A Good understanding of the response of photosynthesis rate (P_N) and transpiration rate (Tr) to stomatal alteration during the diurnal variations is important to cumulative photosynthetic product and water loss of crops. Six wheat genotypes were studied for two years with pot cultivation in rain-shelter. Among different genotypes, stomatal conductance (g_s) was significantly correlated with both P_N and Tr . But for each genotype, though g_s was significantly correlated with P_N regardless of relative air humidity (RH) status and it was also significantly correlated with Tr under lower RH (LRH, 15.4%) and moderate RH (MRH, 28.3%), it was not correlated with Tr under higher RH (HRH, 36.7%) during the diurnal changes. The conditional correlation between g_s and Tr of wheat evoked new thinking on the relationships among g_s , P_N , and Tr . Path analysis was further carried out to clarify the correlations of g_s with the 4 atmospheric factors, that of Tr with g_s and the four factors, and the direct and indirect effects of the factors, during their diurnal dynamic variation. The effects of these factors on g_s or Tr were related to RH. All the 4 factors had a much higher correlation with g_s under HRH than that under LRH and MRH. Air temperature (T) had a rather higher direct effect than RH and photosynthetically active radiation (PAR). And the other factors had a much higher indirect effect on g_s through vapor pressure deficit (VPD) and T. Transpiration rate was highly correlated with g_s under LRH and MRH, with g_s having a higher direct effect on it. In comparison, Tr was not correlated with g_s under HRH but highly correlated with the atmospheric factors, with T, RH, and PAR having a higher indirect effect through VPD.

Stomatal conductance bear no correlation with transpiration rate during their diurnal variation under high air humidity

Abstract

A Good understanding of the response of photosynthesis rate (P_N) and transpiration rate (Tr) to stomatal alteration during the diurnal variations is important to cumulative photosynthetic product and water loss of crops. Six wheat genotypes were studied for two years with pot cultivation in rain-shelter. Among different genotypes, stomatal conductance (g_s) was significantly correlated with both P_N and Tr . But for each genotype, though g_s was significantly correlated with P_N regardless of relative air humidity (RH) status and it was also significantly correlated with Tr under lower RH (LRH, 15.4%) and moderate RH (MRH, 28.3%), it was not correlated with Tr under higher RH (HRH, 36.7%) during the diurnal changes. The conditional correlation between g_s and Tr of wheat evoked new thinking on the relationships among g_s , P_N , and Tr . Path analysis was further carried out to clarify the correlations of g_s with the 4 atmospheric factors, that of Tr with g_s and the four factors, and the direct and indirect effects of the factors, during their diurnal dynamic variation. The effects of these factors on g_s or Tr were related to RH. All the 4 factors had a much higher correlation with g_s under HRH than that under LRH and MRH. Air temperature (T) had a rather higher direct effect than RH and photosynthetically active radiation (PAR). And the other factors had a much higher indirect effect on g_s through vapor pressure deficit (VPD) and T. Transpiration rate was highly correlated with g_s under LRH and MRH, with g_s having a higher direct effect on it. In comparison, Tr was not correlated with g_s under HRH but highly correlated with the atmospheric factors, with T, RH, and PAR having a higher indirect effect through VPD.

Keywords: stomatal conductance; relative air humidity; net photosynthesis rate; transpiration rate; wheat genotypes

1. INTRODUCTION

The water shortage has been the most significant factor restricting plant growth and crop productivity with a deepening water-resource crisis worldwide. Wheat (*Triticum aestivum* L.) is one of the main crops consumed by humans and is cultivated in different environments. Only less than 30% of the rainfall occurs during the wheat growing season in the North China Plain (NCP), the main wheat production region of China, which meets only about 25-40% of the water requirements of wheat. As a result, more than 70% of the irrigation water is used for winter wheat (Mei et al. 2013). Irrigation usage for wheat threatens the sustainability of the groundwater resource (Zhang, Pei & Hu 2003). Therefore, how to conserve soil water to enable sustainable crop production and maximize harvest of fields are becoming the main goals for many efforts of

72 agriculture researchers.

