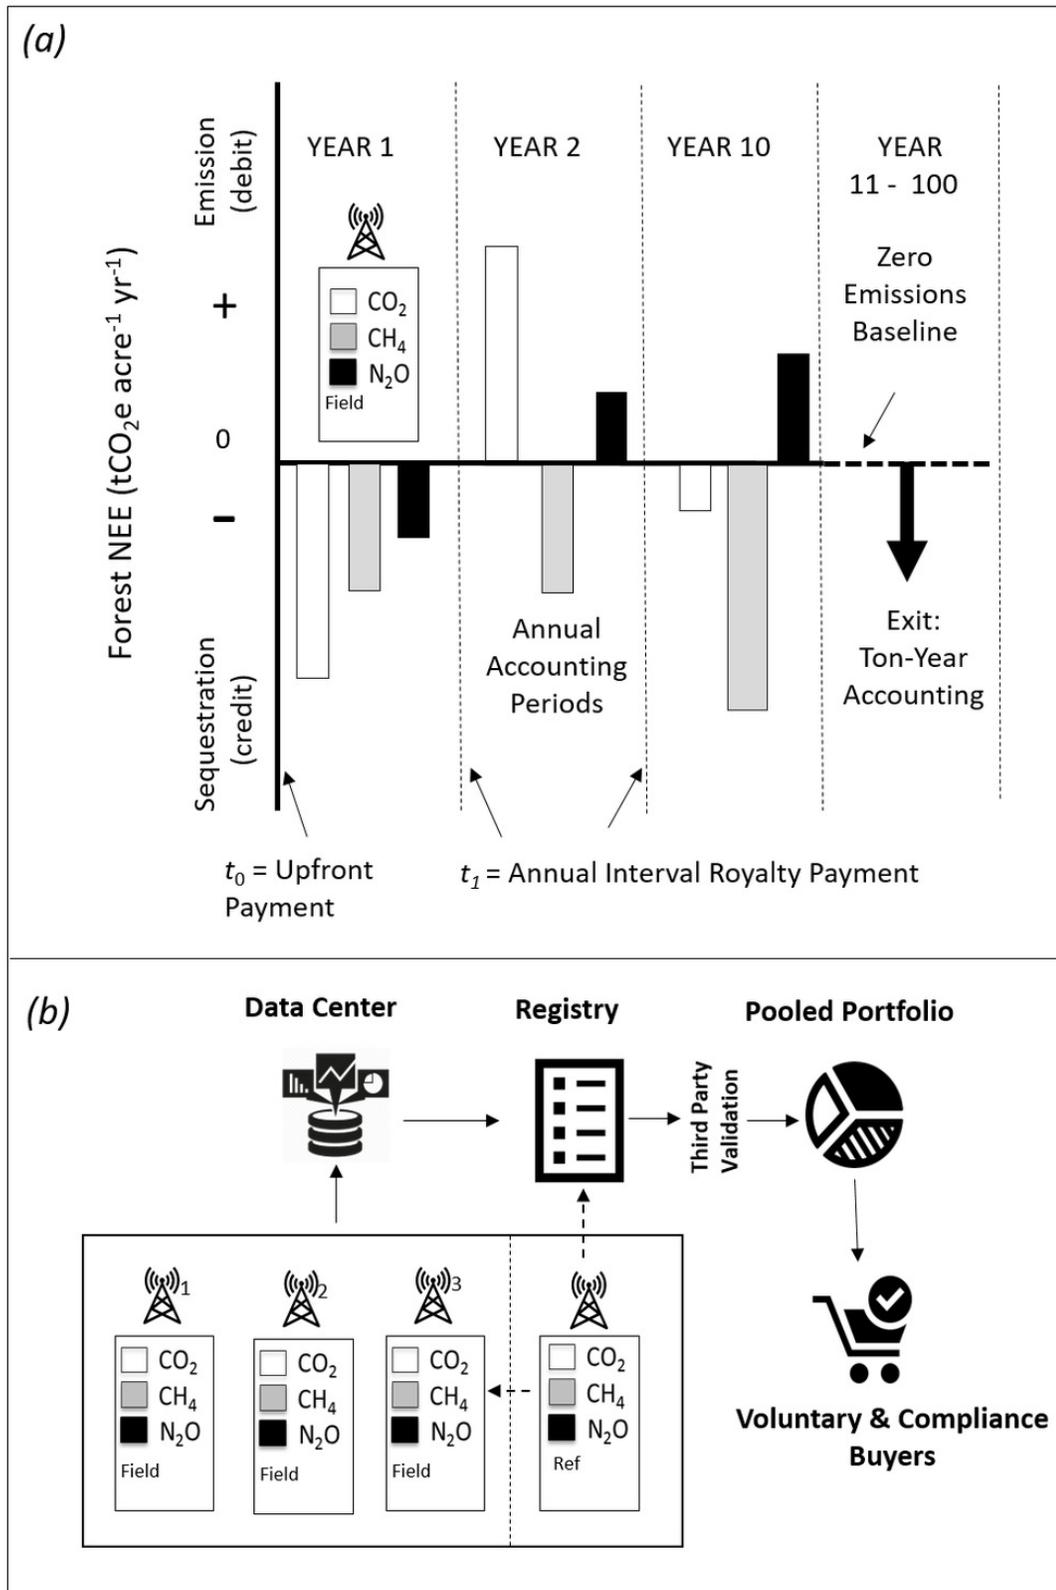

Figure 3

Figure 3 Locations of the eddy covariance sites analyzed in this study.

Figure 3 A. Location of Ankasa Park Tower, Ghana, Africa, (B) Location of Harvard Forest Tower, Massachusetts, USA (Image credits: (A) <http://earthenginepartners.appspot.com/science-2013-global-forest>; inset map: [https://commons.wikimedia.org/wiki/File:Ghana_\(orthographic_projection\).svg](https://commons.wikimedia.org/wiki/File:Ghana_(orthographic_projection).svg); (B) Map credit: Google, Delta SQ, NOAA, US Navy, GA, CEBCO Landsat/Copernicus US Geological Survey 2019); inset map: [https://commons.wikimedia.org/wiki/File:Massachusetts_in_United_States_\(zoom\).svg](https://commons.wikimedia.org/wiki/File:Massachusetts_in_United_States_(zoom).svg))

