The Laurentian Great Lakes are the most studied system in lake geochemistry and have well-preserved chronological profiles. Metals play numerous critical roles in natural and anthropogenic characteristics of lake ecosystems, so patterns in the historical records of metals from sedimentary cores provide important information about environmental baselines and human impacts. Relevant studies of Great Lakes geochemistry are listed, and we follow with encyclopedic descriptions of metals and their oxides in the lakes. These descriptions include likely natural and anthropogenic sources of elements, their known history from previous paleoecological studies, and their status as potential contaminants of concern. Despite the well-studied geology of the Great Lakes catchment, sourcing elements was sometimes difficult due to materials often being moved long distances by glaciation and the global prevalence of atmospheric pollutants. We summarized available information on metals and their roles as geochemical indicators in the Great Lakes.

8 Abstract

9 The Laurentian Great Lakes are the most studied system in lake geochemistry and have well-
10 preserved chronological profiles. Metals play numerous critical roles in natural and
11 anthropogenic characteristics of lake ecosystems, so patterns in the historical records of metals
12 from sedimentary cores provide important information about environmental baselines and human
13 impacts. Relevant studies of Great Lakes geochemistry are listed, and we follow with
14 encyclopedic descriptions of metals and their oxides in the lakes. These descriptions include
15 likely natural and anthropogenic sources of elements, their known history from previous
16 paleoecological studies, and their status as potential contaminants of concern. Despite the well-
17 studied geology of the Great Lakes catchment, sourcing elements was sometimes difficult due to
18 materials often being moved long distances by glaciation and the global prevalence of
19 atmospheric pollutants. We summarized available information on metals and their roles as
20 geochemical indicators in the Great Lakes.

21 Introduction

22 An understanding of past conditions is essential for potential remediation efforts in an aquatic
23 system because it can be used to estimate natural baseline, remediation targets, timing and causes
24 of impacts, and positive effects of existing remedial efforts. During the Anthropocene epoch,
25 human impacts have far exceeded natural changes in the landscape through agriculture and
26 industry, mobilizing sediments and releasing pollutants into the air and water. These activities
27 leave geochemical markers in sedimentary records of aquatic systems. Sediment cores can be
28 collected and dated to reveal local geochemical histories. Metals are of particular interest
29 because they record a history of pollution going back thousands of years (Heim & Schwarzbauer,
30 2012). In order to determine the historical extent of contamination caused by human activity,
31 concentrations of potential pollutants must be compared to the baseline occurrences from natural
32 sources (Alderton, 1985). Geochemistry depends on location-specific soil and bedrock
33 composition, so it is important to consider natural sources of inorganic materials relative to
34 anthropogenic sources. As Tourtelot (1971) describes, "[t]he types of rocks that form geologic
35 units in the Earth's crust supply most of the raw materials from which soils are formed and from
36 which water derives its inorganic constituents."

37 Sediments in lake systems are especially useful in geochemical studies because lakes act as sinks
38 for inorganic materials. The best environments for geochemical studies are aquatic environments
39 that have stable sedimentary basins allowing steady deposition of fine-grained material suitable
40 for fixation of pollutants. Ideally, sediments are reducing (anoxic) at the sediment/water interface
41 and thereby support minimal post-depositional mobility. According to Heim & Schwarzbauer
42 (2012), the Laurentian Great Lakes are the most studied system in lake geochemistry and they
43 have well-preserved chronological profiles (Reavie et al., 2017). These studies reveal a history of
44 contamination starting with European settlement around 1850 and increasing over the next
45 century with increases in industry, forest fires, and the burning of fossil fuels, which supported
46 increased flux of land-based and atmospheric pollutants to the lakes. More recently,
47 environmental regulations such as the Clean Water Act (United States of America, 1972) and the

48   Great Lakes Water Quality Agreement (Canada & United States of America, 1972) have
49   mitigated inputs of these pollutants and have also led to their remediation to some degree. A
50   detailed list of pertinent studies along with associated analytes is provided in Table 1.

Survey methodology

52   This review summarizes what is known of inorganic paleogeochemistry in the Laurentian Great
53   Lakes, itemized by metallic elements. To date, the Great Lakes system has been considered in
54   parts (Table 1), so we aimed to synthesize all relevant literature to create a central understanding
55   of metallic geochemistry in the lakes. This review is the first of a pair of manuscripts exploring
56   this topic, the second being a retrospective geochemical analysis of 11 sediment cores collected
57   from the lakes (Aliff et al., 2020). Here we provide an overview of the metallic elements and
58   oxides with a focus on their relevance in the Laurentian Great Lakes. Major aims were to define
59   the analytes in terms of their sources and characterize their potential importance as
60   anthropogenic stressors.

Geology and Geomorphology of the Great Lakes Basin

62   The geology of the Great Lakes basin has been extensively studied. Broadly, the basin is
63   bounded to the north by the upland Precambrian-age Canadian Shield, which is dominated by
64   intrusive rocks (Fig. 1).

65   The basin is bound to the south by a lowland region of Paleozoic sedimentary rocks such as
66   limestones, dolomites, and sandstones (Fig. 1; Larson & Schaetzl, 2001). The basins of lakes
67   Erie and Michigan, as well as most of the Lake Ontario basin, are in this lowland region. The
68   Lake Superior basin is almost entirely in the Canadian Shield, and Lake Huron straddles the two.

69   The Canadian Shield is the exposed portion of the North American craton, which forms the core
70   of the continent. "The Canadian Shield region north of Lake Superior features a series of
71   Greenstone belts in Archean rocks up to 2.5 billion years. … Near the bottom of typical
72   greenstone strata are ultrabasic volcanic and intrusive [rocks], which can yield chromite and
73   nickel ores. Overlying these beds are mafic and felsic [volcanic rocks], often with ores of gold,
74   silver, copper, and zinc. At the top of the sequence are sedimentary rocks which yield
75   manganese, barite, and iron ores" (Kerfoot & Nriagu, 1999). These greenstone belts are up to
76   hundreds of kilometers long and wide.

77   The Midcontinent Rift System in the western Lake Superior basin is a package of basalt flows
78   and sedimentary rocks up to 25 km thick (Keays & Lightfoot, 2015). Between approximately
79   1.109 and 1.084 billion years ago (Early to Middle Proterozoic, Fig. 1), there was a prolonged
80   period of extension in the middle of what is now North America, which produced large quantities
81   of basaltic magmas and a large number of sills, dikes, mafic intrusive complexes, and intrusions
82   of alkali and carbonatitic composition (Keays & Lightfoot, 2015; Kerfoot & Nriagu, 1999). Most
83   of the exposed rift outcrop is found around Lake Superior, but evidence suggests that it also
84   underlies the Michigan Basin feature of Lower Michigan (Fig. 1).The rift structure extends to the
85   southwest as far as Kansas. Many of the major metallic mineral prospects and ore bodies in the

86   Great Lakes region are part or product of the Midcontinent Rift (Ojakangas, Morey & Green,
87   2001).

88   The Lake Huron basin is largely within the Paleozoic sedimentary rock region, though the
89   northern shore is on the edge of the Canadian Shield (Hough, 1958). Lakes Michigan, Ontario,
90   and Erie are almost all entirely within the Paleozoic province, which is dominated by the
91   sedimentary rocks of the Michigan Basin (Fig. 1). Surrounding the Michigan Basin is an erosion-
92   resistant sequence of Silurian dolomite. On top of this dolomite sandstone, shale, limestone, and
93   evaporite sediments were deposited (LaBerge, 1994). Lake Erie is largely underlain and
94   surrounded by Devonian limestones and shales, and Lake Ontario is underlain by Ordovician
95   limestones and shales. The Silurian rocks outcrop between the two lakes, forming the Niagara
96   Escarpment, which is the foundation of Niagara Falls (Sly & Thomas, 1974; Fig. 1).

97   The overlying sediment in the Great Lakes basin is strongly influenced by glaciation. The
98   lowland region which includes the Erie and Michigan basins along with most of Huron and
99   Ontario is blanketed by glacial sediments often between 50 and 350 m in thickness. The upland
100 region of Superior, Georgian Bay, and Ontario basins has thin discontinuous layers of glacial
101 sediments (Larson & Schaetzl, 2001). For a more detailed description of glacial processes in the
102 Great Lakes, see Larson & Schaetzl (2001) and Sly & Thomas (1974). Because sediments may
103 be derived from glacial till transported long distances, sourcing of materials is difficult without
104 more in-depth mineralogical analyses. Hence, excepting documented and localized metallic ores,
105 confirming ultimate sources for materials found in lake sediment cores can be challenging.

Metals in the Great Lakes

107 A discussion of the influence that rock type can have on elemental concentrations can provide
108 some geological context for the presence of certain metallic analytes in lake sediments. For
109 example, arsenic (As) generally occurs in lower concentrations in igneous rocks compared to
110 sedimentary rocks, as shown in Table 2 which is a combined version of two tables from National
111 Research Council (1977). The range of metal ppm values can be quite broad, even within a
112 specific rock type. For instance, the Biwabik Iron Formation in Minnesota is a sedimentary iron
113 ore deposit, and the range of its As content as reported by Morey (1992) was <3 to 40 ppm which
114 is small relative to the 1 to 2,900 ppm range shown in the table. Other metals show different
115 ranges of composition based on rock type, but it is beyond the scope of this report to provide
116 those details for all metals.

117 These bedrock characteristics can provide some information on sources of metals in the
118 environment, but what best explains an element's presence in Great Lakes sediment cores,
119 especially during the Anthropocene epoch? While bedrock geology is important to consider,
120 unconsolidated surficial materials are the more significant contributors to sediment loading. As
121 reported to the U.S. Army Corps of Engineers by the Great Lakes Commission (2008), more than
122 65 million tons of soil may be eroding annually in the Great Lakes basin based on modeling data
123 by Ouyang & Bartholic (2003), with agricultural land being the largest known contributor to soil
124 erosion in the basin (65 to 77%). Therefore, soils are probably the most relevant source of
125 catchment inputs, but with the understanding that soils are also derived from bedrock sources

126 that may not be proximal to eroding soils, they may not reflect local bedrock geology. A large
127 portion of lake contamination is also sourced atmospherically, such as by fossil fuel consumption
128 and metal smelting (refining), making the identification of a specific contributor even more
129 difficult. What this review shows is that human activity and society's reliance on and demand for
130 natural resources is ultimately the driver for nearly every metal or metal-containing compound
131 whose extraction, production, and use contribute to their presence in the environment above
132 background levels.

133 What follows is an encyclopedic list of metals in Great Lakes sediments. All available research,
134 and best judgement, was used to characterize metals as they pertain to Great Lakes geochemistry.
135 This included as necessary for each analyte: source, known history, and contaminant properties.

