“Yibin Baijiu” (YB) is a special Chinese strong-aroma baijiu (CSAB) originated in Yibin, a western city of China. YB is fermented in cellars lined with pit mud (PM), of which the microbiota affect the quality. In the study, 16S rRNA high throughput sequencing was used to demonstrate the bacterial community structure and diversity in PM of YB. Besides, the physicochemical characteristics of PM were also measured, including moisture content, pH, available phosphorous, ammonia nitrogen and humic acid. Results showed that Firmicutes was the dominant bacteria in all PM samples with the abundance over 70.0%, followed by Euryarchaeota (11.3%), Bacteroidetes (6.5%), Synergistetes (3.0%), Actinobacteria (1.4%) and Proteobacteria (1.2%). Moreover, 14 different genera with average relative abundance > 1% were found. There was no significant difference in Chao1 and Shannon index between the sub-layer and middle-layer PM ($p > 0.05$). However, LEfSe analysis showed that the relative abundance of *Lactobacillus* in the sub-layer PM is significantly higher than middle-layer PM. pH was significantly different ($p < 0.01$) between the two groups. Canonical correspondence analysis revealed that bacterial community in PM was correlated significantly with available phosphorous and pH. Our study provided basic data for further elucidating diversity of microbiota in pit mud of YB and the potential mechanism of Baijiu production.

Abstract

“Yibin Baijiu” (YB) is a special Chinese strong-aroma baijiu (CSAB) originated in Yibin, a western city of China. YB is fermented in cellars lined with pit mud (PM), of which the microbiota affect the quality. In the study, 16S rRNA high throughput sequencing was used to demonstrate the bacterial community structure and diversity in PM of YB. Besides, the physicochemical characteristics of PM were also measured, including moisture content, pH, available phosphorous, ammonia nitrogen and humic acid. Results showed that Firmicutes was the dominant bacteria in all PM samples with the abundance over 70.0%, followed by Euryarchaeota (11.3%), Bacteroidetes (6.5%), Synergistetes (3.0%), Actinobacteria (1.4%) and Proteobacteria (1.2%). Moreover, 14 different genera with average relative abundance > 1% were found. There was no significant difference in Chao1 and Shannon index between the sub-layer and middle-layer PM ($p > 0.05$). However, LEfSe analysis showed that the relative abundance of *Lactobacillus* in the sub-layer PM is significantly higher than middle-layer PM. pH was significantly different ($p < 0.01$) between the two groups. Canonical correspondence analysis revealed that bacterial community in PM was correlated significantly with available phosphorous and pH. Our study provided basic data for further elucidating diversity of microbiota in pit mud of YB and the potential mechanism of Baijiu production.

Introduction

Baijiu is one of the six most famous distilled liquors worldwide (Fan & Qian, 2006; Jin, Zhu, & Xu, 2017; McGovern et al., 2004). It included four main aroma types: strong, light, sauce and rice aromas. Among these, the Chinese strong-aroma baijiu (CSAB) accounts for over 70% of consumption (Liu & Sun, 2018; Liu, Tang, Zhao, et al., 2017). Yibin is one of the birth place of CSAB culture (Zou, Zhao, & Luo, 2018; Yang et al., 2017; You et al., 2016). It is located at the confluence of Min River, Jinsha River and Yangtze River with good water quality. Meanwhile, it has a unique weak acid clay with strong viscosity, good water retention and rich in minerals, which is an excellent natural material for making cellars (Tang et al., 2012). Moreover, Yibin enjoys a mid-subtropical humid monsoon climate, which is perfect for the growth of liquor-making microbes (Zhao et al., 2013). All these provide good resources for the development of “Yibin Baijiu” with unique flavor.

“Yibin Baijiu” is produced by distilling mixed and fermented grains, containing sorghum, glutinous rice, rice, wheat and corn, having the characteristics of sweetness, strong aroma and lasting aftertaste (Zheng et al., 2013; Zheng & Han, 2016). The fermentation of “Yibin Baijiu” is a traditional solid-state fermentation process that occurs in fermentation pits (Barrios-González, 2012), which serve as solid bioreactors. The pit mud (PM) is a complex ecosystem contains a variety of microbial communities, like bacteria, archaea and fungi (Liu et al., 2017). Bacterial communities in PM can break down macromolecules into small peptides and monosaccharides, which produce aromatic compounds, and thus endow the products flavor (Tao et al., 2014; Zhao, Zheng, Zhou, & Shi, 2012). Yet, its mechanism still remains to be discovered. To clarify this

bacterial effect and optimize the brewing technology, it's essential to study the composition and diversity of microorganisms in PM.

Since the 1960s, researchers have used traditional culture method to reveal the microbiota in PM (Wu, Qi, Xue, Guo, & Jie, 1980). *Clostridium*, *Bacillus*, *Pseudomonas* and *Sporolactobacillus* were isolated and identified using traditional microbial classification and identification methods (Yue, Hang, Liu, Hu, & Zheng, 2007). However, the method only detected less than 1% of culturable microorganisms, which failed to fully reveal the structure characteristics (Amann, Ludwig, & Schleifer, 1995). Then, molecular methods, such as polymerase chain reaction–denaturing gradient gel electrophoresis (PCR-DGGE) (Deng et al., 2012; Huang, Xiong, Hu, Liang, & Zhao, 2017), phospholipid fatty acid (PLFA) analysis (Zheng et al., 2013) and clone library analysis of the 16s rRNA gene (Ye et al., 2013), have been extensively employed. These methods not only avoid the tedious process of microbial culture, but also contribute to further understanding PM ecosystem. Thus, Firmicutes, Proteobacteria, Bacteroidetes, Actinobacteria, and Synergistetes were found to be predominant in many PM bacterial communities (Ding, Wu, Huang, Li, & Zhou, 2014; Liang, Luo, Zhang, Wu, & Zhang, 2016). Although these molecular methods provided a first description of abundant populations of PM, the extent of bacterial diversity remains unexplored. Until recently, 16s rRNA high-throughput sequencing was gradually used (Liu, 2017; Zheng et al., 2015). However, most of these studies just focused on samples from one or few enterprises. Due to few samples used, only limited information can be provided. Moreover, Yibin has a brewing history of nearly a thousand years, suitable ecological factors and relatively special brewing techniques, which make its "Yibin Baijiu" special bacterial flora unique. Therefore, considering the complexity of PM microorganisms, it is necessary to study the PM of "Yibin Baijiu" to enrich the information of PM bacterial communities.