73 Stomata, the gateway through which vapor and CO₂ pass, play an important role in
 74 regulating both photosynthesis and transpiration. Low stomatal conductance (g_s) results in low
 75 net photosynthesis rate (P_N) by restricting CO₂ uptake (Farquhar & Sharkey 1982), while high g_s
 76 benefits higher P_N but at a greater expense of water loss via transpiration (Lawson & Blatt 2014).
 77 The ability of stomata to exert rapid control of their aperture to minimize water loss while
 78 maintaining CO₂ uptake is one of the primary evolutionary mechanisms that has allowed
 79 terrestrial plants to survive and spread in an otherwise desiccating atmosphere (Hetherington &
 80 Woodward 2003). A good understanding of the response and behavior of stomata and
 81 transpiration in winter wheat is in urgent need of water saving through the pathway of cultivar
 82 adoption and agricultural practices. Stomata adjusts aperture in response to diverse external
 83 stimuli, such as vapor pressure deficit (VPD) (Devi, Sinclair & Vadez 2010; Leonardi, Guichard
 84 & Bertin 2000), relative air humidity (RH) (Bakker 1991a; Bakker 1991b; Merilo et al. 2018;
 85 Suzuki et al. 2015; Talbott, Rahveh & Zeiger 2003), soil moisture (Belko et al. 2012; Kholová et
 86 al. 2010a; Kholová et al. 2010b), air temperature (T) (Haque et al. 2017; Hetherington &
 87 Woodward 2003), photosynthetic photon flux density (PPFD) (McAusland et al. 2016), and CO₂
 88 (Yoshimoto, Oue & Kobayashi 2005). These atmospheric factors continually vary at diurnal and
 89 seasonal rhythms (Assmann & Wang 2001). Besides, the circadian clock was reported to control
 90 g_s responses partly at least over the diurnal period (Dodd et al. 2005; Hassidim et al. 2017), with
 91 phase of the circadian clock adjusting to environmental cues, such as T and PPFD, etc. (de Dios
 92 et al. 2016; Yin & Johnson 2000). The majority of these studies were conducted with controlled
 93 experiments. Few studies were performed utilizing different gradients of natural conditions,
 94 which may be largely different from those carried out in climate chambers or green houses.
 95 Besides, these researches seldom laid stress on how the influencing factors affect g_s during the
 96 diurnal dynamic change.

97 Our previous study found that RH played an important role in determining the diurnal g_s
 98 pattern of wheat. All tested genotypes under lower RH (LRH, 15.7%) and most genotypes under
 99 higher RH (HRH, 40.7%) displayed a gradual decline pattern from morning through the
 100 afternoon. All genotypes presented a single-peak curve pattern under moderate RH (MRH,
 101 28.3%), but the peak time differed among genotypes (Zhang et al. 2019). Base on the previous
 102 research, this study aims at 1) clarifying how the influencing factors contribute to the diurnal
 103 variation of g_s along with transpiration rate (Tr) of wheat under different RH and soil moisture
 104 regimes; 2) making clear how P_N and Tr of wheat are correlated with g_s during the diurnal
 105 change under different regimes of soil moisture and RH. A deep understanding of the stomata
 106 and transpiration traits of wheat, the influencing factors, and their effect on P_N and Tr under

different conditions have great implications for saving water through cultivars and agricultural practices.

2. MATERIALS AND METHODS

2.1 Plant materials

Six winter wheat genotypes, Jinmai 47, Chang 6878, Jing 411, Zhoumai 18, Lankaoaizao 8, and 12 Song 1 were used as materials, with the names and associated details being listed in Table 1. The 6 genotypes were selected from wheat germplasm nursery affiliated to Luoyang Academy of Agriculture and Forestry, located in Henan Province, China. In April 2016, the jointing stage of winter wheat, stomatal conductance was measured in three replications of different genotypes in the nursery under rain-fed and well-watered conditions. According to the data collected from 9:00 to 11:00am, six genotypes, which were in a wide spectrum of g_s from very low to rather high value in the two water conditions, were tentatively selected as materials.