136 Alkali Metals

137 *Lithium*
138 **Contaminant status in the Great Lakes:** Unknown but possible
139 **Dominant sources:** Weathering of rocks
140 **Background and relevance to the Great Lakes:** Lithium (Li) is the 27th most abundant element
141 in the Earth's crust and has been found to have a concentration of $0.07 - 40$ µg/L in fresh waters
142 (Shahzad et al., 2016). Li is found in small amounts in nearly all rocks, averaging 40 ppm in soil
143 (Emsley, 2002). At low concentrations, it seems to stimulate plant growth (Aral & Vecchio-
144 Sadus, 2008). Lithium's biological impacts are not well understood, although it is commonly
145 used as a psychoactive drug. Li is an issue of emerging concern in surface waters due to its
146 increasing use in drugs, batteries, and alloys (Tkatcheva et al., 2015). However, its prevalence is
147 not well known because environmental releases of Li are not regulated in North America. It can
148 be used in paleolimnology to account for increasing sediment inputs into a system in order to
149 determine what amount of trace metal inputs are from anthropogenic sources in addition to
150 natural sediment inputs (Ikem and Adisa, 2011). Historically, increases in Li in the sediment
151 record of Northeast Germany indicated erosion of the catchment area (Selig, Leipe & Dörfler,
152 2007). Rossmann & Barres (1988) found median Li concentrations (dissolved and particulate)
153 ranged from 0.64 ppb in Lake Superior waters to 2.4 ppb in Lake Ontario in samples collected
154 between 1981 and 1983. They found that Lakes Erie, Michigan, and Ontario had significantly (p
155 > 0.05) higher concentrations of Li than Lake Superior waters. In Lake Superior, Nussmann
156 (1965) found Li concentration did not vary systematically in sediment cores. Concentrations in
157 surface sediments averaged 45 ppm, while the average concentration in glacial sediments was 96
158 ppm. Nussmann (1965) theorized that the fact Li was not sorbed in clays may mean there is little
159 sediment-water exchange of Li in Lake Superior.

160 *Sodium*
161 **Contaminant status in the Great Lakes:** Associated with urban environments, mining and
162 other industries
163 **Dominant sources:** The Michigan basin (Fig. 1) due to evaporation of sea water, road salt
164 applications, domestic and industrial wastewater
165 **Background and relevance to the Great Lakes:** Sodium (Na) is the 6th most abundant element,
166 making up 2.36% of the Earth's crust (Lindsay, 1968; Taylor, 1964). Na is an essential element

167   to life as the principal cation of extracellular fluids in higher animals. It is readily weathered and
168   highly soluble in aqueous environments, where it has a long residence time (Mittlefehldt, 1999b).
169   Na enters the hydrosphere from urban environments through road salt and waste water treatment
170   plants (Chambers et al., 2016). Due to its long residence time, Na has been persistently higher
171   than background levels in Lakes Superior, Michigan, and Huron over the last 150 years, though
172   it did peak in Lakes Erie and Ontario between 1965 and 1975, decreasing in more recent years
173   due to a reduction in point source discharges (Chapra, Dove & Warren, 2012). Kemp and
174   Thomas (1976b) and Kemp et al. (1978) considered Na a conservative element in their cores
175   from Lakes Ontario, Erie, Huron, and Superior over the period from pre-settlement to the early
176   1970s and observed relatively stable concentrations over the interval. Shaw Chraïbi et al. (2014)
177   found increases in Na starting in 1952 with a gradual decline between 1952 and 1990 in their
178   core from eastern Lake Superior. In their core of western Lake Superior, they found stable
179   concentrations of Na up to 1955 ending with an increase in concentration likely resulting from
180   urban inputs in the vicinity of Duluth, Minnesota. Reavie et al. (2005) found that Na
181   concentrations gradually increased in the 1800s with European settlement in their core from
182   Lake George, just downgradient from Lake Superior. Sgro and Reavie (2017) attributed Na in
183   their cores in Lake Erie to road salt impacts and found the highest concentrations in surface
184   sediments. In Lake Huron, Sgro and Reavie (2018) associated Na with edaphic deposits and
185   found concentrations remained stable until around 2011.

186   *Potassium*
187   **Contaminant status in the Great Lakes:** Yes, related to industrial and agricultural activity
188   **Dominant sources:** Weathering
189   **Background and relevance to the Great Lakes:** Potassium (K) is the 7th most abundant
190   element, making up 2.09% of the Earth's crust (Schoeld, 1968; Taylor, 1964). It is found in all
191   soils and exists in several forms, some readily weathered and dissolved. K is an essential nutrient
192   in both plant and animal cells, being more important in plants as Na is more important in
193   animals. K leaches into rivers from fertilizer applications and is released with burning biomass
194   (Schoeld, 1968; Pompeani et al., 2013). Kemp and Thomas (1976b) and Kemp et al. (1978)
195   considered K a conservative element in their cores from Lakes Ontario, Erie, Huron, and
196   Superior over the period from pre-settlement to the early 1970s and observed relatively stable
197   concentrations over the interval except near the sediment-water interface, where they observed
198   increases and decreases in concentration related to fluctuating levels of organic matter. Shaw
199   Chraïbi et al. (2014) found increases in K in 1952 associated with mining activity with a gradual
200   decline between 1952 and 1990 in their core of eastern Lake Superior. In their core of western
201   Lake Superior they found stable concentrations of K up to 1955, ending with an increase in
202   concentration. Pompeani et al. (2015) observed increases in K concentration in their core near
203   Isle Royale, Lake Superior around 5800 BP that matched the dating of Cu artifacts found in the
204   region, suggesting that concentrations were related to ancient mining practices. K concentrations
205   do not increase with modern mining techniques, implying inputs from wood fires or perhaps
206   some other difference between modern and ancient mining (Pompeani et al., 2015).
207

208 *Rubidium*

209 **Contaminant status in the Great Lakes:** None known

210 **Dominant sources:** Lithogenic, silicates, coal burning

211 **Background and relevance to the Great Lakes:** Rubidium (Rb) is a widely distributed element
212 that forms no minerals. It is concentrated in silicates and is soluble in aqueous solutions
213 (Simmons, 1999). It has a concentration of about 90 ppm in the Earth's crust (Mosheim, 1968b;
214 Taylor, 1964). Rb is considered a conservative lithogenic element and can be used to control for
215 natural inputs when measuring the extent of anthropogenic inputs of other elements. Rb is also
216 thought to be immobile in the sediments (Boës et al., 2011). It is considered an ultra-trace
217 element for humans and other organisms, and it undergoes consistent biomagnification in the
218 food web (Campbell et al., 2005). Most Rb in lakes is related to geologic features and minerals in
219 soils. A possible anthropogenic source is coal burning, especially from the Nanticoke Generating
220 Station on Lake Erie, which was the largest coal-fired power station in North America until it
221 was decommissioned in 2013 (Campbell et al., 2005).

222 *Cesium*

223 **Contaminant status in the Great Lakes:** Yes, in the form of ^{137}Cs

224 **Dominant sources:** Erosion and weathering. Radioactive isotope ^{137}Cs from atmospheric
225 deposition after nuclear weapons testing

226 **Background and relevance to the Great Lakes:** Cesium (Cs) is widely distributed in the
227 Earth's crust at low concentrations (Mosheim, 1968a). It averages 1 ppm in granite and 4 ppm in
228 sedimentary rocks. In fresh water, Cs occurs naturally from erosion and weathering and at
229 between 0.01 and 1.2 µg/L. Cs has serious health impacts in the form of its radioactive isotopes,
230 which cause tissue damage and disruption of cellular function. Cs is used in paleolimnological
231 studies because the isotope ^{137}Cs is a radionuclide marker for the early 1960s (Gobeil, Tessier &
232 Couture, 2013). The majority of ^{137}Cs in surface waters in North America, including the Great
233 Lakes, is due to nuclear weapons testing, which began in 1952 and ended in 1963 with the
234 Limited Test Ban Treaty. In the Great Lakes, the maximum deposition of ^{137}Cs was in the spring
235 of 1963, though peaks in the sediment may be as much as two years later (ASTDR, 2004a;
236 Reavie et al., 2005). The radionuclide is strongly bound to expandable lattice clay minerals such
237 as illite in the Great Lakes, so it tends to be a reliable temporal indicator in sediment profiles.

238 Alkaline Earth Metals

239 *Magnesium*

240 **Contaminant status in the Great Lakes:** Some historical contamination associated with
241 taconite tailings in the western part of Lake Superior

242 **Dominant sources:** Limestone in Lake Michigan basin (Fig. 1); dolomite content of bluffs along
243 north shore of Lake Erie (Chapra, Dove & Warren, 2012)

244 **Background and relevance to the Great Lakes:** Magnesium (Mg) is abundant in nature,
245 always as part of a compound. It is the 8th most abundant crustal element and 6th most abundant
246 metallic element, making up 2.5% of the Earth's crust (Gross, 1968). Mg readily dissolves
247 during weathering of rocks and enters the hydrosphere (Mittlefehldt, 1999a). It is a necessary
248 element for life and one of the four bulk metals in the human body (Schroeder, Nason & Tipton,

249 1969). In lake sediment records, increases in Mg are frequently associated with erosion
250 (Mackereth 1966; Norton, Binford & Kahl, 1992), and in more modern times, Mg is associated
251 with road dust (Spengler et al., 2011). Kemp and Thomas (1976b) and Kemp, Thomas &
252 Gregory (1978) found Mg as one of the major elements in the sediment of Lakes Ontario, Erie,
253 Huron, and Superior and found it to be generally uniform in all of their cores. In a sediment core
254 from western Lake Superior, Shaw Chraïbi et al. (2014) found peaks in Mg around 1972, which
255 they associated with taconite processing and waste discharge near Silver Bay, MN. Arthur et al.
256 (1973) found Mg to be a component of the dissolved solids from the tailings. But considering the
257 core locations of Shaw Chraïbi et al. (2014) and the circulation patterns of Lake Superior, the
258 association in their cores is unclear. Pompeani et al. (2015) found Mg concentrations in Lake
259 Superior near McCargoe Cove to be relatively stable over their 8,400 year record, though
260 increases are believed to reflect changes in the delivery of metals to the basin, as high
261 concentrations of Mg are found in the bedrock surrounding Cu lodes.

262 *Calcium*
263 **Contaminant status in the Great Lakes:** Yes, related to runoff and mining
264 **Dominant sources:** Carbonate minerals such as those found in the Midcontinent Rift and in the
265 Paleozoic (carbonate-rich) bedrock surrounding the lower Great Lakes (Fig. 1); detrital material
266 **Background and relevance to the Great Lakes:** Calcium (Ca) is the 5th most abundant element
267 in the Earth's crust. It is one of the most widely distributed elements, present in almost all natural
268 waters. Ca is the most common inorganic element in higher animals and necessary for most life,
269 concentrating in skeletons, exoskeletons, and shells and distributed throughout tissues. It is also
270 needed for plant meiosis and the maintenance of soil pH (Mantell, 1968). In urban environments,
271 Ca pollution comes from building materials (Chambers et al., 2016). The Great Lakes are rich in
272 limestone (especially in the Paleozoic province surrounding the lower Great Lakes (Fig. 1)) and
273 therefore calcium carbonate ($CaCO_3$). In the summer, the lakes can experience periods of
274 "whiting," when warming waters release $CaCO_3$ into the water column and dissolved CO_2 is
275 removed by algae. Sediment cores in the Great Lakes have fluctuating $CaCO_3$ levels with times
276 of warmer climate (Meyers, 2003). Due to its long residence time, Ca has been persistently
277 increasing in Lakes Superior, Michigan, and Huron over the last 150 years, though it did peak in
278 Lakes Erie and Ontario between 1965 and 1975, decreasing in more recent years due partly to
279 the introduction of quagga mussels (Chapra, Dove & Warren, 2012), who use the Ca in
280 formation of shells. In Lakes Superior and Huron, Kemp et al. (1978) considered Ca a
281 conservative element, representing terrigenous sources of materials in their sediment cores. In
282 Lakes Ontario and Huron, Kemp and Thomas (1976b) grouped Ca with the carbonates, finding
283 decreasing concentration in parts of Lake Erie and increases to very high surface concentrations
284 in Lake Ontario above the *Ambrosia* pollen horizon (marking European settlement and
285 deforestation), which they attributed to the dissolution of detritus. Shaw Chraïbi et al. (2014)
286 found increases in Ca in 1952 that they associated with overall mining activity in the basin, with
287 a gradual decline between 1952 and 1990 in their core of eastern Lake Superior. In their core of
288 western Lake Superior, they found stable concentrations of Ca until 1955 followed by an
289 increase in concentration.