In the study, 13 baijiu enterprises in Yibin were chosen to examine the microbiota structure via high-throughput sequencing. Meanwhile, the physicochemical characteristics of PM were measured to explore the correlation between bacterial community structure and environmental factors, which help us to understand the microflora composition and main functional microorganism of PM comprehensively.

Materials & Methods

Sampling

PM samples were collected in December 2017 from 13 distilleries located in Yibin (28° 76' N, 104° 63' E). A total of 68 samples were collected, among which 37 were collected from middle layer of cellar walls and 31 were collected from the substrate layer (100 g PM at each position). PM samples were numbered according to the information of distillery, cellar and layer, and divided into two groups: the middle-layer and the sub-layer (Table S1). The samples were aseptically collected in sterilized bas and kept cold during transport from the distilleries to the laboratory.

Physicochemical properties

The basic physicochemical properties of PM, including moisture content, pH, available phosphorous, ammonia nitrogen and humic acid, were also determined as previously described (Shen, 2014).

DNA extraction, PCR amplification, and Illumina HiSeq sequencing

DNA was extracted from the PM by using the FastDNA SPIN kit for Soil (Mpbio, USA) according to the manufacturer's instructions. The crude DNA was detected quantitatively according to absorbance at 260 nm with NanoDrop™ one spectrophotometer (Thermo Fisher Scientific, USA), and the purity was assessed by agarose gel electrophoresis (Beijing Liuyi Biological Technology Co., Ltd. China).

To amplify the V3-V4 regions of 16s rRNA genes, a pair of universal bacterial primers was employed in PCR reactions: a forward primer (341F) CCTAYGGGRBGCASCAG and a reverse primer (806R) GGACTACHVGGGTWTCTAAT. The reaction mixtures (25 µl) contained 5 µl of 5×TransStart Fastpfu Buffer (Transgen Biotech), 1 µl of DNA sample, 1 µl of each primer, 2 µl 2.5mM dNTPs, and 0.5 µl of TransStart Fastpfu DNA polymerase (Transgen Biotech). The PCR conditions were: 2 min at 95°C; 30 cycles of 20 s at 95°C, 30 s at 55°C, 30 s at 72°C; final 72 °C for 5 min and cooling at 4°C. The PCR products were purified with a universal PCR purification kit (Tiangen, Beijin, China) and sent to a commercial sequencing company for high-throughput sequencing using the Illumina Hiseq sequencing platform (MeiYin Health Technology (Beijing) Co., Ltd., China).

All the raw HiSeq-generated 16s rRNA gene sequence data were processed in the QIIME pipeline (V1.9.1, <http://qiime.org/tutorials/tutorial.html>). After initial QC processing, pairs of reads were merged using FLASH (V1.2.7, <http://ccb.jhu.edu/software/FLASH/>) to acquire raw tags. Then, they were screened by the QIIME uncton (Caporaso et al., 2010) to obtain clean tags. Chimeras were detected and removed using the Uchime algorithm to obtain effective tags (Edgar, Haas, Clemente, Quince, & Knight, 2011). The effective tags, at a similarity threshold of 97%, were grouped into the same operational taxonomic units (OTUs). A representative sequence for each OTU was extracted and annotated using the SILVA database (V119, <https://www.arb-silva.de/>).

Data analysis

The community richness and diversity were estimated by the Chao1 (Chao & Bunge, 2002) and Shannon indices (Shannon, 1997), respectively. Bacterial community differences in two groups of PM were evaluated by principal coordinates analysis (PCoA) in Fast UniFrac (<http://bmf.colorado.edu/fastunifrac/>). Linear discriminant analysis Effect Size (LEfSe) was used to compare the significance of species differences between the two groups (Segata et al., 2011). Canonical correspondence analysis (CCA) between bacterial communities in the PM and physicochemical properties was performed via the vegan package in R (<http://vegan.r-forge.r-project.org/>). All the statistical analyzes, including spearman's test, were performed with the SPSS software (V22.0, IBM Corp., Armonk, NY, USA). All tests for significance were two sided, and *P*-values < 0.05 were considered to indicate significance.

Results

Physicochemical properties of the PM

The physicochemical characteristics of PM of the two groups are shown in Table 1. Among all physicochemical indicators analyzed by independent samples t-test, level of pH was significantly different ($p < 0.01$) between the two groups. However, no significant differences in moisture content, ammonia nitrogen, available phosphorous and humic acid were found.

The diversity of bacterial community in PM

Totally, 68 samples were analyzed for amplicon sequencing. On average, 99,639 Clean Tags were generated for each sample with a minimum of 53,888. 53,493–208,410 effective tags for each sample with an average sequence length of 444 bp. Rarefaction curves was used to assess the degree of completion of a taxonomic survey (Good, 1953). The rarefaction curve showed that all curves approached the saturation plateau, proving that the identified sequences of PM samples represent almost all of bacterial sequences (Figure S1).

