Background. Vulnerable species experiencing inbreeding depression are prone to localised extinctions because of their reduced fitness. For Tasmanian devils, the rapid spread of devil facial tumour disease (DFTD) has led to population declines and fragmentation across the species' range. Here we show that one of the few remaining DFTD-free populations of Tasmanian devils is experiencing inbreeding depression. Moreover, this population has experienced a significant reduction in reproductive success over recent years.

Methods. We used 32 microsatellite loci to examine changes in genetic diversity and inbreeding in the wild population at Woolnorth, alongside field data on breeding success from females to test for inbreeding depression.

Results. We found that maternal internal relatedness has a negative impact on litter sizes. The results of this study imply that this population has entered an extinction vortex and that to protect the population, genetic rescue may be required. This study provides conservation managers with useful information for managing wild devils and provides support for the "Wild Devil Recovery Program" which is currently augmenting small, isolated populations.

Abstract

Background. Vulnerable species experiencing inbreeding depression are prone to localised extinctions because of their reduced fitness. For Tasmanian devils, the rapid spread of devil facial tumour disease (DFTD) has led to population declines and fragmentation across the species' range. Here we show that one of the few remaining DFTD-free populations of Tasmanian devils is experiencing inbreeding depression. Moreover, this population has experienced a significant reduction in reproductive success over recent years.

Methods. We used 32 microsatellite loci to examine changes in genetic diversity and inbreeding in the wild population at Woolnorth, alongside field data on breeding success from females to test for inbreeding depression.

Results. We found that maternal internal relatedness has a negative impact on litter sizes. The results of this study imply that this population has entered an extinction vortex and that to protect the population, genetic rescue may be required. This study provides conservation managers with useful information for managing wild devils and provides support for the "Wild Devil Recovery Program" which is currently augmenting small, isolated populations.

Introduction

For threatened species, a reduction in reproductive success can severely impact population persistence. The Tasmanian devil, *Sarcophilus harrisii*, is one such species that has a decline of up to 80% in areas infected by an infectious clonal cancer, devil facial tumour disease (DFTD) (Loh *et al.* 2006; Pye *et al.* 2016; Lazenby *et al.* 2018). As the apex carnivore in Tasmania, devil population declines are causing trophic cascades in the Tasmanian ecosystem (Hollings *et al.* 2014) and recent modelling has indicated that these populations will begin to succumb to small population genetic pressures (Grueber *et al.* 2018). Declining populations are at risk of reduced

gene flow and loss of genetic diversity (relative to larger, more connected populations) as an outcome of genetic drift and inbreeding (Charlesworth & Willis 2009).

Since the discovery of DFTD in the mid-1990s, the national and international conservation community has rallied and research into Tasmanian devil biology has grown rapidly, including studies of DFTD epidemiology (e.g. Hamede *et al.* 2008; McCallum *et al.* 2009; Hamede *et al.* 2012), devil behaviour (e.g. Sinn *et al.* 2014), ecological impacts (e.g. Hollings *et al.* 2014), population genetics (e.g. Lachish *et al.* 2011; Grueber *et al.* 2015; Epstein *et al.* 2016; Hendricks *et al.* 2017), *ex situ* conservation (e.g. Hogg *et al.* 2016) and translocations (e.g. Rogers *et al.* 2016; Thalmann *et al.* 2016; Wise *et al.* 2016; Grueber *et al.* 2017). As DFTD spread from the north-east across Tasmania, devil populations have been monitored by the Save the Tasmanian Devil Program (STDP) since 2004 (Lazenby *et al.* 2018). One of the last-known DFTD-free populations is located at Woolnorth (40.77° S, 144.77° E), north-west Tasmania (Farquharson *et al.* 2018; Lazenby *et al.* 2018). Since 2014, this population has suffered an extreme decline in reproductive output, the cause of which remains unclear (Farquharson *et al.* 2018).

Here we aimed to test whether the observed decline in wild devil reproductive fitness (specifically litter sizes) is a result of inbreeding depression. Inbreeding depression occurs when an accumulation of deleterious recessive alleles lowers individual heterozygosity, negatively impacting individual fitness relative to less-inbred individuals or populations (Keller & Waller 2002; Frankham *et al.* 2017). Previous genetic research on a captive Tasmanian devil population revealed inter-individual variation in inbreeding, but no signs of inbreeding depression (Gooley *et al.* 2017). Although inbreeding depression is easier to study in controlled environments (such as captivity), it may be more consequential in the wild, as environmental conditions are more severe (Joron & Brakefield 2003; Armbruster & Reed 2005; de Boer *et al.* 2015). Thus, studies of inbreeding depression in captive environments may underestimate the impact on inbreeding on fitness in the wild (Kristensen *et al.* 2008; Gooley *et al.* 2017). In addition, wild populations that experience inbreeding depression are more vulnerable to extinction (Keller & Waller 2002), and so isolated populations may need genetic rescue to combat the effects of inbreeding (Frankham 2015; Frankham *et al.* 2017).