Strontium
Contaminant status in the Great Lakes: Yes, related to mining, fossil fuels, and industry
Dominant sources: Ca-containing rocks and minerals, dust, mining waste, fossil fuels, other industries
Background and relevance to the Great Lakes: Strontium (Sr) is the 15th most common element on Earth, making up 0.034% of the Earth's crust (Höllriegl & München, 2011). Mean dissolved Sr in the Great Lakes ranged from 42 ppb in Lake Superior to 180 ppb in Lake Ontario between 1981 and 1985 (Rossmann & Barres, 1988). There is a small amount of Sr in many rocks and minerals, but it is present in all Ca-bearing rocks, minerals, and soils. Sr is naturally released from the Earth's crust as dust and wind. Human processes that contribute to Sr release include mining, milling and processing, pyrotechnics, and phosphate fertilizers. Other sources for Sr pollution include association with chloride in road salt in the Lake Ontario watershed (Meriano, Eyles & Howard, 2009) and iron corrosion products from residential drinking water distribution systems (Gerke et al., 2013). It is also present in coal and becomes concentrated in coal fly ash (Sherman et al., 2015). Spengler et al. (2011) also attributed increases in Sr with road dust, brake dust, and diesel tail pipe emissions near Buffalo Peace Bridge on the Niagara River between Lakes Erie and Ontario. Sr is chemically similar to Ca and can deposit in bones. In fish, otoliths and other biogenic carbonates Sr and Sr/Ca ratios can be used to reconstruct past water temperatures and salinity because the partitioning constant for those elements varies with those parameters (Limburg et al., 2015; Carilli et al., 2015). Sr found at natural concentrations has low toxicity, but radioactive Sr can be dangerous, especially because it deposits in bones, leading to bone cancer (Hampel, 1968e). Sr has several radioactive isotopes, the longest lived being ^{90}Sr with a half-life of 29 years. Radioactive Sr was released into the atmosphere between 1945 and 1980 via nuclear weapons testing. While present in Great Lakes water, a 1984 study indicated that radioactive Sr was within safe drinking water parameters (Durham & Joshi, 1984), and it is likely that radioactivity has since decreased. Shaw Chraïbi et al. (2014) found increases of Sr from pre-settlement 1952 in their eastern core of Lake Superior associated with mining. In their western core, they found a peak of Sr between 1955 and 1967, which they associated with taconite processing in Silver Bay.

Barium
Contaminant status in the Great Lakes: Yes, listed as a sediment and water contaminant of the Saginaw Bay and the Rouge River Great Lakes Areas of Concern (AOCs) (Hartig and Thomas, 1988)
Dominant sources: Barite, drilling fluid (oil and gas industry)
Background and relevance to the Great Lakes: Barium (Ba) is the 14th most abundant element in the Earth's crust (Hampel 1968a; Smith, 1999). Ba is highly reactive and is precipitated with sulfate and carbonates. Therefore, it is not very mobile in soils and remains bound to particles in circumneutral pH (Madejón, 2013). When soluble, Ba is moderately acutely toxic (Moore, 1991). Barite (barium sulfate) is used as a drilling fluid/mud for oil and gas wells. Ba was historically used as a tracer in place of lead for vehicle emissions via diesel and unleaded gasoline (for example, in sediment cores from an urban Hawaii stream described by Sutherland (2000)), but newer diesel fuels are low-sulfur and do not need to use Ba as a sulfur-scavenging agent (ASTDR, 2007b). Ba was found in at least 798 of 1,684 current or former EPA National

333 Priorities List (NPL) hazardous sites in the United States. In Lake St. Clair, sediment Ba was at
334 non-detect levels in 1983 and up to 48.37 mg/kg in 2010 (Alsaffar, 2017). According to USEPA
335 guidelines, 20–60 mg/kg is considered moderately polluted with Ba, and >60 mg/kg is heavily
336 polluted. In Saginaw Bay, Ba levels up to 422 mg/kg were found (Hartig and Thomas, 1988). In
337 contrast, Ba was one of the elements least enriched by anthropogenic sources in Lake Erie
338 according to Yuan (2017). In Lake Superior, Shaw Chraïbi et al. (2014) saw, in an eastern core,
339 an increase in Ba from post-settlement through ~1952 associated with mining, peaking around
340 1960. In a western core, they observed a Ba peak between 1955 and 1967 associated with
341 taconite processing waste discharge near Silver Bay.

342

343 Transition Metals

344 *Scandium*
345 **Contaminant status in the Great Lakes:** None known
346 **Dominant sources:** Widely distributed
347 **Background and relevance to the Great Lakes:** Scandium (Sc) is the 36th most abundant
348 element in the Earth's crust (Horovitz, 1975). Sc is present in small amounts in hundreds of
349 minerals, as there are no geological processes to concentrate it and it lacks affinity for common
350 ore-forming ions (Emsley, 2014; USDOI & USGS, 2017). Hence, no localized sources of Sc are
351 known in the Great Lakes basin, and no Sc is mined in the United States. Sc is not known to be a
352 nutrient for any organism and has, in fact, been found to be toxic in high concentrations due to its
353 high affinity for proteins (Sánchez-González et al., 2013). According to Horovitz (1975), the
354 average soil content of Sc is 7 ppm, with a range of 3–50 ppm. Sc is a useful reference element
355 that can be compared to the concentration of other, less conservative elements in order to gain
356 more useful information about that element's variability in time (Peirson, Cawse & Cambray,
357 1974; Dias & Prudêncio, 2008). Sc has not been greatly studied in the Great Lakes, although
358 Winchester (1972) found the natural inputs of Sc to Lake Michigan to be 0.004 ppb per year and
359 the natural output to be 0.027 ppb per year. Shimp et al. (1971) and Reavie et al. (2005) found
360 that Sc concentrations did not vary over time in their sediment cores from southern Lake
361 Michigan and Lake George, respectively.

362 *Titanium*
363 **Contaminant status in the Great Lakes:** Some atmospheric contamination from vehicle and
364 coal emissions along with catchment erosion
365 **Dominant sources:** Ubiquitous
366 **Background and relevance to the Great Lakes:** Comprising 0.63% of the Earth's crust by
367 mass, Titanium (Ti) is the 9th most abundant element and the 7th most abundant metal. It is
368 widely distributed in a diverse range of rocks, soils, minerals, and atmospheric dust (Barksdale,
369 1968). According to Woolrich (1973), Ti ranges in concentration in the air from 0.003–0.07 ppb.
370 It is considered a weathering-resistant, immobile mineral, generally insoluble and not mobilized
371 by acidification (Norton, Binford & Kahl, 1992; Schaetzl, Mikesell & Velbel, 2006). Increases in
372 Ti are generally associated with erosion. Titanium dioxide (TiO^2) is useful as an indicator of
373 erosion rates and for the normalization of other trace metals, but one must take care to account

374   for atmospheric concentrations of Ti, which may lead to inconsistent results (Norton, Binford &
375   Kahl, 1992). Spengler et al. (2011) performed a study of air toxics near the Buffalo Peace Bridge
376   U.S. Border crossing on the east end of Lake Erie and found two-fold increases in Ti downwind
377   of the city of Buffalo, which they attributed to coal combustion, traffic emissions, and road dust.
378   In rock, Ti is known to occur in gabbroid rocks in the Midcontinent Rift near the south shore of
379   Lake Superior (Fig. 1; Wisconsin Geological and Natural History Survey 2019), but it is
380   probably much more widespread. Ti is considered a conservative element and was found to be
381   generally constant in sediment cores from Lakes Ontario, Erie, Huron, and Superior (Kemp et
382   al., 1976; Kemp et al., 1978; Pompeani et al., 2015).

383   *Vanadium*
384   **Contaminant status in the Great Lakes:** Yes, especially in Lake Michigan due to past
385   contamination from the BP Whiting Refinery
386   **Dominant sources:** Weathering, fossil fuel emissions
387   **Background and relevance to the Great Lakes:** Vanadium (V) is the 22nd most abundant
388   element in the Earth's crust at around 130 ppm by mass (Foote Mineral Co., 1968; Sigel, Sigel &
389   Sigel, 2013). V is non-toxic at common concentrations, though it can bioaccumulate, and at
390   higher concentrations it can have negative effects on the respiratory system. It is an essential
391   trace element for many organisms, and deficiency is associated with a variety of conditions
392   including problems in growth, reproduction, and blood formation (Gummow, 2011;
393   Venkataraman & Sudha, 2005). V is present in more than 50 minerals and its main natural source
394   in the environment is weathering of rocks, hence it is difficult to determine specific rock sources
395   in the Great Lakes. Anthropogenic inputs are largely atmospheric; V is a major component of
396   coal- powered and other fossil fuel emissions. V has been a contaminant of more recent concern
397   and has been found in 319 out of 1,699 hazardous sites on the EPA's National Priorities List
398   (ASTDR, 2012c). Shahin, Paode & Holsen (2000) found an increase of V dry deposition in the
399   urban area of Chicago compared to other sampling sites around Lake Michigan due to emissions
400   from industrial sources. Kemp et al. (1978) found V to be stratigraphically uniform in most of
401   their cores of Lakes Huron and Superior taken in the early 1970s, though there were
402   anthropogenic inputs. One of the major sources of V pollution on the Great Lakes is the BP
403   Whiting Refinery on the southwestern shore of Lake Michigan. This refinery stored petroleum
404   coke (petcoke), a byproduct of the refining process, at a site in Chicago operated by KCBX
405   Terminals Company until 2016. The mounds of petcoke at this site were a source of windborne
406   V and negatively impacted air quality in the area (ASTDR, 2016). BP also discharged 39 barrels
407   of oil into Lake Michigan in March 2014, and the EPA found that they failed to implement a
408   proper spill prevention plan (Bassler, 2016).

409   *Chromium*
410   **Contaminant status in the Great Lakes:** Yes, listed as a sediment contaminant or water
411   contaminant in 17 AOCs in the Great Lakes (Hartig and Thomas, 1988)
412   **Dominant sources:** Greenstone belts in Archean rocks in Canadian Shield north of Lake
413   Superior (Fig. 1), chromine, steel production, leather tanning
414   **Background and relevance to the Great Lakes:** Chromium (Cr) is an essential human nutrient
415   at low concentrations but is toxic at higher levels, acting on the respiratory tract and as a

416   carcinogen (Ilton, 1999; ASTDR, 2012b). Major anthropogenic sources of Cr in natural waters
417   include waste from electroplating, leather tanning, and textile industries. Cr is important in use of
418   the steel industry, as it is an essential component of stainless steel (USDOI & USGS, 2017).
419   Yuan (2017) included Cr in group of elements most enriched by anthropogenic loading in Lake
420   Erie. Walters, Wolery & Myser (1974) also observed significant enrichment in Lake Erie cores
421   since about 1950. Reavie et al. (2005) associated peaks of Cr in their cores of Lake George with
422   the now defunct Northwestern Leather Company which discharged directly into St. Mary's
423   River, just downstream from Lake Superior. Cr in their cores peaked around 1946 and sharply
424   dropped in the late 1950s after the tannery closed. Kemp et al. (1978) found only small amounts
425   of localized enrichment in their cores of Lakes Superior and Huron.