Eventually, a total of 220,790 OTUs were detected based on 97% similarity in 16s rRNA sequences, of which middle-layer group and sub-layer group had 186,289 and 148,904, respectively. Meanwhile, 114,403 OTUs were shared between the two groups. The mutual and unique OTUs are shown in Venn diagrams for the two groups (Figure S2).

The bacterial richness (Chao1) indices for all samples ranged from 1,214.30 to 42,441.82, and were fairly similar in the two different groups, with $11,296.93 \pm 4,816.73$ in the middle-layer group and $10,549.07 \pm 7,638.48$ in the sub-layer group. Meanwhile, the diversity (Shannon) indices was 7.82 ± 1.68 in the middle-layer group, and 7.57 ± 1.21 in the sub-layer group. There was no significant difference in Chao1 and Shannon between the two groups ($P > 0.05$), suggesting similar overall species diversity (Figure 1). Furthermore, the PCoA analysis showed that there was no explicit clustering of samples within the groups, demonstrating significant inter-individual variations in the bacterial communities (Figure 2).

Bacterial community structure in PM

In total, 49 phyla, 332 families and 811 genera were identified from all samples (Table 2). The most abundant phylum was Firmicutes (71.9%), followed by Euryarchaeota (11.3%), Bacteroidetes (6.5%), Synergistetes (3.0%), Actinobacteria (1.4%), Proteobacteria (1.2%), Cloacimonetes (0.6%), Tenericutes (0.4%), Chloroflexi (0.3%) and Cyanobacteria (0.2%) (Figure. 3). Most notably, Firmicutes constituted more than 70.0% of the bacterial microbiota in all the groups, as well as Euryarchaeota and Bacteroidetes were also predominant in all groups with average relative abundances $> 5\%$. The proportion of these three major phyla in the middle-layer and sub-layer group was 71.2% and 72.3%, 12.7% and 10.0%, and 6.9% and 6.3%, respectively.

At the genus level, dominate genera were similar between the two groups. All samples dominated by the 14 major genera (average relative abundance $> 1\%$ in all groups) including *Ruminiclostridium* 5 (17.9%), *Gelria* (8.4%), *Methanoculleus* (4.9%), *Syntrophomonas* (3.8%), *Lactobacillus* (3.6%), *Syntrophaceticus* (2.8%), *Proteiniphilum* (2.7%), *Aminobacterium* (2.7%), *Petrimonas* (2.4%), *Sedimentibacter* (2.1%), *Methanosarcina* (1.9%), *Methanobacterium* (1.8%), *Methanobrevibacter* (1.8%) and *Caldicoproba* (1.7%), respectively. The most

abundant 10 genera are shown in Figure 4. In addition, the relative abundance of *Clostridium sensu stricto 14* and *Clostridium sensu stricto 12* also exceeded 1% in the sub-layer group, 1.8% and 1.7% respectively. To determine the classified bacterial taxa with significant abundance differences between two groups, the linear discriminant analysis (LDA) effect size (LEfSe) method was used. The LEfSe analysis result showed that *Lactobacillus* is the key discrepant bacteria, and the relative abundance of *Lactobacillus* in the sub-layer PM is significantly higher than middle-layer PM (Figure 5).

Comparison of dominant bacterial communities in different Baijiu' pit mud

Based on previous studies, we compared the dominant microbiota of strong-aroma baijiu in different regions to ascertain the common dominant bacteria, and the unique dominant bacteria of "Yibin Baijiu" (Table 3). There were four common dominant bacteria in strong-aroma baijiu PM in five different regions (Mianzhu, Luzhou, Jiangsu, Hunan, Yibin), including *Lactobacillus*, *Sedimentibacter*, *Syntrophomonas* and *Methanobrevibacter*. Besides, it is noteworthy that *Petrimonas*, *Clostridium*, *Methanosarcina*, *Methanoculleus* and *Methanobacterium* were also detected in our study with the relative abundance above 1%, and almost all of them were affiliated with the Euryarchaeota phylum. Three unique bacteria were also found in "Yibin Baijiu" pit mud, namely *Ruminiclostridium 5*, *Gelria* and *Syntrophaceticus*.

In addition, the common dominant microorganism of strong-aroma baijiu and those of other aroma types (miscellaneous-aroma and sauce-aroma) were compared. The dominant microbiota composition in the Baijiu pit mud of different aroma types were quite different. Only *Lactobacillus* is the dominant microorganism shared by three aroma types of baijiu pit mud. In addition, *Enterobacter* is another dominant microorganism shared by miscellaneous-aroma and sauce-aroma, which was not found in strong-aroma baijiu pit mud. The detailed dominant microflora information of 3 aroma types of Baijiu pit mud are shown in Table 4.

Correlation between environmental factors and bacterial community

CCA was performed to identify the major environmental factors which influence the variation in bacterial communities. The contributions of environmental factors were as followed: available phosphorous ($R^2=0.237$, $P=0.0005$) > pH ($R^2=0.210$, $P=0.0015$) > humic acid ($R^2=0.056$, $P=0.1559$) > ammonia nitrogen ($R^2=0.053$, $P=0.1724$) > moisture content ($R^2=0.049$, $P=0.1959$). The CCA results indicated that available phosphorous and pH had a greater impact on PM bacterial community structure among these five factors. Furthermore, correlation tests between environment factors and the most abundant 35 genera were performed using spearman's correlation coefficient. The result showed that pH was negatively correlated with the relative abundance of *Clostridium sensu stricto 12* ($R= -0.502$, $P=0.002$), *Lachnoclostridium* ($R= -0.473$, $P=0.008$) and *Lactobacillus* ($R= -0.451$, $P=0.020$), at the genus level (Figure 6).