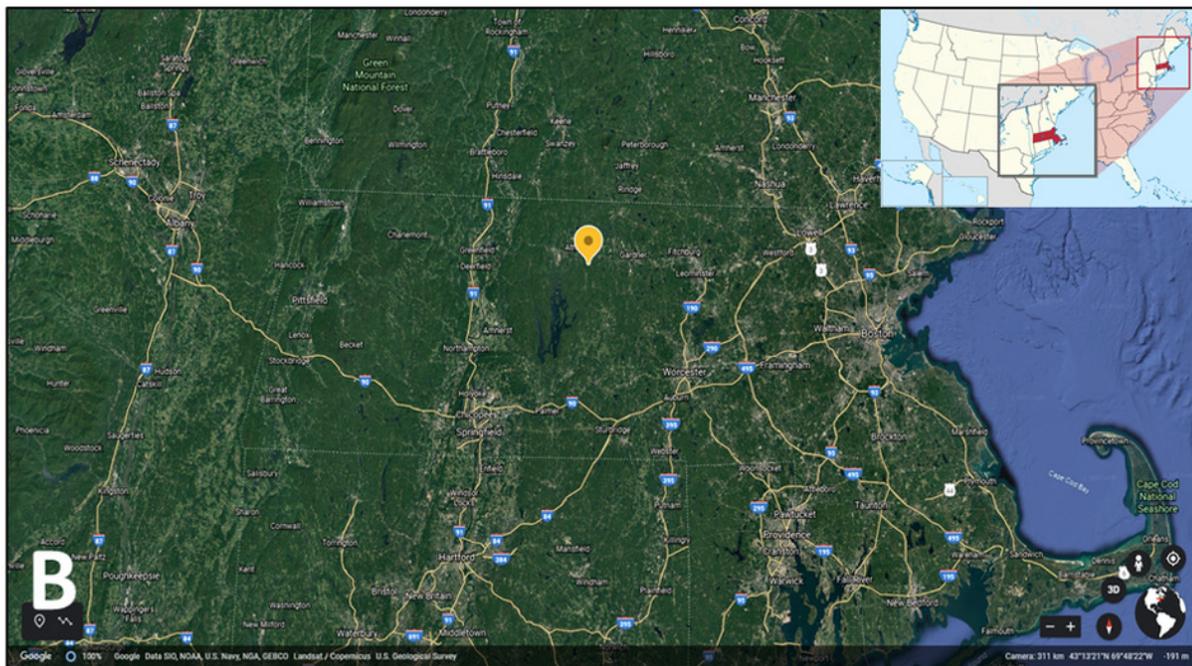

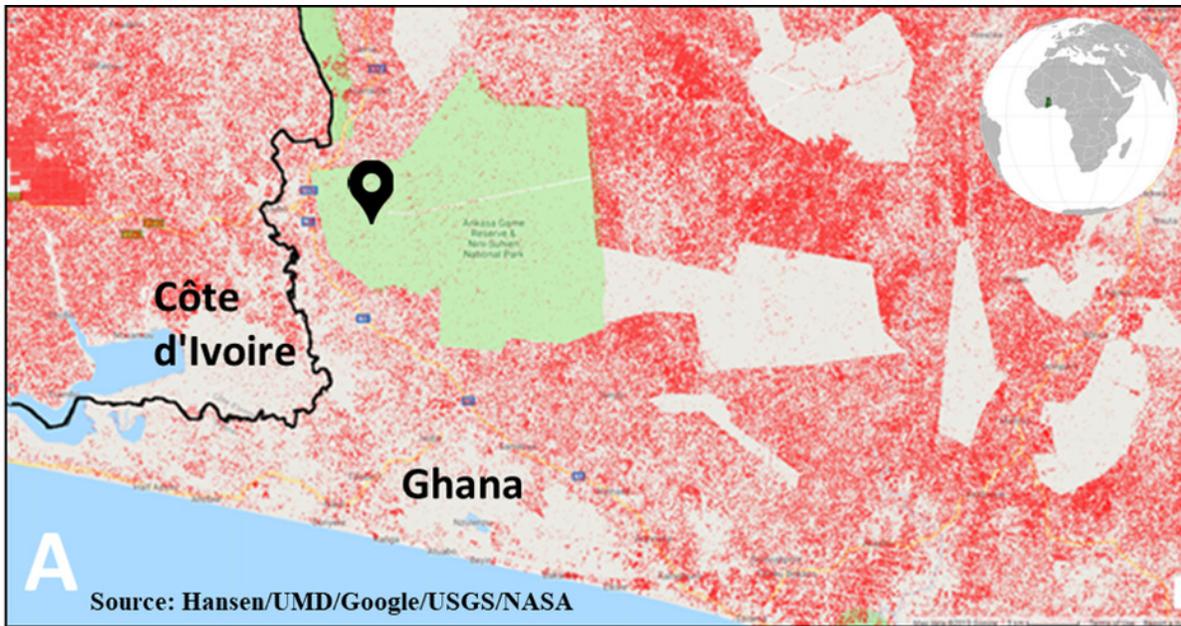

Figure 4

Figure 4 Shows net ecosystem exchange for the Harvard and Ankasa times series.

Figure 4. (A) Annual NEE observed at the Harvard Forest, Petersham, MA, USA and at Ankasa Park, Ghana, Africa. (B) Cumulative NEE corresponding to annual NEE and extrapolated across 100,000 acres are employed for illustration of pre-tax cash flows.