426   *Manganese*
427   **Contaminant status in the Great Lakes:** Yes, listed as a sediment contaminant or water
428   contaminant in of the following AOCs: Clinton River, Cuyahoga River, Oswego River (Hartig
429   and Thomas, 1988)
430   **Dominant sources:** Terrigenous sources including sedimentary rocks overlying the Canadian
431   Shield above Lake Superior (Fig. 1), contaminant from iron and steel production;
432   ferromanganese nodules
433   **Background and relevance to the Great Lakes:** Manganese (Mn) is the 12th most abundant
434   element in the Earth's crust and biosphere and is considered one of the five essential trace
435   elements to nearly all organisms (Hampel, 1968d; Nádaská et al., 2012; Uren, 2013). In high
436   chronic doses Mn impacts the human central nervous system (Nádaská, Lesny & Michalik,
437   2012). Mn is common in the Great Lakes, especially in Lakes Michigan and Ontario where it
438   occurs in nodular concretions and coatings on sand particles and rocks (Sly and Thomas, 1974).
439   Mn preferentially sorbs to heavy metals and nodules can act a sink for those metals; it is
440   especially associated with Co and Fe (Kemp et al., 1978; Uren, 2013), and it diffuses and
441   precipitates with other redox sensitive elements such as Fe and As (Sly and Thomas, 1974;
442   Azcue, Rosa & Mudroch, 1996); hence, Mn is a common co-contaminant from mining activities.
443   Ferromanganese concretions found in Lake Superior are thought to be linked to activity of iron
444   oxidizing bacteria (Dittrich et al., 2015). Mn occurs in sediment cores but often concentrates near
445   the sediment water interface because it is extremely redox sensitive. It tends to migrate through
446   anoxic porewater and then becomes trapped by oxic surface sediments, thereby making it
447   difficult to establish its actual depositional history (Kemp and Thomas, 1976a; Kemp and
448   Thomas, 1976b; Sly and Thomas, 1974; Kemp et al., 1978; Azcue, Rosa & Mudroch, 1996;
449   Reavie et al., 2005; Shaw Chraïbi et al., 2014; Kuzyk, Macdonald & Johannessen, 2015). In
450   Lake Erie and shallow areas of Lake Ontario, which are seasonally anoxic, Mn is able to escape
451   from the sediment and does not accumulate at the surface as it does in other lakes (Kemp and
452   Thomas, 1976b). Peaks in Mn in lower layers of sediment cores are often related to
453   anthropogenic activities such as taconite processing or as a contaminant from iron and steel
454   production (Kemp et al., 1978; Reavie et al., 2005; Chambers et al., 2016), hence the record of
455   Mn is particularly relevant to Lake Superior.

456   *Iron*
457   **Contaminant status in the Great Lakes:** Yes, listed as a sediment contaminant or water

458 contaminant in 16 AOCs in the Great Lakes (Hartig and Thomas, 1988)
459 **Dominant sources:** Terrigenous sources including sedimentary rocks overlying the Canadian
460 Shield above Lake Superior (Fig. 1), weathering, mining
461 **Background and relevance to the Great Lakes:** Iron (Fe) is the 4th most abundant element in
462 the Earth's crust (~7% or 70,000 ppm) and is believed to be the most abundant element on Earth.
463 Fe is essential to the biological function of all animals (Hampel, 1968c; Williamson, 1999b).
464 Some Fe bearing minerals are the result of *Thiobacillus* reactions, which oxidize Fe in aqueous
465 solution. Fe can scavenge trace metals and bring them out of solution, but it can also carry those
466 same trace metals back into solution under acidic or reducing conditions. Increased Fe levels in
467 surface waters can increase algal productivity, especially of cyanobacteria which have higher Fe
468 requirements than eukaryotic algae. Fe becomes accessible to algae in anoxic sediments, which
469 transform it into Fe^{2+}, an ion suitable for algal uptake (Verschoor et al., 2017). In some cases in
470 the Great Lakes, Fe has the potential to be a limiting nutrient in the formation of algal blooms
471 (North et al., 2007). The most important Fe-producing district in the United States is the Mesabi
472 Range within the Lake Superior Watershed, where there was intense taconite processing during
473 the 1960s and 1970s. The Reserve Mining Company in Silver Bay, Minnesota discharged
474 taconite tailings directly into Lake Superior. In sediment cores Fe, like Mn, is a mobile element
475 under reducing conditions which can concentrate at the sediment-water interface. Shaw Chraïbi
476 et al. (2014) found increasing concentrations in their core from the eastern watershed of Lake
477 Superior between 1850 and 1890. In the western watershed they found increases around 1880,
478 with a peak around 1930. Kemp and Thomas (1976b) found Fe levels in their sediment cores
479 from Lakes Ontario, Erie, and Huron remained fairly stable except in Lake Erie, which showed
480 increases near the surface, possibly due to anthropogenic inputs from steel plants of Detroit and
481 Cleveland. Yuan (2017) also found surface enrichments in their sediment cores from the
482 Sandusky Bay of Lake Erie, likely due to a combination of anthropogenic loading and redox
483 driven migration of Fe near the sediment surface.

484 *Cobalt*
485 **Contaminant status in the Great Lakes:** Yes, from mining, fossil fuel combustion, and other
486 industrial sources
487 **Dominant sources:** Natural bedrock sources, mine tailings, industry, fossil fuels
488 **Background and relevance to the Great Lakes:** Cobalt (Co) has an average crustal
489 concentration of 25 ppm (Taylor, 1964). Atmospheric releases of Co are expected to be mostly
490 from natural sources such as windblown soil, forest fires, and volcanoes. Increased Co levels in
491 water may be attributed to anthropogenic sources including mining, the burning of fossil fuels,
492 vehicular exhaust, and the use of phosphate fertilizers (ASTDR, 2004b). According to Smith &
493 Carson (1981) Lake Huron received 76% of its Co from natural sources and Lake Superior
494 received 85.4%. Concentrations of Co are increased in mine tailings of the Keweenaw Peninsula
495 (Lake Superior) and are also waste contaminants related to the production of alloys and metal
496 coating processes (Jeong & McDowell, 2003; Reavie et al., 2005). It is a redox sensitive element
497 much like Mn and Fe and can migrate to the top of sediment cores (Yuan, 2017). Kemp et al.
498 (1978) found uniform concentrations of Co in their cores from Lake Superior and Lake Huron
499 with minor anthropogenic enrichments at some sites.

500 *Nickel*
501 **Contaminant status in the Great Lakes:** Yes, listed as a sediment contaminant or water
502 contaminant in 16 AOCs in the Great Lakes (Hartig and Thomas, 1988)
503 **Dominant sources:** Greenstone belts in the Archean rocks north of Lake Superior (Fig. 1), steel
504 mills, coal-fired power plants, mining, and other industries
505 **Background and relevance to the Great Lakes:** Nickel (Ni) is the 24th most abundant element
506 in the Earth's crust and is more abundant than Cu, Zn, and Pb combined. There are naturally low
507 levels of Ni in surface water (ASTDR, 2005a), and it has toxicity only related to industrial
508 exposure (Adamec & Springer, 1968). There are respiratory, immune system, and birth issues
509 linked to workers in refineries (ASTDR, 2005a). Cole et al. (1990) found increased Ni in a peat
510 core in Northern Indiana, downwind of Chicago, related to steel mills and coal-fired plants.
511 Kemp et al. (1978) found high anthropogenic inputs of Ni in Lake Huron related to
512 contamination from the Ni mining complex in the Sudbury area. This contamination did not
513 extend to Lake Superior, and the authors theorized that this is due to minimal atmospheric
514 contamination and little migration in pore water. In Lake Superior, Nussmann (1965) also found
515 low, natural Ni content in sediments that was concentrated in the clay size fraction. Walters,
516 Wolery & Myser (1974) noted enrichment in their cores of Lake Erie related to electroplating
517 facilities in the Cleveland area, particularly during the late 1940s.

518 *Copper*
519 **Contaminant status in the Great Lakes:** Yes, listed as a sediment contaminant or water
520 contaminant in 31 AOCs in the Great Lakes (Hartig and Thomas, 1988)
521 **Dominant sources:** Precambrian Shield underlying Lake Superior (Fig. 1; Kolak et al.,1999),
522 mining, wastewater, and other industries
523 **Background and relevance to the Great Lakes:** Copper (Cu) is the 26th most abundant element
524 in the Earth's crust (Williamson, 1999a). It is a necessary nutrient for plants, animals, and
525 bacteria, though it is toxic at high concentrations (Grinstead, 1968). Because it is harmless or
526 even beneficial at low concentrations, Kolak et al. (1998) consider it a noncritical contaminant, a
527 group of anthropogenically enriched elements that are considered lower priority for contaminant
528 loading reduction than elements that are toxic at lower concentrations. According to ASTDR
529 (2004c), waste water is the biggest anthropogenic source of Cu in waterways, and considerable
530 amounts of Cu remain in effluent. They calculate that runoff from natural weathering and
531 disturbed sediment accounts for 68% of Cu in natural waters. Cu has been mined for more than
532 6,000 years (Peretti, 1968). Ore deposits in the Keweenaw Peninsula (Lake Superior) were
533 discovered in the 1840s, though evidence of Cu mining on Isle Royale goes back 6,500 years
534 before present (Pompeani et al., 2015). Between 1850 and 1929 the Keweenaw district was the
535 2nd largest producer of Cu in the world (Kerfoot et al., 2016). Cu concentrations above
536 background levels have been found in all of the Great Lakes, whether due to wastewater effluent,
537 mining, or industry, though the levels are decreasing in more recent times, potentially due to
538 legislation and better containment of industrial wastes (Kemp et al., 1976; Kemp et al., 1978;
539 Kolak et al., 1998). In their sediment cores of Lake Superior, Kolak et al. (1999) surmised Cu in
540 the nearshore sediments were related to mining discharge and that offshore was related instead to
541 biological uptake and settling of organic matter. Yuan (2017) also found Cu correlated with
542 organic matter in their surficial sediments from Lake Erie. Kerfoot et al. (1999) determined less

543 than 10% of the Cu loading into Lake Superior was atmospheric, although atmospheric
544 deposition is a source of many other metals into the lake.