2.2 Growth conditions

The experiments were carried out at Shunyi Scientific Experimental Station, Institute of Environment and Sustainable Development in Agriculture, Chinese Academy of Agricultural Sciences, Beijing, China (40°N and 116°E, altitude 34m) in 2017-2018 growing seasons of winter wheat. The precipitation and air temperature of every month during the growing season are presented in Figure 1. Pot cultivation was adopted in this experiment. Polyvinyl chloride (PVC) pots were 30 cm depth and 35 cm in diameter, with a drainage hole on the bottom. The pots were filled with 16 kg plow layer soil, which was sieved through a 5 mm sieve and then fully mixed. The soil nutrients were determined as 0.109 g/kg of total nitrogen, 14.4 g/kg of organic matter, 24.5 mg/kg of available phosphorus, 106 mg/kg of available potassium, and soil pH was 7.7.

For each genotype, 6 pots were planted for two water treatments and three replications. Twenty wheat seeds were sown in each pot on October 5, 2017. Thirteen uniform seedlings were kept for overwintering, with the slender ones being removed on 30 d after emergence. After recovering in the spring, 10 uniform seedlings were eventually selected and kept as materials, with the unqualified ones being eliminated.

2.3 Air humidity and soil water treatments

The treatments were different regimes of air humidity and soil water. The environmental RH gradient was taken as air humidity treatments. April 13, 28 and May 6, 2018, which were LRH (15.4%), MRH (28.3%), and HRH (36.7%) respectively, but similar in T and PAR were specifically selected. The specific diurnal meteorological conditions of the 3 days were shown in Figure 2. Two water treatments were arranged: well-watered (WW) and drought stress (DS) conditions, with soil water content being 75% and 50% of field water holding capacity (FC), respectively. Water withholding for the two treatments was conducted by the weighing method. The plants were watered daily to restore the initial soil water content, between 1 and 2 h after sunset. Water withholding was kept for 30 d from April 6 through May 6. During water treatment periods, rain-shelter was used to prevent the rain on rainy days and was kept rolled up on sunny days to allow the crops to grow in the open-air conditions.

2.4 Leaf gas exchange measurements

The youngest fully expanded leaves of the main tiller were measured for measuring the diurnal variation of gas exchange parameters under LRH, MRH and HRH from 8:00 to 18:00 with the 2 hours interval, utilizing a Licor-6400 portable infrared gas analyzer (LI-COR Inc., Lincoln, Nebraska USA). For each replication, the leaves of three plants were measured and averaged as the value for each time span. With one measurement, 3 parameters concerned, including g_s , P_N , Tr , were obtained in the meanwhile. To eliminate the disturbance to PAR from cloud cover and shading of neighboring leaves, PAR was set as the average value of 5 days in April or May for each time span. And chamber T was set as the same as the air temperature outside the chamber. Relative air humidity could not be set for Li-cor-6400 gas analyzer, RH of the air flowing into the chamber was as same as the air RH. At the same time with diurnal measurement of gas exchange parameters, 4 atmospheric factors were also determined. Air temperature and Relative air humidity were monitored once per minute by an automated temperature and relative humidity system (TH12R, Miaoxin, CN). VPD was calculated by T and RH as follows.

$$VPD = (1 - RH) \times 0.6108 \times e^{\frac{17.27 \times T}{T + 273.3}}$$

For investigating the relationships between g_s with P_N and Tr across genotypes under identical soil water and meteorological conditions, leaf gas exchange parameters were measured with 6 different genotypes under two water treatments at 9:30-11:00am on April 16, 29, and May

5, 2018, the LRH (16.4%) , MRH (25.9%), and HRH (37.8%) day respectively. The same gas analyzer described above were used, with the leaf chamber conditions being set at the same temperature of 25°C, PAR of 1000 $\mu\text{mol}\cdot\text{m}^{-2}\cdot\text{s}^{-1}$.