Discussion

In the study, Illumina Hiseq sequencing platform was used to explore the population diversity of bacteria in middle-layer and sub-layer pit mud of "Yibin Baijiu". According to previous studies, the total number of effective tags of 16s rRNA of microorganisms in pit mud obtained from the Roche 454 or Illumina Miseq sequencing platforms were less than 10,000 (Liu et al., 2017; Tao

et al., 2014). In our study, more than 200,000 effective tags were detected in a single sample with an average of 94,023 tags for all samples. Thus, the result of sequencing can adequately reflect almost all of the sample diversity noted.

A total of 49 phyla, 332 families and 811 genera were detected, which may be helpful to further understand the phylogenetic status of a massive number of uncultured microbes in the pit mud ecosystem. Moreover, although the relative abundance of Firmicutes, Euryarchaeota, Bacteroidetes and Synergistetes differed slightly between middle-layer and sub-layer samples, they were still the key components of the microbiota in the PM of “Yibin Baijiu”. Previous studies also have found that the three most abundant phyla in PM were Firmicutes, Euryarchaeota and Bacteroidetes (Liang et al., 2015; Liu et al., 2017; Tao et al., 2014). Firmicutes is a syntrophic bacteria that can degrade volatile fatty acids such as butyrate and its analogs, and represented mainly by the Clostridia and Bacilli (Garcia-Peña et al., 2011). Euryarchaeota includes diverse groups of methanogens that are interspersed with non-methanogenic lineages. Methanogens are often symbiotic with hexanoic acid bacteria and can effectively increase the content of ethyl hexanoate in strong-aroma baijiu through the "hydrogen transfer" effect between species (Zhao et al., 2017). Bacteroidetes includes three major types of bacteria: Bacteroidia, Flavobacteriia, and Sphingobacteriia. Most of them are capable of degrading macromolecular carbohydrates such as cellulose to produce acid (Guo, Cheng, Sun, Zhu & Wu, 2014). These phyla in PM all play the vital role in the fermentation of baijiu.

In our study, the dominant genera of aroma PM were also very different compared with previous studies. Using PCR-DGGE and high-throughput sequencing technology, Huang et al. (2017) concluded that *Corynebacterium*, *Myroides*, *Sphingobacterium*, *Lactobacillus*, *Clostridium*, *Acetobacter*, *Alcaligenes*, *Enterobacter* and *Acinetobacter* were the dominant bacterial genera in the PM of miscellaneous-aroma baijiu. Wang et al. (2016) detected that *Weissella*, *Lactobacillus*, *Bacillus*, *Enterobacter* and *Paenibacillus* were the dominant bacteria in sauce-aroma baijiu pit mud using nested PCR-DGGE. Wang et al. (2015) proved that *Ruminococcaceae*, *Thermoanaerobacteriaceae* and *Clostridiaceae* were the dominant bacteria in sauce-aroma baijiu pit mud by Illumina high-throughput sequencing platform. Bian et al. (2012) studied the archaea community structure in sauce-aroma baijiu PM through a culture-independent method named ARDRA, and found that they were mainly affiliated with Euryarchaeota, including *Methanoculleus*, *Methanosarcina*, *Methanosaeta*, and *Methanobacterium*.

Obviously, dominant bacteria have great contribution to the formation of different aroma types of baijiu. Among baijiu PM of several aroma types, *Lactobacillus* was a dominant genus, thus, it is speculated that *Lactobacillus* was an important bacteria of baijiu brewing. *Gelria* was found to be the dominant genus in our study, which was rarely reported in previous studies. This illustrates the diversity and complexity of the bacterial composition of PM. Furthermore, Fan et al. (2019) reported that *Gelria* in Daqu was associated with volatile compounds such as alcohols, esters, aldehydes, alkanes, benzene and nitrogen compounds in Baijiu. These volatile compounds are recognized as the key odorants in Baijiu, which effect both the flavor and mouth-feel

properties. Therefore, as a unique dominant genus of “Yibin Baijiu” PM, we speculated that *Gelria* may contribute to the formation of unique flavour of “Yibin Baijiu”.

At the genus level, the dominant bacteria in PM at different regions producing strong-aroma baijiu were compared. A total of 11 dominant genera were detected by Liu et al. (2017) in CSAB’s PM collected from Luzhou, Sichuan province (about 110 kilometers from Yibin city), among which 8 genera were also the dominant bacteria in “Yibin Baijiu” pit mud. Tao et al. (2014) reported that 14 dominant genera in CSAB’s PM which collected from Mianzhu, Sichuan province (about 300 kilometers from Yibin city), 6 of which were different with those of “Yibin Baijiu” pit mud. By comparison, we found that the composition of dominant genera in PM in Mianzhu area was more different from that in Yibin area due to their distant geographical location. Compared with those of Jiangsu area strong-aroma baijiu PM (about 1,700 kilometers away from Yibin city), 7 of the 17 dominant genera in Jiangsu area baijiu PM were shared by “Yibin Baijiu” PM. The dominant genera in Jiangsu area baijiu PM and “Yibin Baijiu” PM were greatly different, which further suggested that geographical location has a great influence on baijiu pit mud bacterial community. Previous studies also have demonstrated that composition of PM bacterial community varied by geographical location (Huang, Wang, Wei, Liu, & Li, 2015; Liang et al., 2016). Interestingly, the dominant genera in the baijiu PM of Hunan region, which is 470 kilometers away from Yibin City, was also similar to the dominant genera in “Yibin Baijiu” pit mud. It was speculated that the identical latitude of Hunan and Yibin, where both have the same climate, especially temperature, has a significant impact on the diversity and structure of microbiota. Although the far distance between the two places, dominant genera of these two baijiu pit muds have were similar.