545 *Zinc*
546 **Contaminant status in the Great Lakes:** Yes, listed as a sediment or water contaminant in 30
547 AOCs in the Great Lakes-St. Lawrence River system (Hartig and Thomas, 1988)
548 **Dominant sources:** Mafic and felsic volcanic rocks overlying the Greenstone belts in Archaean
549 rocks north of Lake Superior (Fig. 1), erosion, urban runoff, mine drainage, other industrial
550 sources.
551 **Background and relevance to the Great Lakes:** Zinc (Zn) is one of the most widely used
552 metals in the world. Though Zn is essential to human life it can be toxic at high concentrations.
553 Zn deficiency and excess can result in problems with metabolism and organ function in humans
554 (Nriagu, 2011). It has been mined extensively and is released into the atmosphere from mining,
555 iron and steel production, and coal and fuel combustion. It is released into waterways through
556 erosion, urban runoff, mine drainage, and municipal and industrial effluent (ASTDR, 2005b).
557 Sources of Zn pollution in urban environments include galvanized steel and automotive exhaust
558 (Chambers et al., 2016). It has been found enriched in post-settlement surface layers of sediment
559 cores throughout the Great Lakes, and authors agree that its sources are largely anthropogenic
560 (Förstner, 1976; Goldberg et al., 1981; Kemp & Thomas, 1976a; Kemp & Thomas, 1976b;
561 Kemp et al., 1978; Marvin et al., 2003; McKee et al., 1989; Nussmann, 1965; Painter et al.,
562 2001; Reavie et al., 2005; Yuan 2017). In their cores of Lake George (between lakes Superior
563 and Huron), Reavie et al. (2005) attributed Zn to the production of alloys and metal coating
564 processes. Goldberg et al. (1981) concluded Zn in Lake Michigan came primarily from the iron
565 and steel industry. Förstner (1976) found major increases in Zn between 1939 and 1955 related
566 to the growth of industry during World War II and the Korean conflict.

567 *Yttrium*
568 **Contaminant status in the Great Lakes:** None known
569 **Dominant sources:** Minerals containing rare-earth elements
570 **Background and relevance to the Great Lakes:** Yttrium (Y) is the 28th most abundant element
571 in the Earth's crust, occurring at an average of 30 ppm. It is twice as abundant as lead. It is found
572 in all rare earth minerals and is sometimes classified with them, although it is not technically part
573 of the group (Emsley, 2002). It is very chemically similar to the rare earth elements and was
574 formed in the Earth's crust by the same geochemical processes (Daane, 1968). Y has no known
575 biological role, though it does occur in all species. It has no apparent toxicity and poses no
576 environmental threat to plants or animals. To date, Y has not been studied in the Great Lakes
577 except as ^{90}Y in water, a short-lived decay byproduct of ^{90}Sr generated as nuclear waste (Amiro,
578 1993).

579 *Zirconium*
580 **Contaminant status in the Great Lakes:** None Known
581 **Dominant sources:** Soil dust
582 **Background and relevance to the Great Lakes:** Zirconium (Zr) is a lithogenic element that is
583 immobile in the sediments and resistant to weathering (Boës et al., 2011; Förstner & Wittmann,

584   1979; Schaetzl, Mikesell & Velbel, 2006). While little studied, Zr seems to have very low
585   toxicity (McClain, 1968). In sediment cores it is largely associated with soil dust, which is
586   mostly atmospherically transported. Nussmann (1965) found Zr in Lake Superior was
587   concentrated in the fine silt and was not related to biological activity or organic matter.

588   *Niobium*
589   **Contaminant status in the Great Lakes:** None known
590   **Dominant sources:** Minerals containing rare-earth elements
591   **Background and relevance to the Great Lakes:** Niobium (Nb) is the 33rd most abundant
592   element in the Earth's crust (Emsley, 2002). It generally occurs with Ta and the rare-earth
593   elements (Schmidt, 1968). It is very similar to Ta in physical, chemical, and electric properties.
594   Niobium is used in the production of high-strength, low-alloy steel and super alloys. It is used in
595   high-pressure pipeline construction and the auto industry (Mackay and Simandl, 2014). Nb has
596   not been studied in the Great Lakes.

597   *Molybdenum*
598   **Contaminant status in the Great Lakes:** Likely
599   **Dominant sources:** Steel mills and other industrial sources
600   **Background and relevance to the Great Lakes:** Molybdenum (Mo) is the 54th most abundant
601   element in the Earth's crust and averages around 2 ppm in soils (Emsley, 2002). It is used in steel
602   making and is found in higher concentrations near mills, industrial sources, and uranium mines
603   (Alloway, 2013a; Giussani, 2011). It is also found in waste water sludge. Mo is an essential trace
604   element in all species, and it is critical for nitrogen fixation in plants. It is generally
605   toxicologically harmless in humans (Sigel, Sigel & Sigel, 2013). Shahin, Paode & Holsen (2000)
606   found significantly higher atmospheric fluxes of Mo near urban sites than more remote sites
607   around Lake Michigan. Yuan (2017) found significantly elevated concentrations of Mo in cores
608   of Lake Erie after 1950 attributed to anthropogenic sources.

609   *Cadmium*
610   **Contaminant status in the Great Lakes:** Yes, listed as a sediment contaminant or water
611   contaminant in 11 AOCs in the Great Lakes (Hartig and Thomas, 1988)
612   **Dominant sources:** Industrial releases
613   **Background and relevance to the Great Lakes:** Cadmium (Cd) is a toxic element on the
614   United Nations Environmental Program's list of top 10 hazardous pollutants and is a priority
615   pollutant according to the United States Environmental Protection Agency (Emsley, 2002;
616   Mudhoo, Garg & Wang, 2012). It is the 65th most abundant element in the Earth's crust at 0.1
617   ppm. In soil, Cd averages 1 ppm, though polluted soil has been found to contain up to 1,500
618   ppm. Cd is thought to be completely non-essential for biological function (Smolders & Mertens,
619   2013; Tchounwou et al., 2012). Cd bioaccumulates and is a particular concern in plants, where it
620   accumulates in leaves and is consumed by animals or humans (Nagajyoti, Lee & Sreekanth,
621   2010). It is also believed to be carcinogenic. Cd is used in electroplating steel and in
622   rechargeable nickel-Cd batteries. It is a known atmospheric contaminant, being released by
623   smelting, fossil fuel burning, and waste incinerations (Norton et al., 2007). Due to greater
624   recognition of its toxicity and increased regulations, anthropogenic Cd emissions have decreased

625 over 90% in the last 50 years since elemental alternatives were identified in the 1960s (ASTDR,
626 2012a). Cd was found to be anthropogenically enriched in sediment cores throughout the Great
627 Lakes (Förstner, 1976; Goldberg et al., 1981; Kemp & Thomas, 1976a; Kemp & Thomas, 1976b;
628 Kemp et al., 1978; Marvin et al., 2003; Reavie et al., 2005; Walters, Wolery & Myser, 1974;
629 Yuan, Depew & Soltis-Muth, 2014; Yuan, 2017). Förstner (1976) attributed Cd in sediment
630 cores from Lake Erie to industrial discharges and specifically found high enrichments in the late
631 1940s corresponding to the growth of the Cleveland electroplating industry. Reavie et al. (2005)
632 associated Cd in a Lake George sediment core with production of alloys, metal coating
633 processes, and leather tanning in the area of Sault Ste Marie. They found decreases in the
634 sediments since the late 1950s, when Northwestern Leather Company closed.

635 *Hafnium*
636 **Contaminant status in the Great Lakes:** None known
637 **Dominant sources:** Zr containing minerals and soil dust
638 **Background and relevance to the Great Lakes:** Hafnium (Hf) is the 45th most abundant
639 element in the Earth's crust at 5.3 ppm. In soils, it averages around 5 ppm, ranging from 2–20
640 ppm. Hafnium has no known biological role or toxicity. Hf is used as a control rod for nuclear
641 reactors and submarines because it effectively absorbs neutrons, but otherwise it has limited
642 applications. It is not known to be an environmental threat (Emsley, 2002; Hampel, 1968b).
643 Kerfoot and Robbins (1999) found Hf concentrations to be moderately enriched in the Point
644 Mills stamp sands on Lake Superior.

645 *Tantalum*
646 **Contaminant status in the Great Lakes:** None known
647 **Dominant sources:** Occurs with Nb and the rare-earth elements in clay and shale
648 **Background and relevance to the Great Lakes:** Tantalum (Ta) is the 51st most abundant
649 element in the Earth's crust at an average of 2 ppm. It is insoluble and there is virtually no Ta in
650 natural waters (Emsley, 2002), so in geochemical records it would be expected to be associated
651 with mineral particulates. Ta has no biological role and is not known to have toxicity properties,
652 hence it is widely used in surgical tools (Wehrmann, 1968). It is an essential metal in modern
653 society and is also used for corrosion resistance, microelectronics, and high-strength, low-alloy
654 steel (Mackay & Simandl, 2014). This element has not been studied in the Great Lakes.

655 *Mercury*
656 **Contaminant status in the Great Lakes:** Yes, related to coal fired power plants, mining, and
657 other industries
658 **Dominant sources:** Atmospheric
659 **Background and relevance to the Great Lakes:** Mercury (Hg) is relatively rare; at 50 ppb in
660 the Earth's crust, it is the 68th most abundant element (Emsley, 2002). In soil it averages 0.01–
661 0.5 ppb, though contaminated soils have up to 0.2 ppm. Despite its overall rarity, it is an element
662 of major concern because its toxicity at very low concentrations threatens environmental and
663 human health. Because harmful levels of Hg can be very low, analytical techniques for Hg
664 require an especially low detection limit, much lower than that required for most other metallic
665 elements. Hg has no known biological role but is present in all life. It is a potent neurotoxin that

666   accumulates and magnifies in aquatic food webs (Sherman et al., 2015). Hg is a pollutant
667   throughout the Great Lakes, and most water bodies in the Great Lakes region have fish
668   consumption advisories due to Hg accumulation in tissues (Risch et al., 2012). As a contaminant
669   of concern, much research has been performed on Hg levels in Great Lakes sediment and
670   sediment cores (Table 1). Sediment cores reveal Hg increases beginning in the mid-1800s and
671   reaching a maximum in the 1970s, decreasing in more recent times with increasing regulation
672   and phasing out of most uses in modern industry (Steinnes, 2013). In modern times, Hg is
673   released into the atmosphere primarily by coal-fired power plants, metal processing, and waste
674   incineration (Chambers et al., 2016; USDOI & USGS, 2017). Historic Hg atmospheric emissions
675   had peaks in 1879 and 1920 from gold and silver mining (Pirrone et al., 1998). Diffuse
676   atmospheric sources are thought to dominate Great Lakes Hg, but there have been a number of
677   localized point sources. Around the Keweenaw Peninsula (Superior), Hg loading was greatly
678   enhanced during the height of Cu mining between 1880 and 1930 due to its presence in tailing
679   piles, smelters, mills, and parent ores (Kerfoot et al., 1999; Kerfoot et al., 2004; Kerfoot et al.,
680   2016). High loadings were found near pulp and paper plants near Thunder Bay, Nipigon, and
681   Munising (Fitchko & Hutchinson, 1975; Kemp et al., 1978). In Lake Erie, major increases in Hg
682   releases were seen around 1939 and 1954, corresponding with establishment and growth of two
683   chlor-alkali facilities (Azcue, Rosa Mudroch, 1996; Wolery & Walters, 1974).

684

685   Lanthanides

686   **Dominant Sources of Rare Earth Elements:** The term "rare earth" is somewhat of a
687   misnomer, as they are not actually rare on Earth but they do appear together. The bulk of the
688   lanthanides are found in eroded material in clay and shale, such as that in the Paleozoic province
689   surrounding Lakes Michigan, Erie, and Ontario (Fig. 1). A very small percent is dissolved into
690   solution. These elements take part in almost no chemical processes. Mobilization may occur
691   during weathering but not likely during erosion and transport. Overall, there are minimal post-
692   depositional changes in sedimentary records (Fleet, 1984).