2.5 Statistical analysis

The collected data were statistically analyzed by SAS software (SAS 9.4, Cary, NC, USA). A Pearson correlation analysis was used to assess correlations between parameters. Significance was considered at $P < 0.05$ and 0.01. Data were presented as means \pm standard errors ($n = 3$).

3. RESULTS

3.1 Main meteorological factors responsible for the diurnal variation of stomatal conductance

The four meteorological factors, T, RH, VPD, and PAR interact and associate with each other. Each factor might directly affect g_s , also indirectly affect g_s through other factors. Path analysis was carried out to clarify the correlations of four terms with g_s and their direct and indirect effects on g_s during diurnal dynamic variation. Table 2 showed how g_s related to diurnally varying atmospheric factors depended on moisture regimes. All the 4 factors had a much higher correlation with g_s under HRH than that under LRH and MRH. The correlation between g_s and the four factors tended to be higher under WW than that under DS when RH was the same level. Of the four factors, g_s was significantly correlated with T and PAR under all the regimes except DS+MRH. All the 4 factors were not correlated with g_s under DS+MRH. Temperature had a rather higher direct effect than RH and PAR on g_s . And other factors had a much higher indirect effect on g_s through VPD and T on g_s .

3.2 Main factors responsible for the diurnal variation of transpiration rate

Stomatal conductance and the four main meteorological factors T, RH, VPD, and PAR were closely related to each other. Path analysis was conducted to clarify the correlations between Tr and the 5 factors, the direct effect and indirect effect through other factors on Tr during their diurnal dynamic variation (Table 3).

Under LRH, Tr was highly correlated with g_s under both WW and DS, with higher direct effect coefficient (DPC=0.7346) and a higher negative indirect effect through VPD and a

positive indirect effect through T under WW, with higher direct effect ($DPC=0.8225$) and a weak indirect effect through other factors under DS. Transpiration rate was also significantly correlated with T, RH, and VPD under WW. The temperature had a higher positive direct effect and a higher negative indirect effect through VPD on Tr . Relative air humidity had a relatively lower direct effect and a higher negative indirect effect through T and a higher positive indirect effect through VPD on Tr . Vapor pressure deficit had a higher direct effect and a higher indirect effect through T on Tr . All the 4 meteorological factors had a lower indirect effect through g_s on Tr .

Under MRH, Tr had an extremely significant correlation with all the 5 factors, with the correlation between Tr and g_s being much higher, that between Tr and RH being negative, and that between Tr and T, VPD, and PAR being positive. Stomatal conductance had a rather higher direct effect than the indirect effect through any other factors on Tr . Of the 4 meteorological factors, VPD had the highest direct effect, and T, RH, and PAR had a higher indirect effect through VPD on Tr . The indirect effect of 4 meteorological factors through g_s on Tr was rather smaller.

Under HRH, Tr was not correlated with g_s but significantly correlated with the 4 meteorological factors except PAR under WW. Vapor pressure deficit had the largest direct effect, while PAR had the smallest direct effect on Tr under DS. The indirect effect of T, RH, and PAR on Tr through VPD was the largest, with that of RH being negative, and that of T and PAR being positive. The indirect effect through g_s of the 4 meteorological factors on Tr was rather smaller.

3.3 Stomatal conductance bear no correlation with transpiration rate in the diurnal change under HRH

The meteorological factors, such as T, RH, and VPD, etc., vary with time diurnally. Meteorological conditions were considered to be identical for different genotypes under the same measurement time span (9:30-11:00am). Across different genotypes, g_s had extremely significant correlations with P_N and Tr under identical meteorological conditions and soil water status (Table 4). The correlations between g_s and Tr under WW were lower than those under DS in the three different RH conditions. For the case of LRH, the correlations under WW were lower than those under DS. While for MRH and HRH, the correlation between g_s and P_N was higher under WW than that under DS. On the other hand, the correlations among g_s with P_N and Tr in the diurnal dynamics were investigated with 6 genotypes individually under WW and DS conditions (Table 5). There were the same results in WW and DS whether respectively or collectively.