The difference between the physicochemical indicators of the middle-layer and sub-layer pit mud of “Yibin Baijiu” was analyzed by t-test. Results showed that the pH of the sub-layer was significantly lower than that of the middle-layer. Meanwhile, CCA analysis showed that the pH value of PM has a great correlation with the bacterial community structure in PM. Spearman analysis revealed that the *Clostridium sensu stricto* 12, *Lachnoclostridium* and *Lactobacillus* were negatively significantly correlated with pH value. LEfSe also showed that *Lactobacillus* and *Clostridiaceae_1* were significantly less abundant in the middle-layer of PM with higher pH level. Specifically, the above three genera that were significantly related to the pH value all belong to the most abundant phylum Firmicutes in PM. Among them, *Clostridium sensu stricto* 12 and *Lachnoclostridium* were affiliated with order Clostridiales, while *Lactobacillus* was affiliated with order Lactobacillales. Order Clostridiales bacteria have metabolic ability of converting organic substances into organic acids (such as butyric, caproic acids, etc.), alcohols, CO₂/H₂, and minerals (Kenealy, Cao, & Weimer, 1995; Zheng et al., 2013). Moreover, Clostridiales are important contributors to form ethyl butyrate and ethyl caproate when butyric and caproic acids reacted with alcohols by enzymatic and non-enzymatic catalysis (Ding, Wu, Zhang, Zheng, & Zhou, 2014). Lactobacillales also play an important role during baijiu brewing because the lactic acid they produce can form ethyl lactate. Ethyl lactate, ethyl butyrate and ethyl caproate are vital flavour compounds in CSAB (Fan & Qian, 2005). Thus, pH level largely

determines the quality of “Yibin Baijiu”. Interestingly, a strong correlation of the bacterial community with the available phosphorous level was also observed by CCA analysis. Available phosphorus provides nutrients for the growth and reproduction of microorganisms. It is a component constituting the cell nuclear membrane and a source of energy substance ATP. Zheng et al. (2013) reported that the low pH and high content of available phosphorus of PM may result in the orthogenesis of the microorganism and Clostridiales, Lactobacillaceae and Bacillales-dominated microbial community structure. However, in the spearman analysis, no bacteria were found to have a significant correlation with available phosphorous level. The reason may be that the spearman analysis only performed a pairwise correlation between environmental factors and the most abundant 35 genera and lacked a reflection of the overall situation. In addition, the available phosphorous level may have a significant correlation with some genera with low abundance in the PM, which were not shown in the spearman’s heat map.

Conclusions

This study demonstrated the population diversity of bacteria in pit mud of “Yibin Baijiu” from 13 distilleries using HiSeq sequencing. Our work suggested the presence of a complex community structure and abundant species in the pit mud of “Yibin Baijiu”. No significant difference was observed in bacterial diversity between middle-layer and sub-layer pit mud. The LEfSe analysis showed that the relative abundance of *Lactobacillus* in the sub-layer PM is significantly higher than middle-layer PM. pH was significantly different ($p < 0.01$) between the two groups. Available Phosphorous and pH had stronger influence on bacterial community structure in PM. Our study provided basic data for further elucidating diversity of microbiota in pit mud of YB and the potential mechanism of Baijiu production.

Table 1 (on next page)

Result of physicochemical indicators of middle and sub layer groups in PMs

** : difference is significant at the 0.01 level.

Table 1 Result of physicochemical indicators of middle and sub layer groups in PMs

Sampling	Value for indicated PM sample (mean \pm SD)		P-value
	Middle	Sub	
moisture content (%)	38.03 \pm 0.07	39.32 \pm 0.08	0.509
pH**	6.00 \pm 1.49	4.69 \pm 1.06	0.000
ammonia nitrogen (mg/100g)	58.51 \pm 23.80	54.16 \pm 22.85	0.448
available phosphorous (mg/100g)	106.55 \pm 118.52	90.31 \pm 107.68	0.560
humic acid (‰)	3.10 \pm 1.67	3.10 \pm 1.35	0.999

**: difference is significant at the 0.01 level.

Table 2(on next page)

Number of classified species at different taxonomic taxa

1 **Table 2** Number of classified species at different taxonomic taxa

Group	Phylum	Class	Order	Family	Genus
Middle	45	88	151	291	680
Sub	46	88	160	304	713
All	49	94	172	332	811

2

Table 3(on next page)

Comparison of dominant microorganism in PM in different regions of strong-aroma baijiu

*Ratio: The ratio of the number of dominant genera which shared with "Yibin Baijiu" pit mud to the total number of dominant genera.

Table 3 Comparison of dominant microorganism in PM in different regions of strong-aroma baijiu