693   *Lanthanum*
694   **Contaminant status in the Great Lakes:** None known but potential
695   **Dominant sources:** Weathering of clay and shale
696   **Background and relevance to the Great Lakes:** Lanthanum (La) is the 28th most abundant
697   element at 32 ppm in the Earth's crust and approximately 26 ppm in soil (Emsley, 2002). La has
698   been shown to be toxic in a number of organisms, and anthropogenic loadings have been found
699   in several German rivers (Kulaksız & Bau, 2011b). In sediment cores of the Great Lakes, Reavie
700   et al. (2005) and Shimp et al. (1971) found little or no variation in concentration from pre-
701   industrial sediments to modern times. Olivarez, Owen & Long (1989) and Neustadter, Fordyce &
702   King (1976) noted that the concentration of La in Great Lakes sediments was controlled by
703   inputs of crustal sediments. However, Herrmann et al. (2016) highlight La's potential role as an
704   emerging contaminant of concern with its use in innovative technologies such as super-
705   conductors, catalysts, lasers, and batteries, and an increase in releases to aquatic environments.

706   *Cerium*
707   **Contaminant status in the Great Lakes:** None known but potential
708   **Dominant sources:** Weathering of clay and shale
709   **Background and relevance to the Great Lakes:** Cerium (Ce) is the 25th most abundant element
710   in the Earth's crust at 68 ppm, averaging 50 ppm in soil (Emsley, 2002). Ce is the most abundant
711   of the rare earth elements. It has no biological role and, like all rare earth elements, has low acute
712   toxicity (Gschneidner, 1968). Ce is found in urban environments due to its use in welded metal
713   plating (Chambers et al., 2016). It has found more modern uses in long-life, low-energy
714   lightbulbs and as a vehicular exhaust cleaner. Ce has been suggested as a reference element in
715   the sediment to account for soil influences so that the percentage of actual anthropogenic influx
716   can be measured. Ce has a radioactive isotope, ^{144}Ce, which is produced in nuclear reactors and
717   was detected in Lakes Superior and Huron in 1974 and 1975 (Durham & Joshi, 1984; Tracy &
718   Prantl, 1983). Reavie et al. (2005) found paleolimnological Ce concentrations in a Lake George
719   core did not change over the most recent two centuries.

720   *Praseodymium*
721   **Contaminant status in the Great Lakes:** None known
722   **Dominant sources:** Weathering of clay and shale
723   **Background and relevance to the Great Lakes:** Praseodymium (Pr) is the 39th most abundant
724   element in the Earth's crust at 9.5 ppm. It is a rare earth element and occurs in minerals
725   exclusively with other members of the group. There is no documented environmental threat from
726   this element. It can also exist as a fission product of U, Th, and Pu (Eyring, 1968; Emsley, 2002).

727   *Neodymium*
728   **Contaminant status in the Great Lakes:** None known
729   **Dominant sources:** Weathering of clay and shale
730   **Background and relevance to the Great Lakes:** Neodymium (Nd) is the 26th most abundant
731   element in the Earth's crust and the 2nd most abundant rare-earth element after Ce. Nd is almost
732   as abundant as Cu at 38 ppm in the Earth's crust and around 20 ppm in soils. It has no known
733   biological role or environmental threat (Emsley, 2002).

734   *Samarium*
735   **Contaminant status in the Great Lakes:** None known but potentially an emerging contaminant
736   of concern
737   **Dominant sources:** Weathering of clay and shale
738   **Background and relevance to the Great Lakes:** Samarium (Sm) is the 40th most abundant
739   element in the Earth's crust at 8 ppm. Sm is found with other rare-earth elements (Emsley,
740   2002). Sm has no known biological role, though anthropogenic Sm was found to be bioavailable
741   to freshwater clams (Merschel & Bau, 2015), and toxicity is uncertain. Sm is an emerging
742   contaminant of concern in river systems. It is used for high-strength permanent magnets and for
743   control rods in nuclear reactors. In the Rhyne River in Germany, a significant amount of Sm
744   pollution was found downstream from a production plant for fluid catalytic cracking (Kulaksiz &
745   Bau, 2013). No pollution is currently known in the Great Lakes region, and in sediment cores

746 from Lake George Reavie et al. (2005) found no changes in Sm concentration over two
747 centuries, indicating solely natural sources.

748 *Europium*
749 **Contaminant status in the Great Lakes:** None known
750 **Dominant sources:** Weathering of clay and shale
751 **Background and relevance to the Great Lakes:** Europium (Eu) is the 50th most abundant
752 element in the Earth's crust at 2 ppm. It is one of the most abundant of the rare earth elements. It
753 appears to have no biological role or pose any environmental threat (Emsley, 2002). It is the
754 most reactive of the rare earth metals and is used for the red phosphor in cathode ray color
755 televisions and fluorescent lamps (Thompson, 1968). Reavie et al. (2005) found Eu in their
756 sediment cores did not vary with sediment depth or composition and Neustadter, Fordyce &
757 King (1976) considered atmospheric Eu over the Great Lakes to be soil derived.

758 *Gadolinium*
759 **Contaminant status in the Great Lakes:** None known but potentially an emerging contaminant
760 of concern
761 **Dominant sources:** Weathering of clay and shale
762 **Background and relevance to the Great Lakes:** Gadolinium (Gd) is the 41st most abundant
763 element in the Earth's crust. It is one of the more abundant rare earth elements at an average of 8
764 ppm. No acute health effects are known, but potential long-term effects of low-level exposure are
765 possible (Kulaksız & Bau, 2011a). Gd has been used as a contrasting agent in magnetic
766 resonance imaging since 1988. It is not removed by wastewater treatment plants and is an
767 emerging micropollutant of concern in surface waters in densely populated areas. Gd chelates
768 can be used as tracers for other emerging microcontaminants that are not removed in wastewater
769 treatment processing, such as steroids and pharmaceuticals. Bau, Knappe & Dulski (2006) found
770 increased Gd levels in the surface water of Lake Erie and the Niagara River, suggesting input
771 from the urban area of Buffalo.

772 *Terbium*
773 **Contaminant status in the Great Lakes:** None known
774 **Dominant sources:** Weathering of clay and shale
775 **Background and relevance to the Great Lakes:** Terbium (Tb) is the 57th most abundant
776 element in the Earth's crust at 1 ppm. It is one of the rarer rare-earth elements and occurs in
777 minerals with the others of that group. Tb does not have many uses, as it is very expensive to
778 acquire and separate from the other rare-earths, but it is used in lasers and low-energy lightbulbs
779 (Emsley, 2002). It has no known biological role and is not considered an environmental threat.

780 *Dysprosium*
781 **Contaminant status in the Great Lakes:** None known
782 **Dominant sources:** Weathering of clay and shale
783 **Background and relevance to the Great Lakes:** Dysprosium (Dy) is the 42nd most abundant
784 element in the Earth's crust at 6 ppm. It is a rare-earth element and is found associated with the
785 other rare-earth elements in minerals. It has no biological role and low acute toxicity (Emsley,
786 2002; Powell, 1968). Kerfoot & Robbins (1999) found that Dy showed modest enrichment in the

787   stamp sands submerged in waterways of the Keweenaw Peninsula over background
788   concentration. Due to its extremely low background level in Lake Michigan, McCown (1979)
789   used Dy to tag experimental simulated oily waste in order to determine its motion in freshwater.

790   *Holmium*
791   **Contaminant status in the Great Lakes:** None known
792   **Dominant sources:** Weathering of clay and shale
793   **Background and relevance to the Great Lakes:** Holmium (Ho) is one of the rarer rare-earth
794   elements at 1.4 ppm in the Earth's crust and ~1 ppm in soils. It has no biological role and poses
795   no environmental threat. Ho has the highest magnetic strength of any element (Emsley, 2002). In
796   a sediment core of Lake Superior, Korda et al. (1977) found Ho concentrations varied between
797   0.7 and 1.4 ppm and had no apparent anthropogenic component.

798   *Erbium*
799   **Contaminant status in the Great Lakes:** None known
800   **Dominant sources:** Weathering of clay and shale
801   **Background and relevance to the Great Lakes:** Erbium (Er) is one of the more abundant rare-
802   earth elements at 4 ppm in the Earth's crust and ~1.6 ppm in soil (Emsley, 2002). It has no
803   biological role and poses no environmental threat. Korda et al. (1977) found Er concentrations
804   between 1.8 and 3.1 ppm in their core of Lake Superior.

805   *Thulium*
806   **Contaminant status in the Great Lakes:** None known
807   **Dominant sources:** Weathering of clay and shale
808   **Background and relevance to the Great Lakes:** Thulium (Tm) is the second rarest rare-earth
809   element after promethium at 0.5 ppm in the Earth's crust and an average of 0.5 ppm in soil.
810   Mayfield & Fairbrother (2015) examined the concentrations of rare-earth elements in the tissues
811   of various freshwater fish, and Tm was the only element that was not detectable in the species
812   examined.

813   *Ytterbium*
814   **Contaminant status in the Great Lakes:** None known
815   **Dominant sources:** Weathering of clay and shale
816   **Background and relevance to the Great Lakes:** Ytterbium (Yb) is one of the rarer rare-earth
817   elements at 3 ppm in the Earth's crust and around 2 ppm in soil. It has no biological role and
818   does not pose an environmental threat (Emsley, 2002). In an undated sediment core from western
819   Lake Superior, Korda et al. (1977) found concentrations of Yb ranged from 1.6 to 3.1 ppm. In
820   cores of Lake George, Reavie et al. (2005) found Yb concentrations did not vary over time or by
821   sediment composition, indicating that natural sources were dominant, although Kerfoot and
822   Robbins (1999) found moderate enrichment of Yb in the stamp sands of Lake Superior.

823   *Lutetium*
824   **Contaminant status in the Great Lakes:** None known
825   **Dominant sources:** Weathering of clay and shale
826   **Background and relevance to the Great Lakes:** Lutetium (Lu) is one of the rarer of the rare

827   earth elements at 0.5 ppm in the Earth's crust. Lu has no known biological role and is thought to
828   pose no environmental threat. Lu is found in minerals that contain all of the lanthanides (Emsley,
829   2002). In their sediment cores of Lake George, Reavie et al. (2005) found that Lu did not vary
830   with sediment depth or composition, showing no anthropogenic changes in Lu downstream from
831   Lake Superior.

832

833   Basic Metals

834   *Aluminum*
835   **Contaminant status in the Great Lakes**: Some historical contamination associated with
836   taconite tailings in the western part of Lake Superior
837   **Dominant sources**: Feldspars and clay minerals, runoff and erosion
838   **Background and relevance to the Great Lakes**: Aluminum (Al) is the most abundant metal
839   (7%) in the Earth's crust (Khan et al., 2013). Al has a strong sorption tendency, binding strongly
840   to clay minerals and natural organic matter (Lum and Leslie, 1983; Driscoll, 1985). Al is not
841   known to be a nutrient for any plants or animals (Discroll and Schecher, 1990). Elevated
842   concentrations of ionic Al are also important because Al acts as a buffer and influences the
843   cycling of elements such as P and C through adsorption and coagulation reactions (Driscoll and
844   Schecher, 1990). It is highly insoluble and unreactive under most conditions, but below a pH of 6
845   Al can dissolve from substrates and become available in its ionic form, at which point it becomes
846   bioavailable and can be toxic (Bache, 1986). Ionic Al is released in acidic waters often related to
847   acid rain and acid mine drainage (ATSDR, 2008). Fluxes in total Al in lakes and streams are
848   virtually all associated with sediment transport and runoff and erosion (Driscoll, 1989; Norton,
849   Binford & Kahl, 1992; Long et al., 2010). Lakes are sinks for Al because of their acid
850   neutralizing capacity (Driscoll, 1989), so toxic levels of Al in the Great Lakes are unlikely.
851   Spikes in overall Al levels in sediment cores are often associated with land clearing and logging
852   (Selig, Leipe & Dörfler, 2007), which expose clay/Al-bearing soils to erosion. In Lake Superior,
853   both Kemp et al. (1978) and Shaw Chraïbi et al. (2014) saw an increase in Al correlated with the
854   input of taconite tailings between 1955 and 1967. According to Oxberry, Doudoroff & Anderson
855   (1978), Al from fresh taconite tailings is not soluble in Lake Superior waters, which are slightly
856   alkaline and have a pH generally above 7.3, so there was not likely to be toxicity effects. In
857   sediment cores taken from Lakes Ontario, Erie, and Huron, Kemp and Thomas (1976b) found
858   the concentration of Al to remain generally uniform over the period from pre-settlement to the
859   early 1970s.