227 Stomatal conductance was closely correlated with P_N and Tr under LRH and MRH. Interestingly,
 228 though g_s was still closely correlated with P_N , it did not significantly correlate with Tr for each
 229 genotype under HRH in the diurnal variation. This proved the high dependency between g_s and
 230 P_N , also revealed the minor role of g_s on determining Tr diurnal variation under HRH. It might
 231 be other factors, mainly the meteorological factors, that predominantly control Tr in the diurnal
 232 variation in such case.

233 4. DISCUSSION

234 4.1 Factors influencing the diurnal variation of stomatal conductance and transpiration 235 rate

236 Stomata adjust aperture in response to environmental factors, such as soil water stress and
 237 atmospheric factors, as reported by many studies (Xu et al. 2016; Hernandez-Santana et al. 2016).
 238 The present study aimed at the relations between g_s of wheat with the influencing factors during
 239 the diurnal dynamic variation, and found that the relations was associated closely with RH.
 240 Stomatal conductance was not correlated with RH and VPD under LRH+DS and MRH+DS
 241 regimes, but highly correlated with the two factors under HRH. Moreover, stomatal conductance
 242 displayed a higher correlation with the influencing factors under WW than under DS. Thus, it
 243 seems that only when g_s of wheat was relatively higher in the case of high air RH and soil
 244 moisture, it was closely related to atmospheric factors during the diurnal variation. The reduced
 245 stomatal aperture could not respond to diurnally varying factors sensitively under dry soil and air
 246 moisture, which explain the rather lower correlation between them. Stomatal conductance of
 247 wheat was significantly correlated with PAR in most of the regimes. Sabir & Yazar (2015) found
 248 that g_s was better correlated with PAR for all the tested grapevines cultivars than the other
 249 measured meteorological parameters, including RH and T, etc. This is consistent with the case
 250 under DS+LRH and WW+MRH in our study, implying that sunlight had a significant effect on
 251 stomatal diurnal response under the two regimes.

252 Transpiration rate is controlled by the plant itself through stomatal adjustment on one hand.
 253 As a passive diffusion process of water, it was also regulated by surrounding factors, such as T,
 254 RH, and solar radiation intensity (Yang et al. 2012). Which factors mainly restrict Tr during the
 255 diurnal variation depended on RH, as the present study showed. Higher correlation between g_s
 256 and Tr of wheat existed under LRH and MRH, but no correlation under HRH. This might imply
 257 that increased g_s under HRH was not restricting factors for Tr , instead, atmospheric factors
 258 restricted Tr in this case. While reduced g_s became the main limiting factor for Tr under lower

RH. Vapor pressure deficit had the highest direct effect of the four atmospheric factors, and other factors had the highest indirect effect through VPD under almost all the regimes.

4.2 Correlations between stomatal conductance with transpiration rate and photosynthesis rate in the diurnal dynamics

Across different genotypes under identical meteorological conditions and soil water status, extremely significant correlations existed between g_s with P_N and Tr , as reported by some previous studies (Wong, Cowan & Farquhar 1979; McAusland et al. 2016). This indicates the important contribution of cultivars with different stomatal traits to photosynthesis and transpiration, and in turn to yield formation and water consumption, in the case of identical environmental conditions.