Locations	Dominant microorganism	Ratio*	Reference
Mianzhu (31°43'N, 104°12'E) 300 km	<i>Lactobacillus</i> , <i>Petrimonas</i> , <i>Clostridium IV</i> , <i>Sedimentibacter</i> , <i>Syntrophomonas</i> , <i>Spirochaetes SHA-4</i> , unclassified <i>Porphyromonadaceae</i> , <i>Anaerobrancaceae</i> , <i>Clostridiaceae I</i> , <i>Ruminococcaceae</i> , <i>Methanoculleus</i> , <i>Methanosarcina</i> , <i>Methanobacterium</i> , <i>Methanobrevibacter</i>	8/14	(Tao et al., 2014)
Luzhou (28°53'N, 105°27'E) 70 km	<i>Methanobrevibacter</i> , <i>Caproiciproducens</i> , <i>Petrimonas</i> , <i>Lactobacillus</i> , <i>Sedimentibacter</i> , <i>Proteiniphilum</i> , <i>Syntrophomonas</i> , <i>Aminobacterium</i> , <i>Christensenellaceae R-7</i> , <i>Caldicoprobacter</i> , <i>Olsenella</i>	8/11	(Liu, Tang, Guo, et al., 2017)
Jiangsu (35°20'N, 121°57'E) 1700 km	<i>Lactobacillus</i> , <i>Ruminococcus</i> , <i>Caloramator</i> , <i>Clostridium</i> , <i>Sedimentibacter</i> , <i>Syntrophomonas</i> , <i>Sporanaerobacter</i> , <i>Pelotomaculum</i> , <i>T78</i> , <i>Prevotella</i> , <i>Blvii28</i> , <i>Methanobacterium</i> , <i>Methanobrevibacter</i> , <i>Methanosaeta</i> , <i>Methanoculleus</i> , <i>Methanosarcina</i> , <i>Nitrososphaera</i>	7/17	(Hu, Du, Ren, & Xu, 2016)
Hunan (28°21'N, 109°45'E) 470 km	<i>Petrimonas</i> , <i>Lactobacillus</i> , <i>Sedimentibacter</i> , <i>Clostridium</i> , <i>Ruminococcus</i> , <i>Syntrophomonas</i> , <i>Symbiobacterium</i> , <i>Methanobacterium</i> , <i>Methanobrevibacter</i> , <i>Methanoculleus</i> <i>Methanosarcina</i>	8/11	(Wang, Du, & Xu, 2017)
Yibin (28°76'N, 104°63'E) 0 km	<i>Ruminiclostridium 5</i> , <i>Lactobacillus</i> , <i>Gelria</i> , <i>Methanoculleus</i> , <i>Syntrophomonas</i> , <i>Syntrophaceticus</i> , <i>Aminobacterium</i> , <i>Proteiniphilum</i> , <i>Petrimonas</i> , <i>Sedimentibacter</i> , <i>Methanobrevibacter</i> , <i>Caldicoprobacter</i> , <i>Methanosarcina</i> and <i>Methanobacterium</i>	14/14	This work
Unique	<i>Ruminiclostridium 5</i> , <i>Gelria</i> , <i>Syntrophaceticus</i>	—	This work
Common	<i>Lactobacillus</i> , <i>Sedimentibacter</i> , <i>Syntrophomonas</i> , <i>Methanobrevibacter</i>	—	All

*Ratio: The ratio of the number of dominant genera which shared with "Yibin Baijiu" pit mud to the total number of dominant genera.

Table 4(on next page)

Comparison of dominant microorganism in PM of different aroma types of baijiu

Table 4 Comparison of dominant microorganism in PM of different aroma types of baijiu

Representative aroma	Dominant microorganism	Reference
miscellaneous-aroma	<i>Corynebacterium, Myroides, Sphingobacterium, Lactobacillus,</i>	(Huang et al., 2017)
	<i>Clostridium, Acetobacter, Alcaligenes, Enterobacter and</i>	
	<i>Acinetobacter</i>	
sauce-aroma	Clostridiaceae, Ruminococcaceae and Thermoanaerobacteriaceae	(Wang et al., 2015)
	<i>Methanoculleus, Methanosarcina, Methanosaeta and</i>	(Bian, Ye, Yang, Ni, & Li, 2012)
	<i>Methanobacterium</i>	
strong-aroma (common)	<i>Weissella, Lactobacillus, Bacillus, Enterobacter and Paenibacillus</i>	(Wang, Zhang, & Liu, 2016)
	<i>Lactobacillus, Sedimentibacter, Syntrophomonas and</i>	—
	<i>Methanobrevibacter</i>	

Figure 1

The Chao1 richness indices (A) and the Shannon diversity indices (B).

The Box-plots exhibit the first (25%) and third (75%) quartiles, the median and the maximum and minimum observed values within each data set.

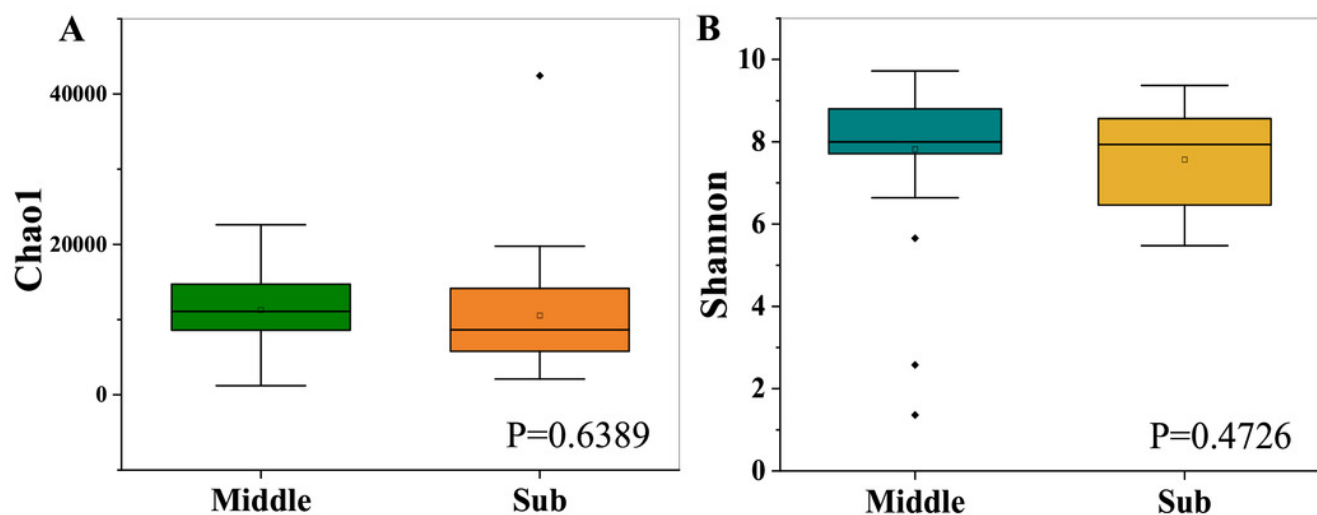

Figure 2

PCoA of Weighted Unifrac distance (A) and Unweighted Unifrac distance (B) for the microbiota at PM of middle-layer group and sub-layer group.