860   *Gallium*
861   **Contaminant status in the Great Lakes:** None known but possible
862   **Dominant sources:** Clay minerals, coal fly ash
863   **Background and relevance to the Great Lakes:** Gallium (Ga) is more abundant than Pb in the
864   Earth's crust, averaging 18 ppm, but unlike Pb, Ga is not concentrated in any minerals, so it is
865   more difficult to obtain using industrial processes (Emsley, 2002). Some Ga is incorporated in
866   clay minerals, and it can substitute for Al in sediments (Nussmann, 1965). Ga is recovered as a
867   byproduct of processing Zn ores and bauxite and is used in microchips, lasers, solar cells, and

868 LEDs (USDOI & USGS, 2017). Ga has no biological role, and Reid, Rengel & Smith (1996)
869 demonstrated Ga toxicity to green algae, though they found it to be less toxic than Sc and Al. Ga
870 averages 7 ppm in coal, but in coal ash, Ga averages 100 ppm (Blowes et al., 2014). In surficial
871 sediments from Lake Michigan, Cahill (1981) found Ga concentrations from 0–20 ppm.
872 Nussmann (1965) found Ga in Lake Michigan averaged 19–22 ppm, and Ga content of Lake
873 Superior sediments averaged 13.2 ± 5.4 ppm, seeming to increase slightly near the top of the
874 sediment cores, though this increase was not statistically significant.

875 *Tin*
876 **Contaminant status in the Great Lakes:** Yes, attributed to industry and fossil fuel emissions
877 **Dominant sources:** Largely atmospheric emissions from smelting
878 **Background and relevance to the Great Lakes:** Tin (Sn) is the 49th most abundant element in
879 the Earth's crust at 2 ppm. It averages around 1 ppm in soil. Sn is insoluble and its ore is very
880 resistant to weathering, so the amount of Sn in soil and natural waters is low (Emsley, 2002).
881 There is some evidence that it might be an essential micronutrient in mammals, though it is also
882 a part of compounds which are enzyme disruptors in aquatic organisms (Alloway, 2013b). Some
883 of its uses include plating cans and containers, solder, and fungicides (Blowes et al., 2014), and it
884 has become an anthropogenic contaminant in natural systems. Robbins (1980) found Sn to be 2nd
885 only to Hg in terms of enrichment in Southern Lake Huron. Biegalski & Hopke (2004)
886 determined that Sn in the atmosphere in the Great Lakes region was attributable to smelting.
887 Goldberg et al. (1981) traced Sn sources in Lake Michigan to coal, coke and fuel oil, noting that
888 it had similar profiles in sediment cores to charcoal. Yuan (2017) categorized Sn with the most
889 enriched elements in Lake Superior sediments.

890 *Lead*
891 **Contaminant status in the Great Lakes:** Yes, related to fossil fuel emissions, mining
892 **Dominant sources:** Leaded gasoline, shoreline bluffs of Lake Erie
893 **Background and relevance to the Great Lakes:** Lead (Pb) is not a particularly abundant
894 constituent in the Earth's crust; at 14 ppm, it is the 36th most abundant element (Emsley, 2002).
895 Pb is used as a proxy for human activity because it has a relatively low background concentration
896 in sediments, averaging 23 ppm worldwide, with 18 ppm in Lake Erie (Azcue, Rosa & Mudroch,
897 1996; Pompeani et al., 2013). Pb is a contaminant of particular interest because it is a cumulative
898 poison that can damage organisms at low concentrations (Forsythe & Marvin, 2009). Releases
899 from anthropogenic sources, most notably as a fuel additive, dwarf those from natural sources
900 (ASTDR, 2007c). The main current anthropogenic sources of Pb in the environment are mining
901 and smelting, manufacture of Pb containing products, combustion of coal and oil, and waste
902 incineration. As for all metals, natural sources of Pb from catchment soil and bedrock include
903 fluvial and shoreline bluff erosion, such as that detailed by Kemp et al. (1976b) and Ritson et al.
904 (1994) in Lake Erie. A great number of sediment cores have examined Pb concentrations in the
905 Great Lakes over time (Table 1). It is enriched in surface sediments of all of the lakes due to
906 anthropogenic activity. Rossmann, Pfeiffer & Filkins (2014) found the following trends in Lake
907 Michigan: in 1850 Pb levels increased above background levels correlated with coal and gas
908 consumption. Pb loading increased with industrial activity during World War II and began to
909 decline with the Clean Air Act of 1970 and the phasing out of leaded gasoline. According to

910   Rossmann, Pfeiffer & Filkins (2014), Lake Michigan loading in 1995 was 52% lower than peak
911   loading in 1970. However, in the Sandusky Bay of Lake Erie, Yuan (2017) found only a 36%
912   reduction from 1970 to 2010. Yohn et al. (2004) found that anthropogenic loading from the
913   1930s to the 1970s was mainly driven by regional sources such as leaded gasoline and since the
914   1970s has been much more closely correlated to local population density. This was attributed to
915   legacy pollution and Pb cycling, since Pb does not degrade in the sediments. Pompeani et al.
916   (2013, 2015) found periods of increased Pb loading in the Keweenaw Peninsula 8000–5000
917   years ago which they associated with Cu mining.
918

919   Semimetals

920   *Silicon*
921   **Contaminant status in the Great Lakes:** Possibly some as dust
922   **Dominant sources:** Rocks, minerals, soils, dust
923   **Background and relevance to the Great Lakes:** Silicon (Si) is the second most common
924   element in the Earth's crust after oxygen. It makes up 28% of Earth's crust and is the key
925   component of soil, occurring in almost all minerals (Emsley, 2002). Si is the third most abundant
926   element in the human body and is involved in bone mineralization. It is also a carcinogen and is
927   responsible for silicosis, a disease that occurs from inhalation of Si dust (Martin, 2013). Si never
928   occurs in sediments uncombined; it occurs either with oxygen as SiO_2 (silica) or with oxygen and
929   metals as silicates (Lanning, 1968). Si is relatively unreactive and insoluble. Increases in Si
930   concentration come from more intensive weathering of silicates and are associated with warmer
931   or wetter conditions. According to Chambers et al. (2016), Si levels are relatively high in some
932   urban waters due to its use in building materials such as clay and sandstone. Si was found to be a
933   conservative element that remained relatively constant in sedimentary records from Lakes
934   Ontario, Erie, Huron, and Superior (Kemp et al., 1976; Kemp et al.; 1978; Kemp & Thomas,
935   1976a; Kemp & Thomas, 1976b). Mudroch (1985) considered Si to be of terrigenous origin in
936   the Detroit River, and Holsen et al. (1993) also considered it a crustal element. In their core of
937   the western basin of Lake Superior, Shaw Chraïbi et al. (2014) found peaks in Si around 1960
938   related to the period of taconite processing waste discharge in Silver Bay. Minerals containing
939   silica comprise more than 95% of the Earth's crust (ASTDR, 2017b). Silica, in the form of
940   quartz, is extremely resistant to weathering. In the form of other minerals, SiO_2 is able to dissolve
941   in water to form bioavailable silicic acid, an important compound for biological use by some
942   plants and algae. In the Great Lakes, there is an inverse relationship between SiO_2 concentration
943   and spring diatom population size, as diatoms take up all available SiO_2 from the water column
944   (e.g. Lake Erie; Reavie et al., 2016). As the main component in cell walls of diatoms, biogenic
945   silica is a critical compound for algal communities. Schelske et al. (1987) used SiO_2
946   concentrations in Lakes Michigan, Erie, and Ontario as indices of eutrophication because as P
947   loading increased, diatom production increased, eventually leading to SiO_2 depletion and limited
948   diatom production. In modern times, the inverse is occurring in Lake Ontario, where SiO_2 levels
949   are increasing as a symptom of the proliferation of invasive zebra and quagga mussels leading to
950   decreasing diatom populations (Dove, 2009).

951   *Arsenic*
952   **Contaminant status in the Great Lakes:** Yes, listed as a sediment contaminant or water
953   contaminant in 10 AOCs in the Great Lakes (Hartig and Thomas, 1988)
954   **Dominant sources:** Mining and other industry, fossil fuel burning
955   **Background and relevance to the Great Lakes:** Arsenic (As) averages around 1.5 ppm in the
956   Earth's crust and 1–10 ppm in soil (Emsley, 2002). It is a deadly poison and is carcinogenic
957   (Plant et al., 2014). As occurs naturally in soil and airborne dust and is associated with fine
958   particles (Sweet, Weiss & Vermette, 1998). Anthropogenic releases of As are much higher than
959   natural releases and As ranks high on hazardous substances lists (ASTDR, 2007a). Arsenic's
960   primary use is as a wood preservative to prevent rot, though it was previously used as a
961   component of pesticides and fungicides. It is also associated with mining and smelting of Cu, Pb,
962   Zn, and Sn and is present in coal and phosphate fertilizers. In the Great Lakes, As is associated
963   with ferromanganese nodules in Lake Michigan, particularly near Green Bay, and is released
964   with weathering and erosion. Increased As concentrations in aerosols over Lake Huron and Lake
965   Michigan have been related to fossil fuel use and smelters (Biegalski & Hopke, 2004; Shahin,
966   Paode & Holsen, 2000). Nriagu (1983) measured changes in As concentrations near smelters at
967   Sudbury Ontario that mirror Cu and Ni production. In Lake Superior, As was found increased
968   five fold in taconite, mine tailings, and the Freda stamp sands compared to a control area (Korda
969   et al., 1977). Reavie et al. (2005) found anthropogenically enriched As concentrations in post-
970   settlement sediments of Lake George, which they attributed to herbicide use. Förstner (1976) and
971   Walters, Wolery & Myser (1974) saw major increases in Lake Erie sediments between 1939 and
972   1955, which they related to the growth of industry related to WWII and the Korean conflict.