Here we use multilocus heterozygosity to investigate inbreeding and inbreeding depression at the DFTD-free population of devils at Woolnorth. We aimed to test: 1) whether inbreeding is occurring in the devil population at Woolnorth, and 2) whether inbreeding is associated with the observed reduction in reproduction (specifically litter sizes). The results of this study will inform the ongoing management of fragmented devil populations in the face of DFTD.

Materials & Methods

Sample collection and genotyping

Samples were collected by the STDP following their Standard Operating Procedure (see Appendix 5 in Hogg *et al.* 2019) and shared with the University of Sydney for genetic analysis. DNA samples and corresponding reproductive and demographic data were available for years 2006, 2007, 2009, 2014, 2015 and 2016. Reproductive output for females was taken as the

estimated count of offspring produced (i.e. “litter size”), following Farquharson *et al.* (2018). Female devils are limited to a maximum of 4 offspring per breeding event (Guiler 1970). For our data, litter size was estimated either by the presence and count of pouch young, or, for monitoring trips that occurred later in the year, by the presence and count of active teats (indicating pouch young had been denned) (following Keeley *et al.* 2012; Farquharson *et al.* 2018). In total, 168 wild Tasmanian devils (90 females and 78 males) were included in this study. Male reproductive output could not be examined in this study.

DNA from ear biopsy samples from the 2006, 2007 and 2009 monitoring trips had been previously extracted (Hendricks *et al.* 2017), whilst samples from 2014, 2015 and 2016 were extracted using a phenol-chloroform technique (Sanbrook *et al.* 1989) and stored at -20°C. Samples were genotyped with 32 neutral microsatellite markers following Gooley *et al.* (2017) and Jones *et al.* (2003). A randomly chosen set of 7% were re-genotyped to estimate genotyping error. We tested for null alleles at each locus using Micro-Checker (van Oosterhout *et al.* 2004). GenAlEx (Peakall & Smouse 2006, 2012) was used to calculate observed (H_O) and expected heterozygosity (H_E) for each locus, each year, and conduct Hardy-Weinberg exact tests.

Inbreeding and inbreeding depression

Internal relatedness (IR), a multilocus heterozygosity statistic that is expected to be positively correlated with individual inbreeding coefficient (Amos *et al.* 2001), was calculated using the package *Rhh* (Alho *et al.* 2010) for R (R Core Team 2018). IR incorporates allele frequencies, because there is a higher chance that rare-allele homozygosity is the result of inbred mating, relative to common-allele homozygosity (Amos *et al.* 2001). All available samples, male and female, were used to estimate allele frequencies. We examined whether inbreeding was accumulating by testing for a change in IR over time using a linear model fitted in R with year as the fixed predictor and IR as the response ($N = 168$).

To interpret associations between heterozygosity and litter sizes as inbreeding depression, molecular data must reflect variation in inbreeding levels among individuals, i.e. identity disequilibrium (Szulkin *et al.* 2010). This variation was quantified with the g_2 statistic (David *et al.* 2007; Szulkin *et al.* 2010), using the package *inbreedR* (Stoffel *et al.* 2016) for R, with its precision evaluated using 1,000 Monte Carlo iterations.

We tested for inbreeding depression by determining whether IR was a predictor of female litter size using linear regression; we predict a negative slope (i.e. increased IR is associated with decreased litter sizes). Litter size was modelled as a binomial response, where the number of events (successes) equalled the inferred litter size (based on pouch status; $N = 90$ unique females), and the number of trials equalled the maximum possible litter size of four. Along with IR (our predictor of interest), age (based on tooth wear observations, Pemberton 1990) and year were also included as continuous fixed predictors (with year = 0 for 2006).

Results

We found no evidence of null alleles at any of our loci, and missing data was low: >90% of individuals were successfully genotyped for >90% of loci. Genotyping error rate was 0.6%. Microsatellite diversity of Woolnorth devils was low (Table 1), and similar to observations of

other wild sites and captive populations (e.g. Gooley *et al.* 2017; Storfer *et al.* 2017; Grueber *et al.* 2018). Levels of IR remained constant across the study period (linear regression: $\beta_{\text{Year}} = 0.003 \pm 0.005$ SE, $p = 0.546$; $\beta_0 = -5.621 \pm 9.295$ SE, $p = -0.546$, $N = 168$ devils, Figure 1).

We detected statistically significant identity disequilibrium in our dataset ($g_2 = 0.017$, SE = 0.007, p -value = 0.003), indicating that variation at our molecular markers reflects variation in the level of inbreeding among individuals. We found evidence that inbreeding depression is occurring in the devil population at Woolnorth: IR had a statistically significant negative effect on female litter sizes (increased homozygosity [IR] was associated with decreased fitness) (Figure 2; Table 2).