The principal coordinate combination with the highest contribution rate is selected for graph display.

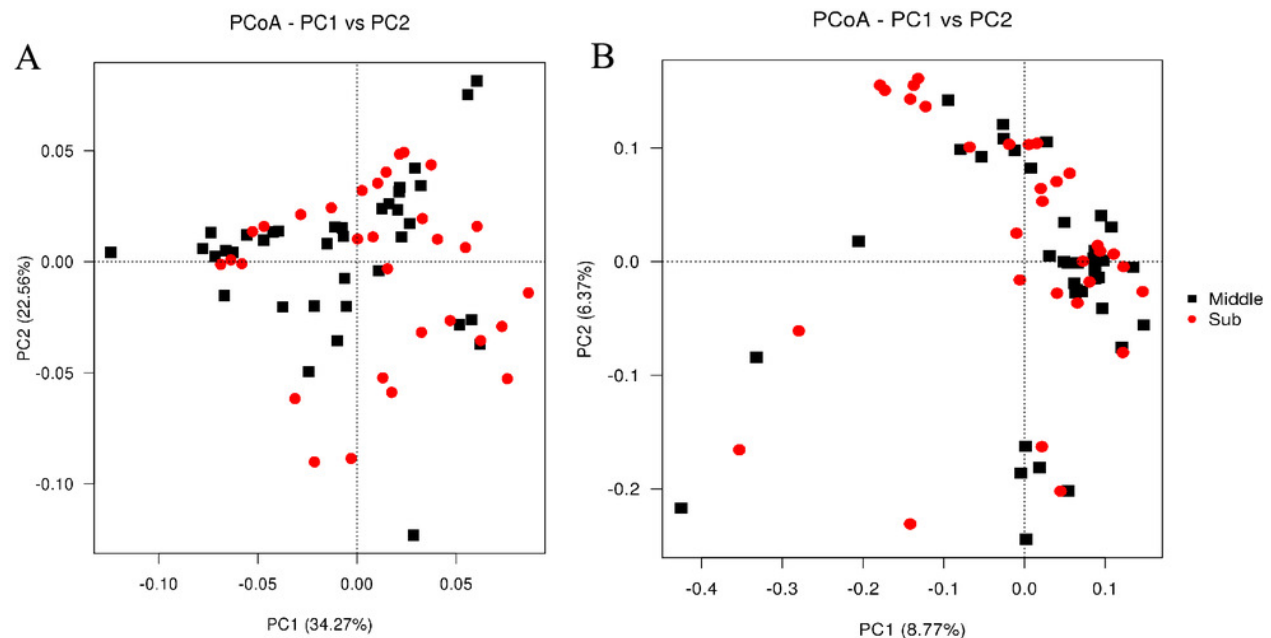

Figure 3

Taxonomic classifications of the bacterial communities in PM samples from sub-layer and middle-layer at the phylum level.

The “Others” refers to the group which could not be accurately assigned to any known bacterial taxonomic group at the phylum level, as well as the group which ranked after 10 phyla with most relative abundance.