973   *Antimony*
974   **Contaminant status in the Great Lakes:** Yes, related to mining and other industry
975   **Dominant sources:** Anthropogenic sources
976   **Background and relevance to the Great Lakes:** Antimony (Sb) is the 63rd most abundant
977   element in the Earth's crust at 0.2 ppm. It has an average abundance of approximately 1 ppm in
978   soil (Emsley, 2002). Sb has relatively low mobility in soils, has no biological role, and is highly
979   toxic. While naturally rare, Sb is anthropogenically enriched in soils and lakes. According to
980   Clemente (2013), Sb is enriched on the order of 70 times compared to background
981   concentrations in the United States. Sb contamination comes from mining and other activities
982   that result in releases of metal particles such as shooting ranges and brake dust (ASTDR, 2017a).
983   It is a priority pollutant according to the USEPA (Chen et al., 2003; Filella, Belzile & Chen,
984   2002). Reavie et al. (2005) found Sb enriched in the sediment of Lake George related to the
985   production of alloys and metal coating processes in the adjacent watershed. Biegalski & Hopke
986   (2004) found Sb highly enriched from crustal sources in aerosols over the north shore of Lake
987   Huron. Robbins (1980) determined Sb was the fourth most enriched pollutant in the surface
988   sediments of Lake Superior, after Hg, Sn, and Pb. In Lake Erie, initial major increases in Sb
989   concentrations occurred between 1948 and 1953 due to industrial uses and more diffuse sources
990   (Walters, Wolery & Myser, 1974).

991

992 Nonmetals

993 *Phosphorus*
994 **Contaminant status in the Great Lakes:** Yes, as a nutrient pollutant
995 **Dominant sources:** Agriculture, industry, sewage
996 **Background and relevance to the Great Lakes:** Phosphorus (P) is one of the most widely
997 distributed elements. At 1,000 ppm in the Earth's crust, P is the 11th most abundant element and
998 averages 1.5 ppb in surface waters. P is necessary for all life, though in its elemental form P is
999 highly poisonous and reactive. In nature, P exists primarily as PO_4 (Emsley, 2002; Whaley &
1000 Currier, 1968). As a limiting nutrient for algal growth, anthropogenic P loading is a problem in
1001 natural waters such as the Great Lakes because too much P can support cultural eutrophication
1002 (Manning, Lum & Birchall, 1983). Sources of anthropogenic P in urban environments include
1003 laundry detergent, fertilizer, food waste, and sewage (Chambers et al., 2016). Primarily as a
1004 response to increasing concerns about eutrophication, the United States and Canada implemented
1005 The Great Lakes Water Quality Agreement (Canada & United States of America, 1972). Both
1006 countries implemented P removal programs aimed at industrial and municipal point sources and
1007 reductions in phosphates in detergents (Baker et al., 2014). P levels have been a particular
1008 concern in Lakes Erie and Ontario. Lake Superior, the most oligotrophic of the Great Lakes, is
1009 thought to be P limited (Baehr & McManus, 2003). Analyzing sedimentary P can be a poor
1010 indicator of actual P levels and eutrophication due to variable retention and post-depositional
1011 diagenesis. For this reason, diatom-inferred P levels are used to give a better picture of
1012 eutrophication, as they provide a surrogate measure of P levels that are not subject to these
1013 factors (Reavie, Heathcote & Chraïbi, 2014). In an Eastern core of Lake Superior, Shaw Chraïbi
1014 et al. (2014) found P levels peaked between 1990 and 1994. In the Western Core they found a
1015 peak in P around 1960, which they associated with taconite processing near Silver Bay. In
1016 sediment cores from Lakes Ontario, Huron, and Erie, Kemp & Thomas (1976a and 1976b) found
1017 increases in P related to anthropogenic loading.
1018

1019 Actinide Series

1020 *Thorium*
1021 **Contaminant status in the Great Lakes:** Yes, part of the Port Hope Area of Concern
1022 **Dominant sources:** Naturally ubiquitous and a byproduct of U mining and processing
1023 **Background and relevance to the Great Lakes:** Thorium (Th) is a typically radioactive metal
1024 which is ubiquitous in the environment, occurring naturally in the Earth's crust at concentrations
1025 between 8 and 12 ppm (ASTDR, 1990). Th is strongly adsorbed by clays, with a mean
1026 concentration of 30 ppm in clay minerals (Langmuir & Herman, 1980). Th is also generated as a
1027 byproduct of U mining and processing. This can result in anomalously large, localized
1028 concentrations of Th in the environment that may be harmful. In the Port Hope Area of Concern
1029 (north shore of Lake Ontario), water quality and environmental health were threatened by Th
1030 contamination, a result of poor operation and waste management practices of Eldorado Mining
1031 and Refining between 1933 and 1953 (Government of Canada, 2017). An estimated 85,000 –
1032 95,000 cubic meters of sediment containing radioactive material is present in this harbor in

1033   Ontario on the north shore of Lake Ontario. Sakaguchi et al. (2006) examined Th in the sediment
1034   records of Lake Baikal. They used Th as a proxy for terrestrial materials, as it has low solubility
1035   and is resistant to weathering. They found that it was enriched in the fine grain components of
1036   their core. In cores of Lake George, Reavie et al. (2005) found Th concentrations largely
1037   invariant with sediment composition and depth.

1038   *Uranium*
1039   **Contaminant status in the Great Lakes:** Yes, part of the Port Hope Area of Concern
1040   **Dominant sources:** Ubiquitous, also associated with mining and nuclear power and weapons
1041   generation
1042   **Background and relevance to the Great Lakes:** Uranium (U) is present at 2 ppm in the Earth's
1043   crust and 0.7–11 ppm in soil. In agricultural soil with phosphate fertilizer, the soil concentration
1044   averages 15 ppm. Coal combustion is also a significant source of U in the environment. U is
1045   ubiquitous and is found in most rocks and soils, though it is higher in rocks that are enriched in
1046   Na, K, or Si (Seaborg, 1968). It is naturally dominated by isotopic forms; ^{238}U accounts for 99%
1047   of natural U by mass. There is no known biological need for U, and it is both chemotoxic and a
1048   radiotoxic (Alloway, 2013c). U is mined and used for power generation and nuclear weapons,
1049   though it is naturally present in low concentrations in the Great Lakes as a result of weathering
1050   (Ahier & Tracy, 1995). Nearly all of the steps of nuclear power generation have occurred in the
1051   Great Lakes basin in the forms of mining, fuel preparation, power production, and waste
1052   management (Ahier & Tracy, 1995). In the Port Hope Area of Concern (north shore of Lake
1053   Ontario), water quality and environmental health were threatened by U contamination, a result of
1054   poor operation and waste management practices of Eldorado Mining and Refining between 1933
1055   and 1953 (Government of Canada, 2017). An estimated 85,000 – 95,000 cubic meters of
1056   sediment containing radioactive material is present in this harbor in Ontario on the north shore of
1057   Lake Ontario. Contaminated soils from Port Hope have U concentrations of up to 258 ppm. .
1058   Stable U concentrations have not been analyzed in sediment cores of the Great Lakes.
1059

1060   A Note on Oxides
1061   Several metals in aquatic systems are commonly present as detrital oxides. Fe and Mn oxides are
1062   particularly major sources of metals from river systems. Heavy metals are frequently sorbed to
1063   the surface of oxide molecules. Oxides may represent portions of an element that are not part of
1064   other rocks, i.e. the actual mineral formations or ores. Some notable oxides include hematite
1065   (Fe_2O_3), an economically important iron ore that is found around the southern and northwestern
1066   shores of Lake Superior in Michigan, Wisconsin, and Minnesota, as well as ilmenite (Fe_2TiO_3),
1067   the major source of Ti (Klein & Dutrow, 2008).

1068   **Summary/Discussion**

1069   Many studies have been devoted to analyzing inorganic geochemistry in the Great Lakes, and we
1070   have summarized metals as they relate to geochemistry and environmental stress in the lakes.
1071   Through these studies, natural conditions and anthropogenic impacts have been measured over
1072   time through the sourcing of metals from catchments, industry, agriculture, mining, and other
1073   human activities. Several studies also show reductions in these metals in the atmosphere, water,

1074 and lake sediment after legislation and mitigation efforts. With a few exceptions, it is difficult to
1075 pinpoint sources of contaminant metals due to their ubiquity in minerals comprising the bedrock
1076 and soils in the Great Lakes catchment. This comprehensive summary of Great Lakes-relevant
1077 metals serves as a key reference for the companion manuscript that details the implications of
1078 this review. This summary was a natural first step in developing background information for a
1079 partner study on applied metals geochemistry throughout the Great Lakes (Aliff et al., 2020).
1080 The companion paper features an analysis of 11 sediment cores collected from all five Great
1081 Lakes. Taken together we believe that these two papers represent a thorough summary of the
1082 knowledge to date of geochemistry in sediment cores in the Great Lakes system.

Kerfoot et al. (2016)	Keweenaw Peninsula	80 cm (1800 - 2004)	Cu, Hg
Yin et al. (2016)	Lake Michigan	1720 – 2013	Hg
Alsaffar (2017)	Lake St. Clair	142 cm (2015)	As, Ba, Cd, Cr, Cu, Fe, Hg, Mn, Ni, Pb, Zn
Sgro & Reavie (2017)	Lake Erie	49 cm (1870 – 2011)	Al, Ca, CaO, Cd, Cu, Fe, K, Mg, MgO, Na, Ni, Pb, Si, SiO$_2$
Yuan (2017)	Sandusky Basin, Lake Erie	40 cm (1800 – 2012)	Al, Ca, Fe, K, Mg, Mn, Na, As, Ba, Be, Cd, Co, Cr, Cu, Mo, Ni, Pb, Se, Sn, Ti, V, Zn
Sgro & Reavie (2018)	Lake Huron	36 cm (1823 – 2012)	Al, Al$_2$O$_3$, As, Ba, BaO, Ca, CaO, Cd, Co, Cr, Cs, Cu, Dy, Er, Eu, Fe, Fe$_2$O$_3$, Ga, Gd, Ho, K, K$_2$O, La, Li, Lu, Mg, MgO, Mn, MnO, Mo, Na, Na$_2$O, Nb, Nd, Ni, P, P$_2$O$_5$, Pb, Pr, Rb, Sb, Sc, Si, SiO$_2$, Sm, Sn, SrO, Ta, Tb, Th,

Range of As concentrations in ppm in different rock types.

Modified and combined version of two tables presented and included in a study by the National Research Council (1977).

Arsenic Concentration, ppm

Igneous Rocks	No. Analyses	Range Usually Reported	Average
Ultrabasic	37	0.3–16	3.0
Basalts, gabbros	146	0.06–113	2.0
Andesites, dacites	41	0.5–5.8	2.0
Granitic	73	0.2–13.8	1.5
Silicic volcanic	52	0.2–12.2	3.0
Sedimentary Rocks	No. Analyses	Range Usually Reported	Average
Limestones	37	0.1–20	1.7
Sandstones	11	0.6–120	2.0
Shales and clays	324	0.3–490	14.5[a]
Phosphorites	282	0.4–188	22.6
Sedimentary iron ores	110	1–2,900	400?
Sedimentary manganese ores	—	(up to 1.5%)	—
Coal	1,150	0–2,000	13[b]

2   Estimated on the basis of data of Onishi (1969) and Boyle and Jonasson (1973).

3   [a]Excluding one sample with arsenic at 490 ppm

4   [b]Boyle and Jonasson (1973) gave 4 ppm

Figure 1

Geological map of the Great Lakes watershed.

Geology of the region is summarized by geological age which is matched to rock types in the description. The basin is bounded to the north by the upland Precambrian-age Canadian Shield. The basin is bound to the south by a lowland region of Paleozoic sedimentary rocks. The Midcontinent Rift System makes up the western Lake Superior basin. United States data are from the USGS (USGS, 2018) and state geological surveys. Canadian data are taken from GeologyOntario (Ontario Ministry of Energy, Northern Development and Mines, 2019).