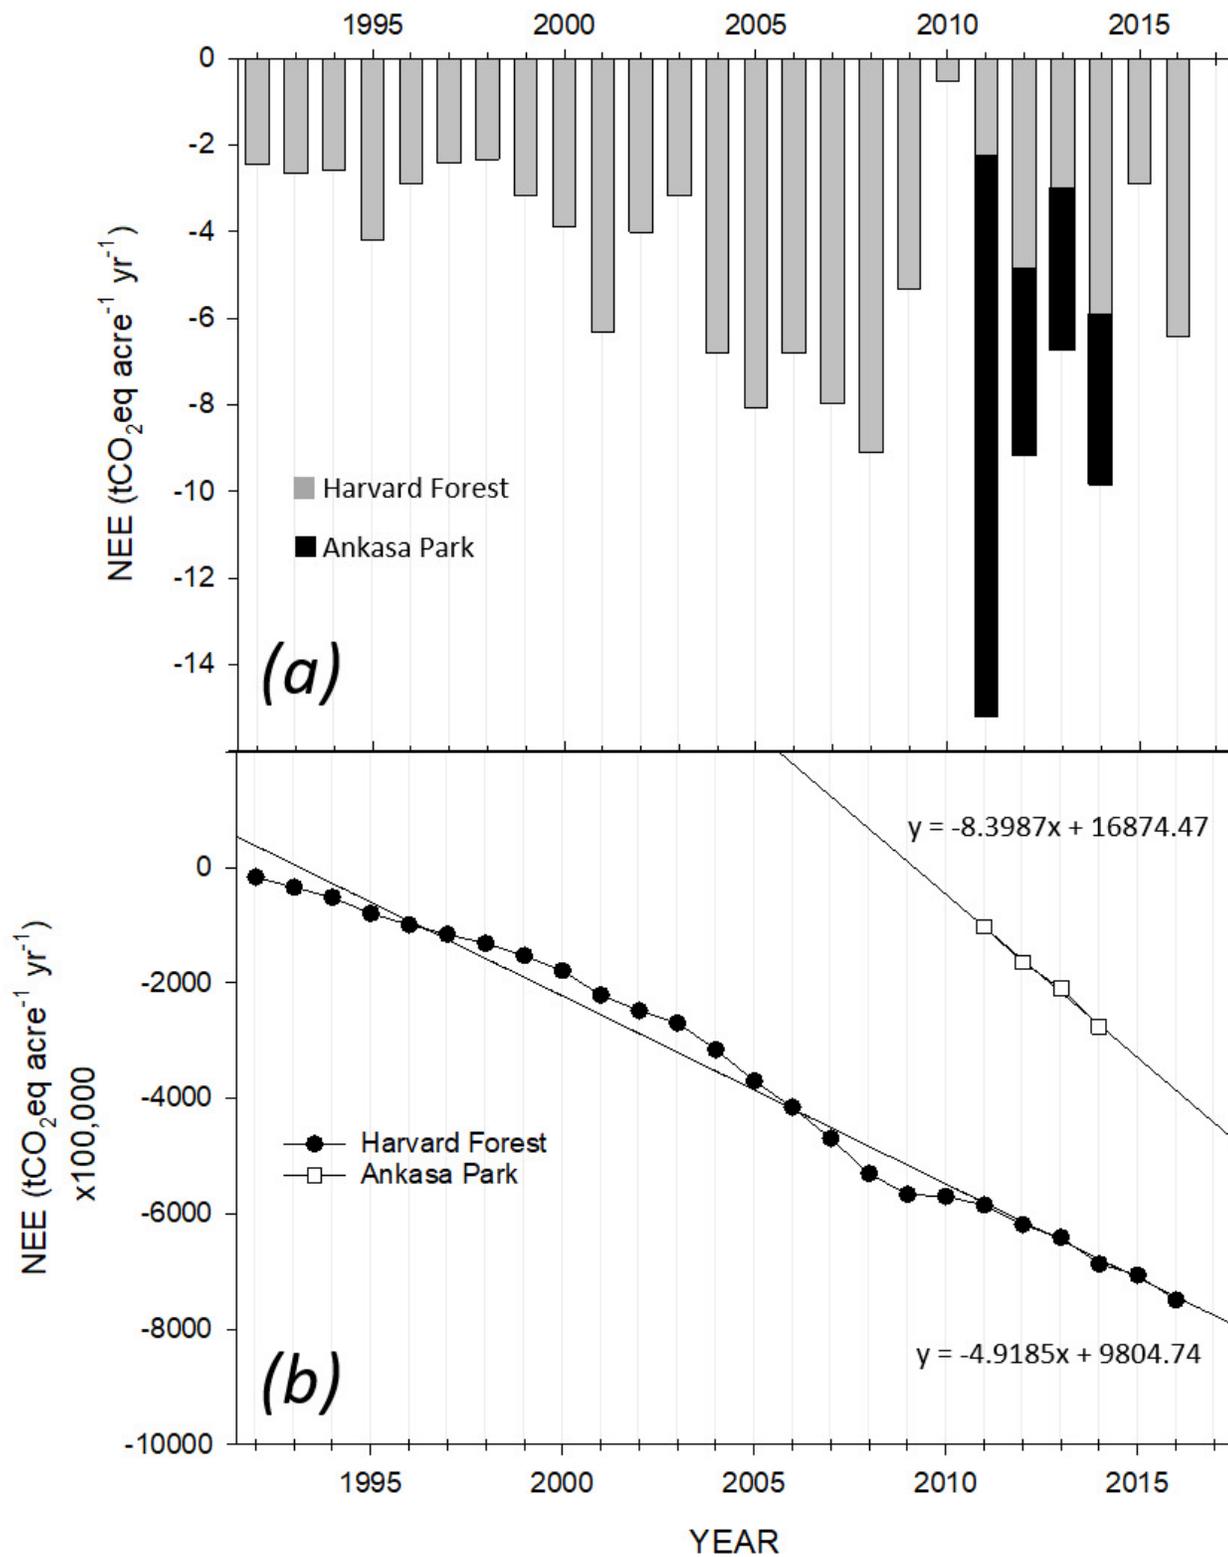

Figure 5

Figure 5 shows the pre-tax cash flow for two hypothetical cases for landowner revenue associated with forest carbon management.

Figure 5. The graph depicts projected cash flows for landowners for the two cases described for Harvard Forest, USA, and Ankasa Park, Africa. Upfront payments are paid to the landowner prior to project initiation. Additional cash flows are created by selling carbon products after the initial year of monitoring (Figure 1). Case 1 (unfilled bar, Harvard Forest; filled black bar, Ankasa) shows the total pre-tax cash flow for an upfront payment of 10% of the projected