Discussion

Here, we show that one of the last-known DFTD-free wild populations of Tasmanian devils is experiencing inbreeding depression. Although our data did not detect an increase in inbreeding over the timescale of our study, we did show that maternal IR has a negative impact on reproductive output (litter size) in wild devils. A significant decline in reproduction over time has been observed at Woolnorth (Farquharson *et al.* 2018); inbreeding depression may be either partially responsible for this trend, or a worrying consequence of it. Taken together, these observations suggest that the Woolnorth population may be close to a tipping point, whereby inbreeding reduces reproductive rates (perhaps in concert with other factors), which in turn further reduces population size and exacerbates the occurrence of inbreeding and inbreeding depression. This raises the management option of genetic rescue whereby supplementation could increase the fitness of this population, which is now effectively isolated as a result of devil facial tumour disease causing 80% declines in adjacent devil populations (Whiteley *et al.* 2015; Lazenby *et al.* 2018).

Small populations that exist in fragmented landscapes are expected to increase in mean inbreeding levels over time (Wright *et al.* 2007; Frankham *et al.* 2017) and monitoring this process is an important element of genetic management in conservation (Fredrickson *et al.* 2007; La Haye *et al.* 2012). Given the short time-period in which litter size appears to be decreasing at Woolnorth (Farquharson *et al.* 2018), our failure to detect a corresponding change in IR over time may indicate that a measurable increase in population mean inbreeding is yet to occur. This interpretation is not unprecedented: for example, the southernmost Swedish population of arctic fox did not show an increase in inbreeding coefficients until four years after population fragmentation that occurred in the late 1990s (Noren *et al.* 2016). In any case, the declining reproductive output seen here, and previously (Farquharson *et al.* 2018), could lead to a decrease in effective population size. If true, the result will be an eventual increase in inbreeding, and a strengthening of its negative effects. To test this hypothesis, it will be important to continue monitoring of the trajectory of demographic and genetic processes occurring in this population, given its importance as the last DFTD-free wild population of Tasmanian devils.

Devil populations, with and without DFTD, are fragmented across the landscape, so inbreeding depression may be occurring at other sites, particularly those affected by DFTD. It would be informative to quantify inbreeding depression into the future to facilitate effective management of wild populations. Evidence of inter-individual variation in inbreeding at

Woolnorth (g_2 analysis) indicates that we have the molecular tools available to test for inbreeding depression; it will be informative to determine whether this is also true for other sites. The results can be used to predict the outcomes of the STDP management strategy of augmenting small wild populations to promote gene flow (Grueber *et al.* 2018; Fox & Seddon 2019).

Conclusions

In conclusion, we have presented the first documented evidence of inbreeding depression in a wild population of Tasmanian devils. Whether inbreeding is the driver of the observed reproductive decline at Woolnorth, or the reproductive decline is driving the increase in inbreeding cannot be determined. Nevertheless, our data do show that inbreeding is detrimental in this population, and that it is poised to become more prevalent: this population appears to be at the cusp of the extinction vortex. Augmenting this population with genetic material from other locations across Tasmania may alleviate the effects of inbreeding and minimise inbreeding depression.

Acknowledgements

We thank the Save the Tasmanian Devil Program for the collection of samples over the years of this study, this research could not be conducted without their hard work. Thanks also to B. Lazenby for valuable comments on the draft manuscript and E. Johnson for assistance with DNA extractions.

¹ The ten “Sh” markers were developed by Jones *et al.* 2003; the remaining 22 “Sha” markers were developed by Gooley *et al.* (2017)

Gooley R, Hogg CJ, Belov K, Grueber CE (2017) No evidence of inbreeding depression in a Tasmanian devil insurance population despite significant variation in inbreeding. *Scientific Reports*, **7**, 1830.

Jones M, Paetkau D, Geffen E, Moritz C (2003) Microsatellites for the Tasmanian devil (*Sarcophilus laniarius*). *Molecular Ecology Notes*, **3**, 277-279.

Table 2(on next page)

Predictors of the number of joeys (proportion out of a maximum of four; binomial model) produced by female Tasmanian devils ($N = 90$).

Table 2: Predictors of the number of joeys (proportion out of a maximum of four; binomial model) produced by female Tasmanian devils (N = 90).

| Predictor | Estimate | SE | p-value |
|-----------|----------|-------|---------|
| Intercept | 0.594 | 0.377 | 0.116 |
| Age | 0.145 | 0.143 | 0.312 |
| IR | -2.374 | 0.680 | < 0.001 |
| Year | -0.319 | 0.038 | < 0.001 |

Abbreviations: N = sample size, SE = standard error, IR = internal relatedness

Figure 1

Internal relatedness of Tasmanian devils at Woolnorth (males and females) across years.

Dotted line is at IR = 0. Note: annual monitoring trips were not conducted in 2008, 2010, 2011, 2012 and 2013.

Figure 2

Effect of IR on litter size.

Marginal effect of IR based on the model shown in Table 2. The bold solid line is the fitted effect of IR on litter size at the mean of age and year in the wild population. Note that year has a strong effect on litter size, so the vertical positioning (intercept) of this line will vary for other years from the trend shown (later years having a lower intercept than earlier years; Table 2). The fine solid lines indicating the 95% CIs; raw data are overlaid.