During the diurnal dynamics, g_s was significantly correlated with Tr in all the wheat genotypes tested under LRH and MRH, but not under HRH (Table 5), indicating the correlation between them depended on RH. As a physical process of water passive diffusion, transpiration is not only controlled by the plant itself through stomatal adjustment but also driven by soil moisture and atmospheric factors. In some cases, Tr is mainly regulated by RH or VPD, instead of g_s . Devi et al. (2010) found that Tr increased over VPD rising, with a break point occurring in some genotypes above which there was little or no further increase in Tr of peanut. Stomatal conductance declined with VPD increasing (Leonardi, Guichard & Bertin 2000; Talbott, Rahveh & Zeiger 2003), or RH declining (Fanourakis et al. 2016; Fanourakis et al. 2019), which implied that Tr did not decline with g_s reducing, but increased with VPD rising. And the occurrence of Tr breakpoint might be due to that g_s continuously declined and turned to be the restricting factor of Tr . Also, Aliniaieifard et al. (2016) conducted an experiment with *Chrysanthemum morifolium* plants in the growth chamber. Similarly, they found higher g_s but lower Tr under low VPD (high RH) in comparison with growth under moderate VPD. Consistently, Giday et al. (2015) found cultivar differences in plant transpiration rate at high relative air humidity were not related to genotypic variation in stomatal responsiveness. The transpiration rate did not increase with g_s rising but lowered down with increased RH. These indicated that it was VPD but not g_s that controlled Tr in such cases. Whether g_s is closely related to Tr depends on if g_s is restricting Tr under the specific circumstance. In the present study, the correlation coefficients between g_s and Tr of wheat under LHR and HRH were contrasting (Table 5). This might be ascribed to the different limiting effects of g_s on Tr . Stomatal conductance went down and turned to be the limiting factor of Tr under LRH. While enhanced g_s is no more a limiting factor of Tr under HRH, and weakly correlated with Tr . It might be either the regulating and limiting effect of g_s to

292 *Tr* or the synchronous response of g_s and *Tr* to the atmospheric factors that result in the high
293 correlation between g_s and *Tr* under MRH.

294 Stomatal conductance was highly correlated with P_N of wheat in the diurnal dynamics for
295 each genotype, also across different genotypes at identical environmental conditions,
296 highlighting the strong dependency between photosynthesis and stomatal regulation. However,
297 as reported, stomata did not respond to environmental cues with P_N synchronously, but an order
298 of magnitude slower than P_N (Lawson & Blatt 2014). The lag in stomatal behavior and the
299 temporal disconnect between P_N and g_s challenge the notion that stomata adjust the aperture to
300 regulate P_N . Moreover, Mott (1988) reported that it was CO_2 concentration inside the leaf (C_i)
301 rather than that outside the leaf influenced stomatal aperture. Afterwards, series of studies carried
302 out by Roelfsema et al. (2002; 2006) found that red light-induced stomatal opening is mediated
303 by the reduction of C_i which is in turn caused by the increased photosynthetic activity of
304 mesophyll cell. A recent study in maize (*Zea mays* L.) identified 2 *Ca* genes which encode
305 carbonic anhydrase mediated the response of plants to increased C_i (Kolbe et al. 2018). As an
306 organism of high auto-regulation, plants respond to environmental cues positively within its
307 adaptation limits. Under some specific circumstances, photosynthesis, the initiative anabolism
308 process, might be capable of regulating g_s according to its demand for CO_2 through affecting C_i ,
309 though g_s has been proved to be a limiting factor of photosynthesis by most studies (Carmo-Silva
310 et al. 2012; Chastain et al. 2014).

311 5. CONCLUSIONS

312 Relative air humidity played an important role in affecting the correlation between g_s with
313 P_N and *Tr* of wheat during the diurnal variation. The transpiration rate was not significantly
314 correlated with g_s but mainly affected by the atmospheric factors under HRH. In particular, VPD
315 had a rather higher direct and indirect effect on *Tr*. The notion that stomata continuously adjust
316 aperture in response to environmental factors to optimize the trade-off between photosynthesis
317 and water loss was challenged. Thus the definite interrelationship among P_N , *Tr*, and g_s of wheat
318 need to be elucidated conditionally. In these cases that g_s is not the key influential factor for *Tr*,
319 any efforts to artificially reduce g_s of wheat may not contribute significantly to water saving, but
320 pay the price of photosynthetic reduction and yield loss. But when meteorological and soil water
321 conditions were identical, g_s was significantly correlated with *Tr* and P_N across different
322 genotypes. Thus, to select and adopt appropriate wheat cultivars with specific stomata traits is
323 undoubtedly a good strategy for realizing water saving. Taking yield issue into account,
324 genotype adoption has to compromise the requirement for yield and water saving, and needs to

325 match the water availability of areas with stomatal sensitivity of wheat genotypes to water stress.