annual revenue. Case 2 (light shaded bar, Harvard Forest; dark shaded bar, Ankasa) shows the total pre-tax cash flow for an upfront payment of 8% of the projected annual revenue plus deferred payouts of 6% of the realized revenue from the sale of all carbon products. The vertical bars represent the impact of a $\pm 20\%$ market variance on realized revenue. These examples are provided for purposes of illustration and do not represent actual carbon products by type or cashflow.

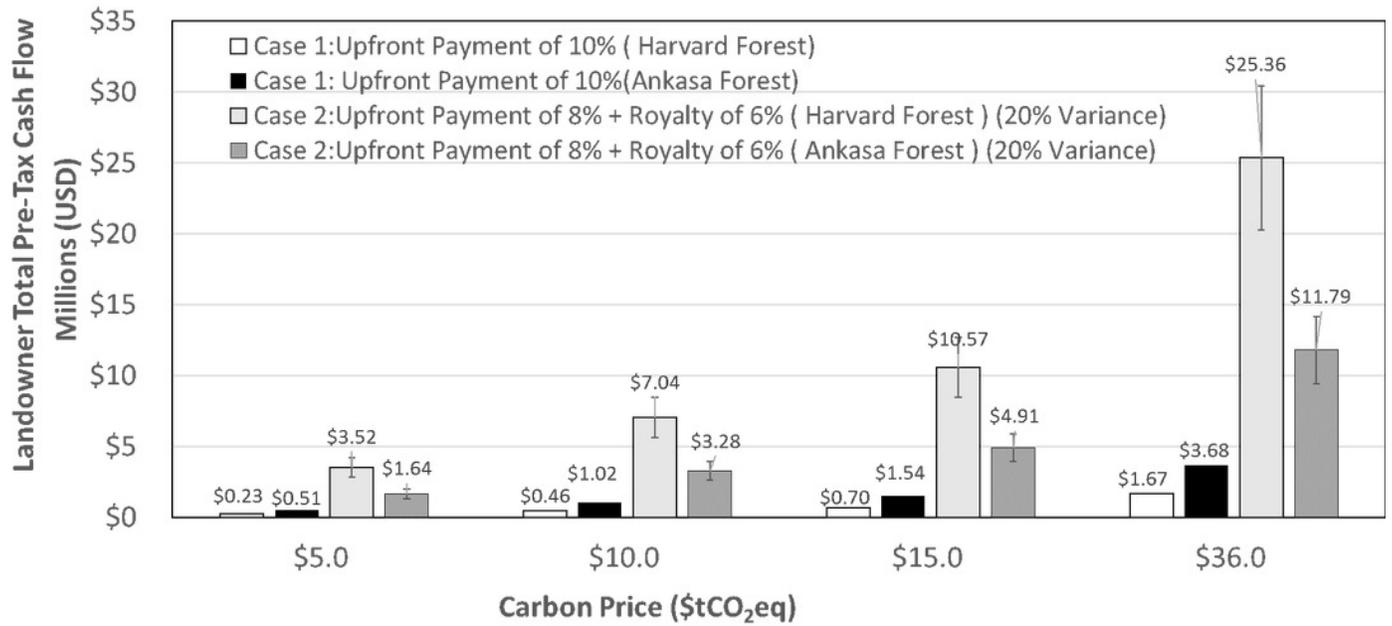

Figure 6

Figure 6 shows projected pre-tax cash flows for the Harvard and Ankasa forest over the time series studied.