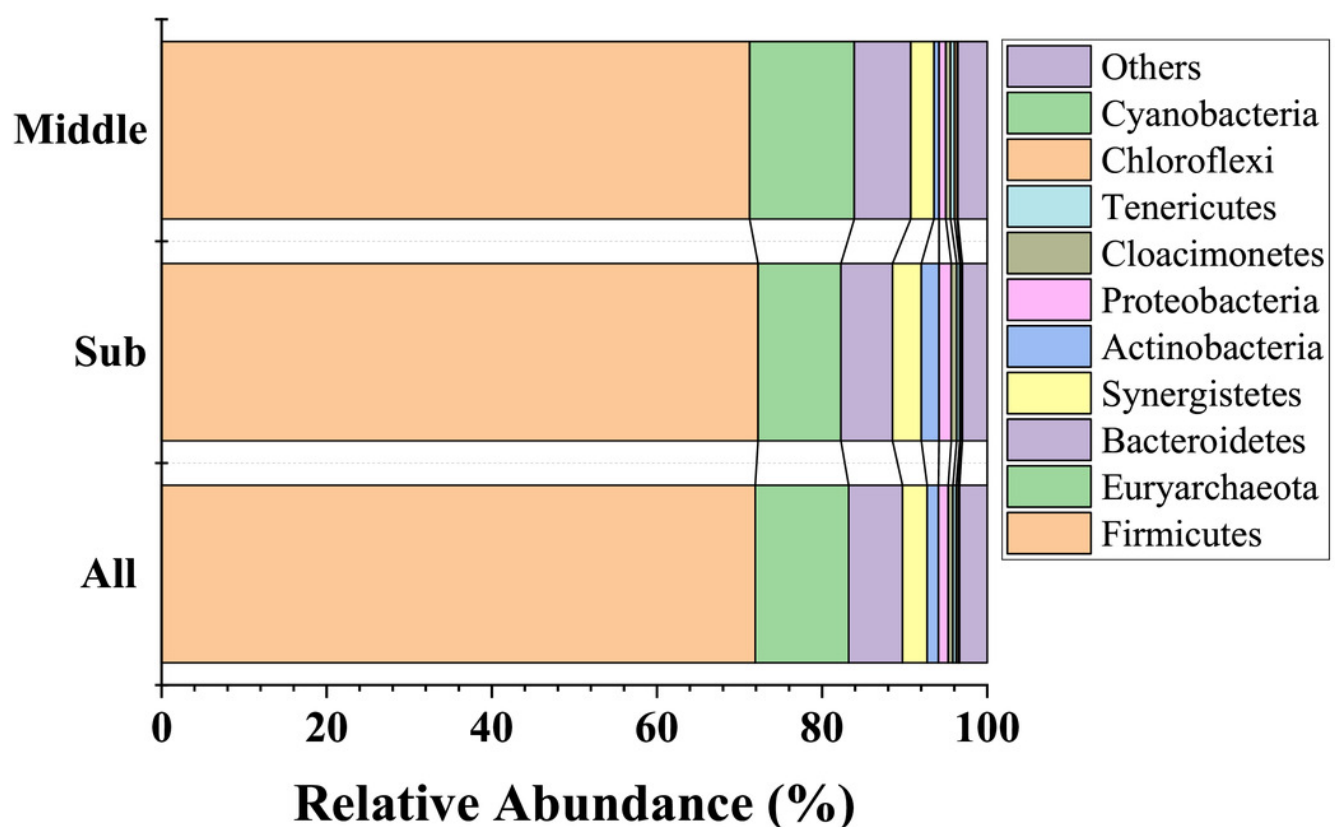

Figure 4

The most abundant 10 genera in Bacterial community at genus level.

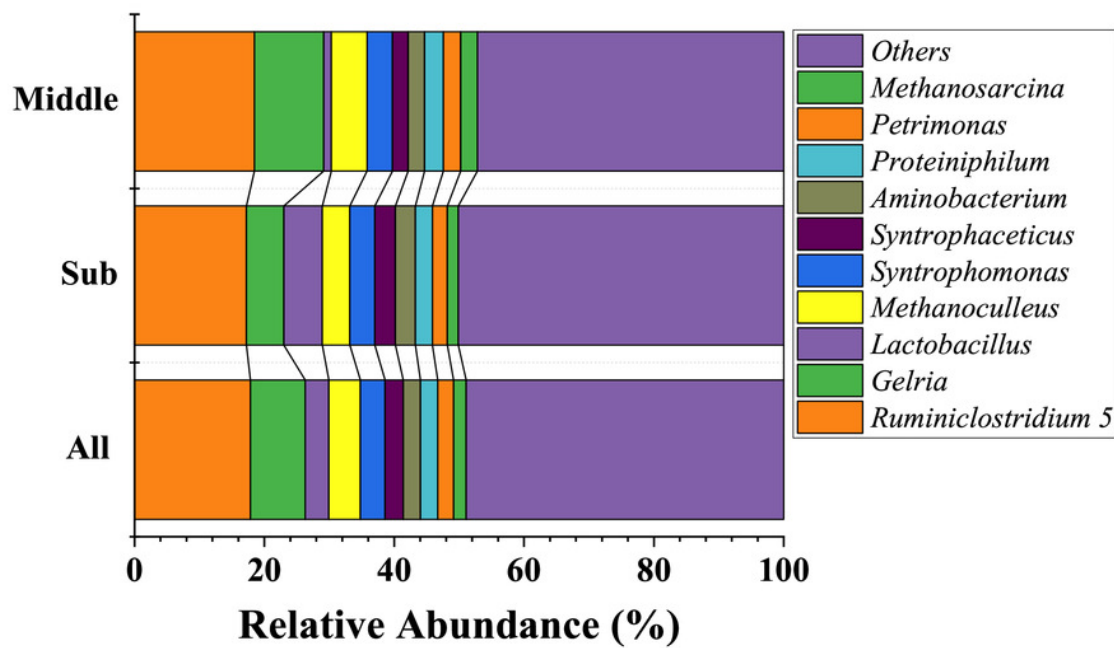

Figure 5

LDA score map with a threshold value of 4.0.

The length of the histogram represents the effect size of the species with significant difference in abundance in different groups.

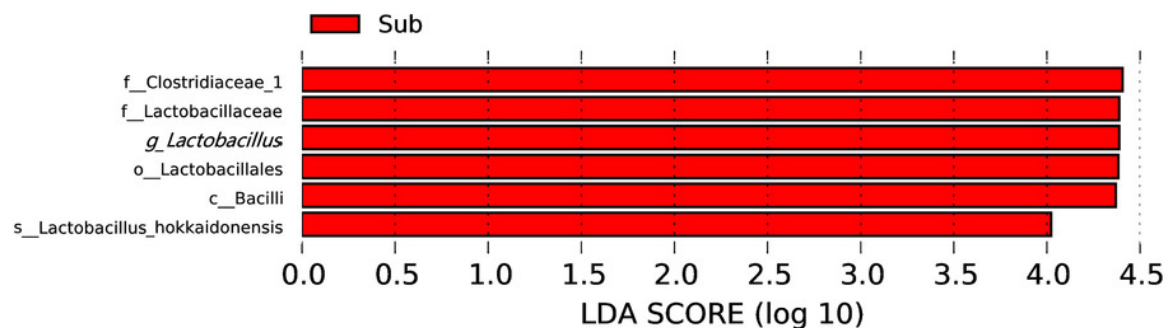

Figure 6

Heat map showing the spearman correlation coefficient of environmental factors and bacterial community in PM.

The horizontal direction is the species information, the longitudinal direction is the environmental factor information, the heat map corresponds to the Spearman correlation coefficient R , and the R value ranges from -1 to 1, $R < 0$ is a negative correlation, and $R > 0$ is a positive correlation.