Figure 6. Landowner pre-tax cash flows are depicted based on a price of \$10 per tCO₂e across the minimum, mean and maximum values recorded for the Harvard Forest, USA (unfilled bars), and the Ankasa Park forest, Africa (filled bars), extrapolated to 100,000 acres for the historical record of each site. The vertical bars represent the impact of a $\pm 20\%$ market variance on realized pre-tax revenue. These examples are provided for purposes of illustration and do not represent actual carbon products by type or cashflow.

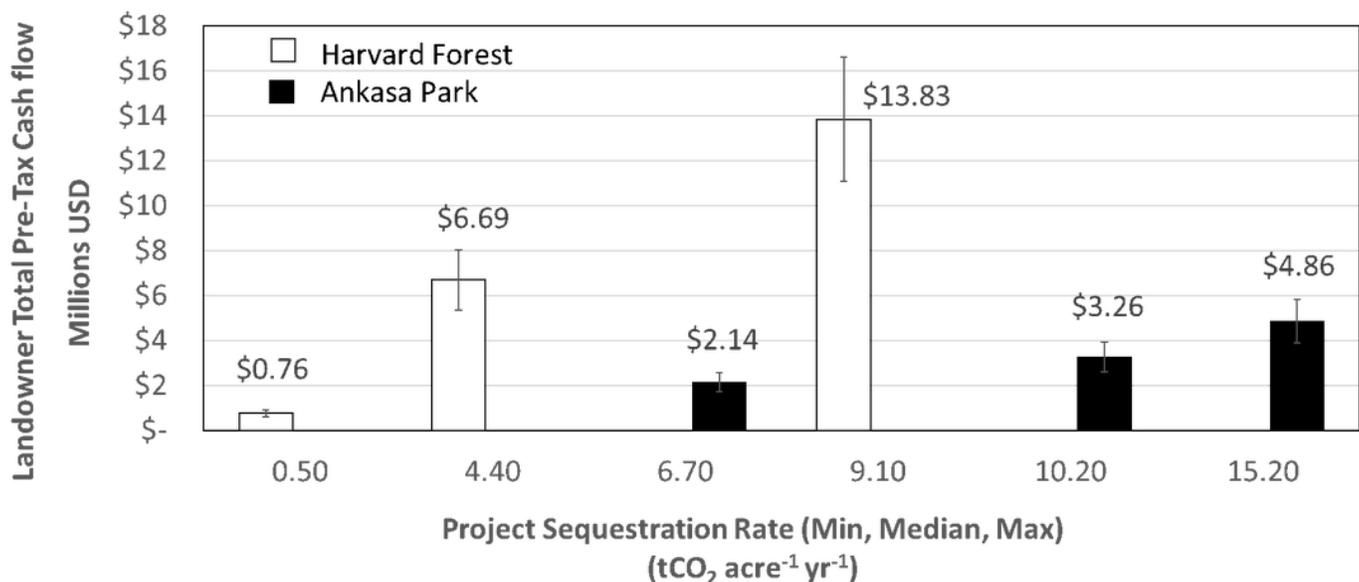

Figure 7

Figure 7 Shows hypothetical mixed carbon product types and projected pre-tax cash flows.

Figure 7. The graph shows hypothetical mixed carbon product types and projected pre-tax cash flows associated with each based on the example product inventory noted. Total pre-tax cash flow for the Harvard Forest, USA (light shaded bar), and the Ankasa Park, Africa (dark shaded bar), is \$16,380,000 and \$7,610,000, respectively. Both project projections illustrate the potential value of offering a mix of products and pricing to maximize revenue. Products may also incorporate additional GHG's (e.g., CH₄, N₂O), isotopic species of the GHG's, aspects of the project land and cultural features related to landownership and stewardship. These examples are provided for purposes of illustration and do not represent actual carbon products by type or price.
